The complete mount consists of four parts: (a) the platform, (b) the adjustable stage, (c) the rotating mechanism, and (d) the bundle holder. The assembled mount is shown in Fig. 1, while in Fig. 2 is shown the adjustable stage.

(a) The Platform

The platform, 1 (Figs. 1 and 2), consists of an aluminum plate to which is fastened perpendicularly a steel shaft machined to fit into the specimen post socket located at the center of the graduated quadrant. The center-line of this shaft is considered to be the geometrical center of the system to which the sample is to be brought at all times in order to obtain at the counter diffracted radiation of maximum intensity. The pivot pin, 3 (Figs. 1 and 2), is attached to the platform to furnish the center for the angular adjustment of the stage. Fastened to the platform and concentric with the pivot pin are two outrigger bearing surfaces, 26 (Figs. 1 and 2), which support the adjustable stage at its outer edges and prevent it from tilting.

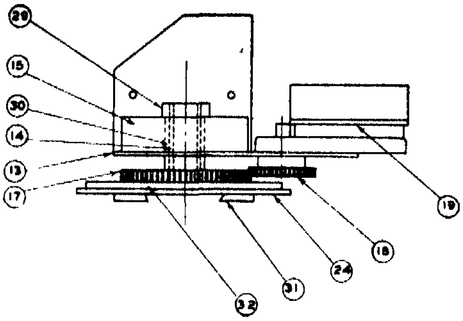

FIG. 4. Top view of rotating mechanism and bundle holder with clamps removed.

(b) The Adjustable Stage

This (Figs. 1 and 2), which permits centering the sample both in the x-ray beam and over the geometrical center, consists of three components which afford angular, transverse, and parallel adjustments.

Fastened to the underside of the brass plate, 21, is the gear, 2, for angular adjustment. This gear rests on the platform and is held centered by the pivot pin, 3, which fits snugly into the bore of the gear. The driving gear, 12 (Fig. 1), is fitted to the shaft and knob, 11, which projects through to the underside of the platform. Rotation of the knob causes the whole stage to rotate about the pivot pin as center, thus swinging the plane of the sample bundle into a position normal to the primary beam.

Transverse adjustment is accomplished by the movement of the transverse slide, 4 (Fig. 2), across the primary beam. This brass slide with beveled edges along its length moves between two brass rails which are fastened to the plate and whose undersides are so beveled that they serve to hold down the transverse slide. The transverse adjustment screw, 5 (Figs. 1 and 2), is threaded through a bar fastened to the plate. The screw presses against the slide and is opposed at the other end by the compression springs, 6 (Fig. 2), which are placed between the slide and a bracket fastened to the plate. The center portion of the transverse slide is open to allow insertion of the parallel adjustment slide, 7 (Figs. 1 and 2).

The parallel adjustment slide moves parallel to the primary beam, and its beveled edges slide in corresponding bevels along the edges of the open section of the transverse adjustment slide. Forward movement is caused by the action of the adjusting screw, 8 (Figs. 1 and 2), bearing against the lever arm, 9, which in turn presses against the back edge of the slide. The lever arm and threaded bracket for the parallel adjusting screw are both mounted on the transverse slide. The compression springs, 10 (Fig. 2), oppose the lever arm and afford backward movement. The purpose of this adjustment, in the direction parallel to the primary beam, is to bring the fiber bundle over the geometrical center.

---

† Although the North American Phillips spectrometer was used here, any appropriate x-ray apparatus may be used, perhaps with slight adaptations.

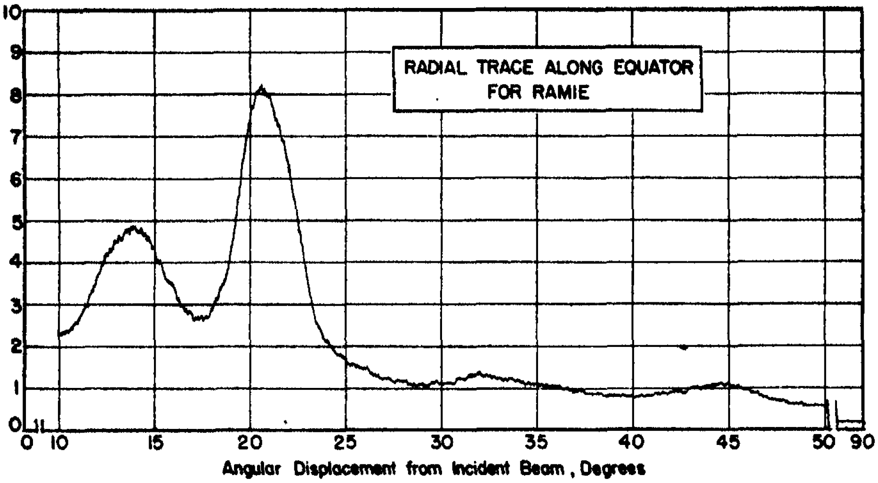

FIG. 5. Radial trace along equator for ramie.

(c) The Rotating Mechanism

The rotating mechanism, shown in Figs. 3 and 4, which also include the bundle holder, is that portion of the unit which rotates the bundle in the x-ray beam, causing the diffraction arcs to move across the window of the Geiger counter tube. An electric timing motor of two revolutions per hour (however, other speeds could be used) with right-hand, one-way friction drive, 19 (Fig. 4), turns the bundle holder through two gears, 17 (Figs. 3 and 4), and 18 (Fig. 4). The driven gear, 17, is securely mounted on a hollow shaft, 14 (Figs. 3 and 4), which turns with very little friction in the bushing, 30. The shaft and assembly are held in place by the hub, 29. The bushing holder, 15, and the synchronous motor are fastened to the upright portion of a 90° bracket, 13. The bottom horizontal portion of the bracket is fastened to the parallel adjustment slide. The primary x-ray beam which strikes the fiber bundle held by the holder mounted on the driven gear, passes through the hollow shaft, 14.

(d) The Bundle Holder

To facilitate loading, the bundle holder is detachable from the rotating mechanism. Attachment is made to the driven gear by means of a dove-tailed tongue and groove, 32 (Figs. 3 and 4). A positioning setscrew, 34 (Fig. 1), through the plate, 24 (Fig. 1), of the holder and bearing against the driven gear prevents sliding as the holder rotates. A dove-tailed groove, 31 (Figs. 3 and 4), on the front face of the plate, but at right angles to the tongue on the back face, holds the slides to which are fastened the clamps, 20 (Fig. 1). The purpose of the tongues and grooves on the back and front faces being at right angles to each other is to supply a further aid in centering the bundle.

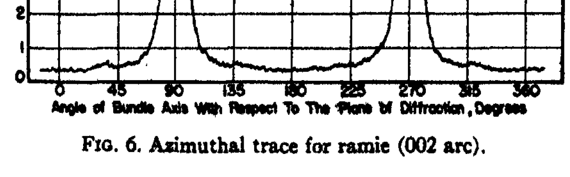

FIG. 6. Azimuthal trace for ramie (002 arc).

The lower jaw, 23 (Fig. 3), of each clamp is bolted to a slide, of which there are two. One of these slides has a set screw which locks it against the plate, while the other is forced outward by means of compression springs, 28 (Figs. 1 and 3), which are held in alignment by the internal, sliding rods and sleeves, 22 (Fig. 3). The steel combs, 27 (Fig. 1), located on the outer edges of the lower jaws serve to keep the fibers in the bundle parallel while under tension. The upper jaws of the clamps are tightened against the bundle by the hexagonal nuts, 25 (Figs. 1 and 3).

Vertical adjustment as such was not embodied in this model. The vertical dimensions of each component were held critical so that in the final assembly the horizontal diameter of the rotating bundle holder coincided with the center of the primary x-ray beam. A vertical adjustment can be incorporated by cutting a suitable thread on the upper portion of the steel shaft for a thin, knurled ring, internally threaded. This ring upon being rotated would raise or lower the entire assembly by bearing against the upper surface of the specimen post socket.

APPLICATION

For evaluating the crystallite orientation of a bundle of parallel fibers, the tentative procedure outlined below has been followed.

With the bundle holder detached and the combs in contact at the center of the opening, the bundle of fibers (weighing about 30 milligrams, combed and prepared in the conventional manner except not tied)

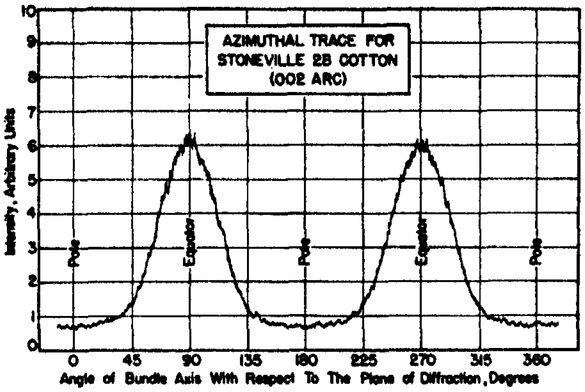

FIG. 7. Azimuthal trace for Stoneville 2B cotton (002 arc).

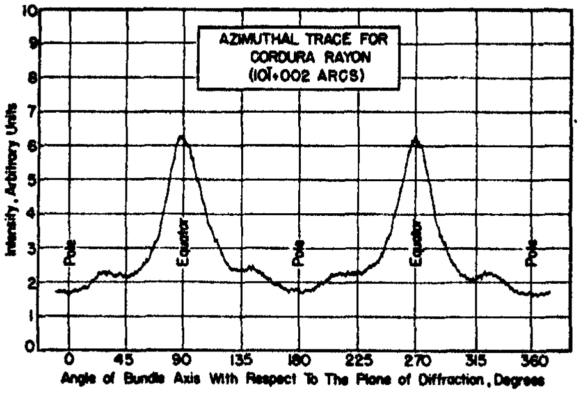

FIG. 8. Azimuthal trace for cordura rayon (10$\bar{1}$+002 arcs).

is inserted perpendicularly across the combs. The movable comb is then displaced to the edge of the opening, thus maintaining the fibers parallel. The jaw is then screwed down on the ends of the fibers, fixing them rigidly in place. The screw of the fixed comb is now loosened, and this comb moved to the other edge of the center opening. The jaw is tightened on the fibers, and the screw again tightened to fix the position of this jaw. The bundle is placed under tension by inserting the springs. The holder is centered on the mount and then rotated so that the axes of the fibers in the bundle are in the vertical plane. The x-ray port is now opened to irradiate the bundle.

For cellulosic as well as most other fibers the position of the diffraction arc to be scanned is located by first operating the scanning arm radially in the usual manner in conjunction with the strip recorder. Figure 5 shows the trace resulting when a bundle of ramie fibers was scanned radially across the equatorial arcs from 70° to within 10° of the primary beam. The chart is set to move at the rate of 1 inch per minute, although other speeds may be selected.

The scanning arm is next moved to the angular position indicated by the peak of the selected diffraction arc, and the exact position for the maximum intensity is found by a series of short scans. The recorded height of the peak may be varied within a considerable range by adjustments made at the recorder. After the counter is positioned at the point of maximum diffracted radiation, the chart of the strip recorder is shifted to bring one of the chart lines under the pen, and the apparatus is ready to scan the selected diffraction arc (azimuthal trace). Since the counter, tube, the primary beam, and the center of the bundle are located in the horizontal plane of diffraction, the equatorial diffractions will be recorded when the bundle axis is in the vertical position. The recorder and the rotating specimen holder are started simultaneously.

Figure 6 shows the recorded intensities of the radiation diffracted by the 002 planes of ramie cellulose while Fig. 7 shows a similar trace for the 002 planes of cotton cellulose. Figure 8 shows the trace received from the combined 10$\bar{1}$ and 002 planes of high tenacity rayon, the close juxtaposition of the two diffraction maxima preventing any appreciable resolution.

The marked differences in the shapes of the recorded intensities are due to the crystallite orientation of the fibers—ramie having the greatest orientation, high tenacity rayon and cotton having somewhat less—and the differences in type of cellulose (native and hydrate). The differences shown in peak intensities are related to factors other than orientation, such as bundle size, intensity of x-ray beam, etc.

It might be pointed out that in the present design one complete, recorded azimuthal scan of the two symmetrical diffraction arcs is obtained every 30 minutes from the time the bundle holder begins to rotate. This is to be compared to the large amount of time, as well as effort, required by the usual photographic method of obtaining similar data. By suitable selection of time motors and chart speeds the rate of recording may be varied.

A thorough study is being made of the variables in the method for the purpose of adapting this technique to a routine basis.

Synchrotron Radiofrequency System

MITCHELL H. DAZEY, JACK V. FRANCK, A. C. HELMHOLZ, CRAIG S. NUNAN, AND JACK M. PETERSON
Radiation Laboratory, Department of Physics, University of California, Berkeley, California

(Received September 14, 1949)

A description of the radiofrequency system of the Berkeley synchrotron is given.

INTRODUCTION

THE electron beam in the Berkeley synchrotron is accelerated to a peak energy of 335 Mev in three steps. The electrons are injected at a voltage of about 100 kv and are then accelerated to about 2 Mev by betatron action. Finally they are accelerated to 335 Mev by a radiofrequency voltage applied across a gap in the beam orbit. This paper will describe the design, construction, and operation of the radiofrequency system now used in the Berkeley synchrotron.*

SPECIFICATIONS

The Berkeley synchrotron has an orbit radius of one meter, with a magnetic gap of approximately $3\frac{3}{4}$ in. The vacuum chamber is a toroid of elliptical aperture. In cross section the outside dimensions are $3\frac{1}{2}$ by $6\frac{1}{4}$ in. and the nominal wall thickness is $\frac{5}{16}$ in. Fused silica (quartz) was the material used for the manufacture of the vacuum chamber or donut.

Space limitations made it desirable to utilize a section of the donut as a quarter-wave resonator, with the open, or high voltage end being the gap across which the acceleration of the electrons takes place. The dielectric constant of fused silica is four, so that one-eighth of the donut was required to form a resonator with the proper frequency. For ease of manufacture and handling it was decided to have the donut made in eight 45° sections. The segment and spares to be used for resonators were ordered with slightly larger wall thicknesses, $\frac{7}{16}$ in., since this would lead to a 40 percent increase in the theoretical Q over a resonator with a $\frac{5}{16}$-in. wall.

The complete donut was assembled by covering the eight joints with 4-in. wide, $\frac{1}{16}$-in. thick butyl rubber bands. A smooth surface under the bands was obtained by baking on the ends of the silica segments a 2-in. wide band of red glyptal. Heavy lubriseal was used under the rubber bands to insure a good vacuum seal. To prevent chipping of the segments and to insulate adjacent sections from each other, the ends were separated by a $\frac{1}{16}$-in. thick teflon gasket. All of the segments except the resonator were coated inside with du Pont No. 4817 air drying silver and grounded so as to avoid the accumulation of static charges. The grounding circuit was designed to distribute uniformly the betatron accelerating voltage over the several gaps between segments. The circuit consists of a ring of eight 1000-ohm resistors tied to ground at the injector; the two ends of each segment (except the resonator) are connected through 10-ohm resistors to a junction between 1000-ohm resistors. The resonator segment is grounded via the transmission line to the oscillator.

The electrical specifications for the radiofrequency system were as follows.

(a) Frequency. The nominal frequency of the synchrotron is 47.7 mc. The desired tuning range is determined by the radial width of usable magnetic field at the orbit. Since the usable field extends from 93 to 106 cm radius, the desired tuning range of the radiofrequency is from 45.0 to 51.1 mc.

(b) Voltage. Assuming a final energy of 341 Mev at the synchronous orbit (6 Mev are lost in collapsing to the target), the instantaneous energy (E_s) of the electrons can be written as a function of time (t), thus

$$E_s = 341\times 10^6 \sin(2\pi 32t)\text{ev},$$

since 32 cycles/sec. is the frequency of the magnetic field and the energies are essentially relativistic throughout. The mean energy gain per turn (V_t) is then

$$V_t = \frac{1}{47\times 10^6}\frac{dE}{dt} = 1450\ (\cos 2\pi 32t)\text{ ev per turn.}$$

The radiation loss, L, which varies as $(E_s)^4$, is 1200 v per turn at peak magnetic field. Adding V_t and L, the minimum accelerating voltage is 1450 v just after the betatron period and is less than 1450 v for the remainder of the accelerating period. Experience with the General Electric 70-Mev synchrotron[1] indicated that a gap voltage of two or three times the minimum is adequate for accelerating the electron beam. For this reason there was specified a voltage of up to 3500 peak volts at the radiofrequency gap in the electron orbit.

(c) Pulse length. Varying the pulse length is a convenient way to change the energy of the output beam, and the pulse length was therefore specified to be variable from zero to greater than 7800 μsec. ($\frac{1}{4}\times\frac{1}{32}$ sec.).

(d) Pulse shape. The envelope of the radiofrequency pulse was specified as a square wave with a rise time to full voltage of about 10 μsec.

(e) Repetition rate. The repetition rate of the radiofrequency system is the same as that of the magnet, which is a maximum of six pulses per second. It was specified that the radiofrequency pulse should be started by a circuit associated with the magnetic field.

---

* A more detailed report is given in the AEC document number AECU-578.

[1] Elder, Gurewitsch, Langmuir, and Pollock, J. App. Phys. **18**, 810 (1947).

(f) Eddy currents. An important requirement is that eddy currents induced in the conducting surfaces of the resonator by the alternating magnetic field be small, both to preserve uniformity of magnetic field and to avoid excessive heating. For ease of compensation it was specified that the mean eddy current field be less than 0.8 gauss; to avoid excessive distortion of the electron orbit, the maximum deviation of the eddy current field from its mean was specified as 0.2 gauss.

THE RESONATOR

A quarter-wave resonator, somewhat similar to the one used in the General Electric synchrotron,[1] was constructed. The rough exterior of the fused silica resonator section† was ground with silicon carbide grinding wheels to obtain a smooth surface and a thickness uniform within $\pm\frac{1}{32}$ in. The resonator section, shown in Fig. 1, was treated by the following procedure.

The section was filled with hydrofluoric acid for about 24 hr. to etch the inner surface glaze. It was cleaned by washing in acetone and then fired at about 1200°F to oxidize any remaining organic matter. When the section had cooled to room temperature, Liquid Bright platinum solution was applied by brush and the section was fired in an amply ventilated furnace. The temperature was brought up slowly to burn out the organic material in the Liquid Bright solution. When most of these materials had been vaporized, the coating was "set" by running the temperature up to about 1150°F for 15 min. Two or three coats give sufficient surface conductivity to allow good electroplating.

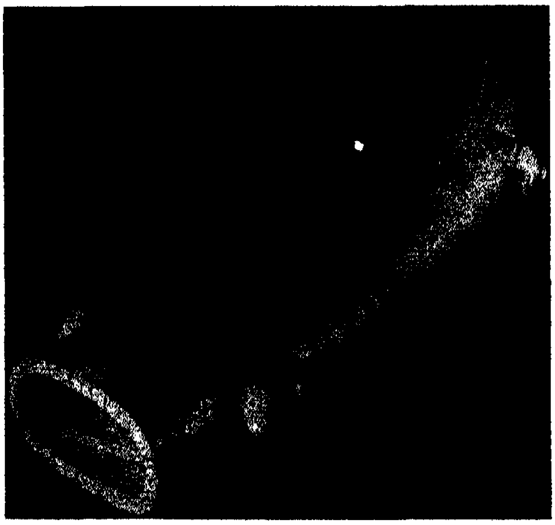

FIG. 1. Resonator. (A) Cross strap. (B) Feedpoint. (C) Accelerating gap. (D) Scribe lines.

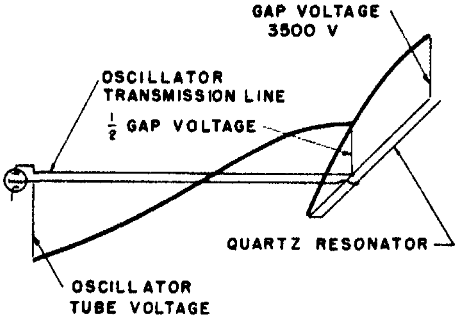

FIG. 2. Oscillator voltage distribution.

Eddy currents in conductors in a magnetic field go up rapidly as the area of the conductor is increased, so it was necessary to scribe "stop-off" lines before electroplating, leaving strips of metal to form the resonator. Scribe lines (see Fig. 1) were laid out by painting glyptal on with a rotating wheel device attached to a long radius arm.

The resonator was placed in a copper sulfate bath. Fixed anodes were shaped so as to be approximately $1\frac{3}{4}$ in. and equidistant from the surfaces to be plated. Copper fingers were added to protrude into the resonator bumps at the feedpoint and near the gap. It was found desirable to flash plate at about 15 amp. total current, using a small movable anode to plate areas which did not plate from the fixed anodes. After the complete surface was covered with a thin coat, the current was reduced to 5 amp. total and the plating was built up uniformly, using movable and fixed anodes. A reverse-plating method was used which consisted of 10 sec. plating, and 2 sec. de-plating. Although it was not possible to measure the thickness of the plating with any accuracy, it was estimated that about 0.003 in. of metal was applied.

After the plating, the glyptal was dissolved from the scribe lines with methyl ethyl ketone. The metal from the Liquid Bright solution was first ground out by an abrasive cut-off disk (carborundum) and then burned out electrically.

After the scribe lines were cleaned up, a coupling strap (A, Fig. 1) was painted around the resonator using du Pont air drying silver solution No. 4817 both on the inside and outside surfaces at a position which experimentally was found to give the highest Q. This strap was then electroplated by the technique mentioned previously.

The resonator has a $\frac{3}{8}$-in. wide accelerating gap (C, Fig. 1) and is driven at the half-voltage point by a coaxial transmission line from the oscillator. The plating on the inside surface is brought out through a hole and a copper-plated quartz plug is soldered into the hole to allow connection to the transmission line inner conductor. The gap in this resonator is not radial, but no difference in operation was observed with a radial gap. The bumps at the gap end are used for ports in other segments but serve no purpose in the resonator.

---

† The quartz sections were supplied by Amersil Company, Inc., Chestnut Avenue, Hillside 5, New Jersey.

When the resonator is installed in the synchrotron there is ⅛-in. clearance top and bottom between the resonator and the magnet pole tips. This small clearance allows considerable radiofrequency power to be dissipated in the pole tips. When the cross-strap was painted at the accelerating gap, the resonator Q was measured as 225 between the pole tips and 409 when away from the pole tips. The optimum position for the cross-strap was found to be about 45 percent of the distance from the gap to the high current end of the resonator. This gave a Q of 445 between pole tips and 545 away from the pole tips. These figures refer to the resonator shown in Fig. 1. Note that at the ends of the resonator the scribe lines connecting inner and outer surfaces are "radial" (i.e., perpendicular to the inner and outer surfaces). This gave a higher Q than "vertical" scribe lines.

The resonator was then placed in an alternating magnetic field and the delay in time of zero field due to eddy currents in the plating was measured with peaking strips. The delays corresponded, when converted to the conditions of operation at injection, to fields of 0.4 to 0.8 gauss over the radial aperture except at the cross-strap, where it was 2.2 gauss. Most of the variation was azimuthal; the maximum radial variation over the 4-in. radial range was measured as 0.15 gauss. The resonator field is compensated along with the rest of the magnetic field by coils around each 45° segment of the pole tips. The eddy current heating is still large enough so that it is necessary to cool the resonator with a blower supplying 200 cu. ft./min. and designed to produce 30 ft./sec. flow of air over the resonator surface. Without cooling, the lubriseal used under the wide rubber bands to make the vacuum seals becomes warm and flows.

ELECTRICAL

In this radiofrequency system, the quartz resonator, the transmission line to the tube, and the tube with its associated circuit components comprise a single resonant circuit. In terms of transmission lines, the resonant circuit is three-quarters of a wave-length long: the quartz section is equivalent to a quarter of a wave-length, and the transmission line with the tube and its associated circuit components is electrically a half-wave-length long. Figure 2 represents, approximately, the voltage distribution along the quartz resonator and the transmission line to the oscillator tube.

Figure 3 is a schematic diagram of the circuit and indicates the approximate location of components. The 2500-watt air-cooled oscillator tube (Eimac 3X2500A3) is connected in a grounded grid circuit across the high voltage end of the transmission line. The tuning capacitor (C_1) controls the frequency of the entire radiofrequency system between 45 and 51 mc. It is located at the top of the oscillator tube housing and is remotely controlled from the synchrotron control desk with a selsyn motor.

The feedback for the oscillator tube is obtained by coupling to the magnetic field in the transmission line with an adjustable loop. A series connected variable capacitor or phasing capacitor (C_2) compensates for the

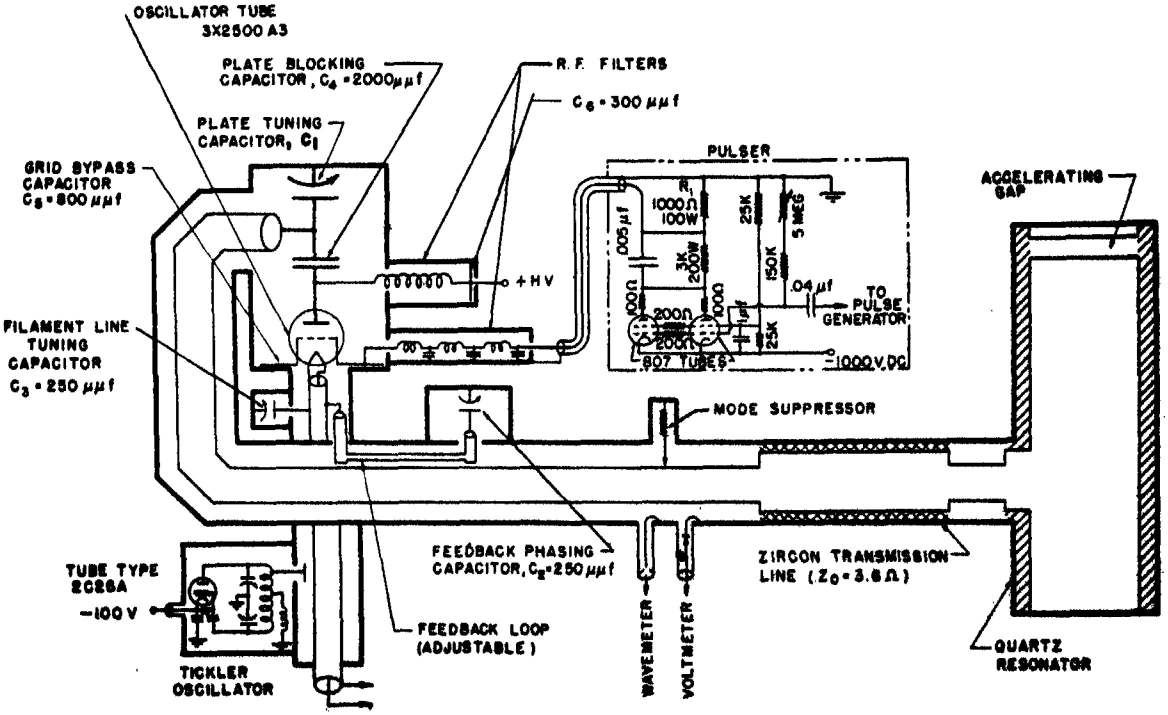

FIG. 3. Schematic diagram of radiofrequency oscillator.

effect of the self-inductance of the feed-back loop. This circuit allows the drive to be adjusted in phase as well as in amplitude. The transmission line is "curled back" upon itself to keep this feed-back circuit as short as possible and at the same time have the loop couple near a magnetic field maximum.

Since the tube filaments are connected to the d.c. ground it is necessary to use a plate d.c. blocking capacitor (C_4) and a grid d.c. blocking capacitor (C_5). A copper-plated disk of titanium dioxide was used as a plate-blocking capacitor since this shape fits into the geometry of the circuit and gives the necessary voltage insulation (6000 v d.c.) and capacity (approximately 2000 $\mu\mu$f). This capacitor is clamped between two rows of spring fingers. The tube rests upon its grid connector which is part of a brass disk forming the grid blocking capacitor. Two pieces of 0.005-in. sheet polystyrene are used as the dielectric to give a capacity of about 800 $\mu\mu$f and to insulate for 2000 v d.c. The grid bias resistor (R_1) for the oscillator is mounted in the pulser chassis about fifty feet away. The tickler oscillator helps initiate oscillations and reduces the jitter time to 0.1 μsec.

When the oscillator was first tested, two spurious modes of oscillation were observed. These were eliminated by installing a 300-ohm globar mode suppressor resistor across the transmission line at the voltage node of the fundamental mode.

The resonator is driven at the half-voltage point rather than at the gap in order to simplify the design of the insulating surfaces at the feedpoint. Between the mode suppressor and the resonator is a section of transmission line (approximately an eighth wave-length) using zircon as the dielectric. This section of low impedance line acts as an impedance transformer to allow the oscillator tube to operate at approximately twice the feedpoint voltage in order to obtain good oscillator efficiency.

The oscillator delivers approximately 6-kw peak power at approximately 60 percent plate efficiency when operating at the maximum gap voltage (3500 volts peak) and the nominal pulse length (7800 μsec.). At the maximum repetition rate (6 c.p.s.) the duty cycle is 1/20. Most of the energy goes into conduction losses in the resonator plating and in the transmission line. Dielectric heating of the quartz is negligible. The forced air cooling mentioned in connection with eddy currents dissipates this heat. Forced air cooling is used to cool the grid-to-plate seal and the plate of the oscillator tube. The filament seals of the tube are cooled by high pressure air supplied through the inner conductor of the filament transmission line.

The oscillator is keyed by controlling the fixed grid bias voltage with the pulser shown in Fig. 3. During the offtime the pulser holds the grid of the oscillator tube at about $1\frac{1}{4}$ times the cut-off voltage. To initiate the radiofrequency pulse, the leading edge of a negative square wave of voltage from a "one-shot" multivibrator cuts off the 807 switch tubes, allowing the bias voltage on the oscillator grid capacitor to discharge through the grid resistor R_1. When the bias rises above cut-off, the tube functions as a class *C* oscillator, establishing its own bias across R_1. To terminate the radiofrequency pulse, the trailing edge of the negative square wave puts the 807's sharply into conduction, which places sufficient negative bias on the grid of the oscillator to stop the oscillations.

The length of the negative square wave of voltage generated by the one-shot multivibrator is varied by a potentiometer adjusted from the synchrotron control desk by means of selsyn motors.

OPERATION

None of the radiofrequency pulse parameters has been found to be critical. In normal operation the electrons are accelerated by betatron action for the first 100 μsec. to 2 Mev. The radiofrequency pulse can be started at any time over a 5-μsec. range without appreciable difference in x-ray beam intensity. The resonator is driven at about 47.1 mc/sec. The beam intensity decreases rapidly when the frequency is tuned beyond 48.1 or 46.6 mc/sec. and is fairly constant between these limits.

At peak magnetic field the electrons lose energy by radiation at the rate of about 1200 volts per turn. When the radiofrequency pulse is ended, the electrons lose energy by radiation and spiral into an internal target. In normal operation at full energy the electrons begin to strike the target about 120 μsec. after the end of the radiofrequency pulse and the x-ray beam lasts for about 10 μsec. For some types of experiments it is desirable to have the x-ray pulse last for a longer period in order to allow counters to function for a longer time during each synchrotron pulse; for a given beam intensity the pile-up of independent counts within the resolving times of the counters is correspondingly reduced. For this purpose the duration of the x-ray pulse has been increased to as much as 2500 μsec. by shaping the oscillator plate voltage so that it decays over the last few milliseconds of the radiofrequency pulse. This type of operation has been of considerable value in experiments involving proportional and scintillation type counters.

We wish to thank Professor E. M. McMillan for advice and encouragement.

The work described in this report was performed under the auspices of the AEC.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 5 MAY, 1950

X-Ray Determination of Slip Planes and Slip Directions

R. W. TURNER, T. L. WU, AND R. SMOLUCHOWSKI
Metals Research Laboratory, Carnegie Institute of Technology, Pittsburgh, Pennsylvania

(Received December 27, 1949)

An application of x-rays for determination of active slip systems based on a comparison of distortion of Laue spots is described.

WHENEVER they are applicable, direct visual methods offer the simplest approach to the study of slip systems: The orientation of the sample may be determined by study of etch pits with an optical goniometer, and the slip plane may be determined by noting the orientation of the slip line on the surface. Slip direction is more difficult to determine, except in the case of samples having at least two, non-parallel surfaces polished for careful visual observation. However, it is frequently desirable to study slip in samples which are not suitable for these methods. In our laboratory, we came up against the problem in connection with the study of slip in small, thin, flat crystals of aluminum, such that only one surface could be polished for visual studies. The problem was solved using x-rays, and the various methods are here reported.

Aluminum is known to slip on the (111) planes in (110) directions. Hence, since the orientation of the crystal was known, the slip plane was determined in the usual way by noting the direction of the slip lines on the one polished surface and referring to the projection of the crystal.[1] This method, however, did not indicate the slip direction; it was necessary to turn to x-ray methods for this information. As a first step, samples were studied in which the slip plane was known but the slip direction was not. In this case, a Laue exposure offers probably the simplest and most direct method. The crystal was oriented so that the normal to the slip plane was not quite parallel to the x-ray beam. In this orientation, the zone of all planes belonging to this direction was recorded in its entirety, and the reflections were indexed by plotting on a stereographic projection. The planes normal to the direction of the active slip were identified by a distorted or split reflection. This identification of the active slip system is based on the general theory of strain hardening according to which a local curvature appears on the active slip plane in the direction of slip. As a check, it was desirable to reorient the specimen so that two reflections of the same form (*hkl*) in the zone under consideration were located at equal distances from the central spot. These two spots were then compared directly as shown in Fig. 1. Here the beam was almost parallel to $(1\bar{1}1)$, and we compared the $(\bar{1}\bar{1}0)$ and (011) reflections. A further reorientation showed the $(\bar{1}01)$ reflection to be most distorted.

If it is necessary to determine the slip plane by means of x-rays, then a similar method may be used. Here the

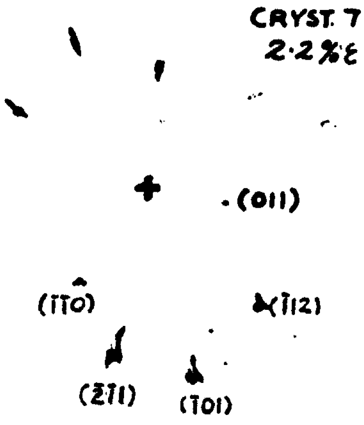

FIG. 1. Laue transmission. Beam roughly parallel to $(1\bar{1}1)$.

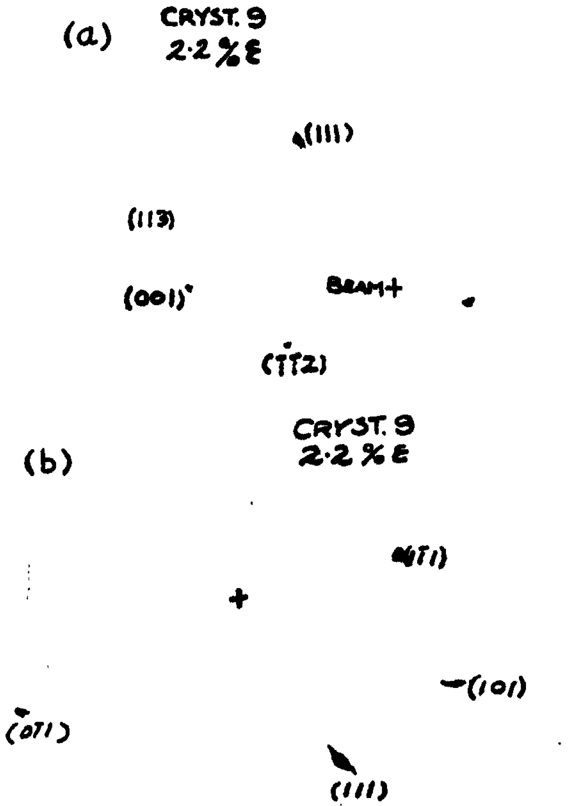

FIG. 2. Laue transmission. (a) General orientation. (b) Beam roughly parallel to $(\bar{1}01)$.

---

[1] C. S. Barrett, *Structure of Metals* (McGraw-Hill Book Company, Inc., New York, 1943).

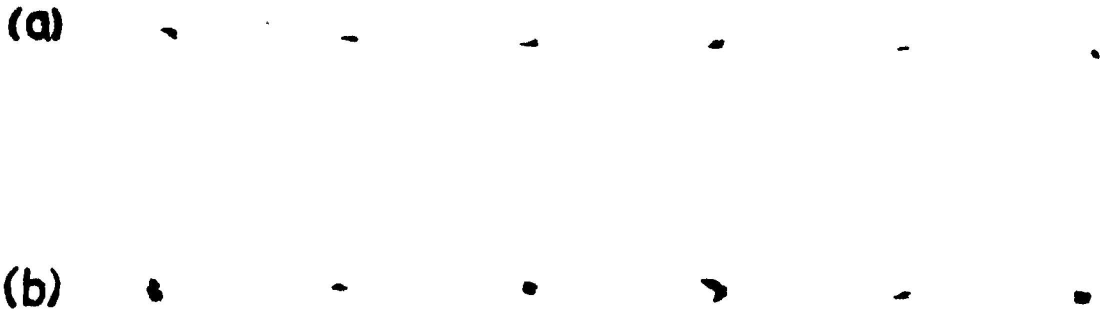

FIG. 3. Weissenberg method. Rotation around (111). Reflections from various {110} planes in an almost strain-free (a) and in a deformed sample (b).

beam is adjusted almost parallel to a (110) direction, and one can compare the various (111) reflections. Figure 2(a) illustrates the results obtained with the crystal in random orientation. Indexing was again done with the aid of a stereographic projection. As before, it was desirable to make a check by an exposure with the sample oriented so that two reflections of the same form were equidistant from the center for comparison. This is shown in Fig. 2(b). Here the beam was almost parallel to ($\bar{1}01$), and we compared the (111) and (1$\bar{1}$1) reflections.

It was our experience that this transmission method represents the simplest and most straightforward approach to the problem. It has the great advantage that the alignment of the specimen is only moderately critical. Furthermore, all exposures are short, and a glance at the film is sufficient to determine whether or not further adjustment is necessary. The back-reflection Laue method may have to be used in certain cases, but it was somewhat limited in usefulness in our problem.

An attempt was made to measure the rotation of the crystal lamellae which occurs during slip: the tensile axis of the specimen makes a smaller angle with the slip direction after slip than before. This method requires precision measurements of orientation or large deformations. In our case the rotations were small, and the results were not conclusive.

Finally, a comparison of reflections in one zone was made using a Weissenberg camera. For this, it was necessary that the slip plane and its orientation be known so as to orient this plane perpendicular to the axis of rotation. The equatorial layer line will now contain the reflections from all the planes perpendicular to the slip plane, and the slip direction will be the normal to those planes which show maximum distortion. In Fig. 3, reflections from "strain-free" and deformed samples are compared. Although the planes normal to the slip direction show the most distortion, almost all reflections show some distortion. This indicates the very high sensitivity of the method. In fact, it is too sensitive if only the directions of slip rather than the general conditions of strain in the sample are to be determined. The time and trouble involved in proper alignment of the sample do not seem to be justified for a simple determination of slip plane and slip direction.

Another variation of the Weissenberg method would be to have the specimen oriented with the slip plane normal to the axis of rotation, and the x-ray beam reflecting from this plane. As the sample is rotated, the reflection would change, and in that direction which corresponds to the active slip direction it will be most distorted. This technique has not been tried.

It appears that for a critical study of the state of strain in the sample, the Weissenberg technique recording the reflections of planes perpendicular to the plane of slip would be the most informative. On the other hand, the Laue technique is more suitable when the problem consists only in determining slip plane and slip direction. In general, transmission Laue is easier and faster than back-reflection Laue. If the sample has been subjected to large deformations, measurement of the rotation of the crystal lamellae may be more convenient than other methods. In all cases, comparison exposures of a strain-free section of the sample help to clarify and establish the interpretation.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 5 MAY, 1950

An Electron Pair Spectrometer of Lens Type for Hard Gamma-Radiation

KAI SIEGBAHN AND STIG JOHANSSON
Nobel Institute for Physics, Stockholm, Sweden

(Received January 5, 1950)

A new type of pair spectrometer is described. The rotation of the image in a short magnetic lens is used to separate negatrons and positrons by putting the pair converter a little aside from the optical axis of the lens. It is then possible to obtain coincidence "lines." The apparatus has been tried on the 2.62-Mev γ-ray of ThC″ and the 2.76-Mev γ-ray of Na^{24}.

THE γ-radiations emitted during transmutation experiments (by means of particle accelerators or nuclear reactors) are normally much more energetic than those emitted from ordinary radioactive bodies. If one wants to study, β-spectrometrically, the energy of such high energy γ-radiation by means of secondary electrons in order to get good accuracy and possibilities to analyze any complex radiation, one is faced with the difficulty that the line-producing photo-effect (as well as the Compton effect) is getting small at higher energies. Instead, the pair production effect increases. The fact that the whole γ-energy is consumed in the simultaneous emission of the electron positron pair can very conveniently be utilized in two ways: First, the background can be effectively reduced to a minimum by using two detectors in a coincidence arrangement, second, it is possible to obtain coincidence "lines" characteristic of the γ-energies in question. If the electron pair converter is put in a transversal homogeneous magnetic field, the negatron and positron in the pair are bent away in opposite directions. The electrons are normally registered after 180° and a coincidence line occurs at a magnetic field, corresponding to an energy $=\frac{1}{2}(E_\gamma-1.02)$ Mev, where E_γ is the energy of the γ-ray. This device has successfully been used before.[1,2]

It has not yet been tried to use any other type of focusing except the semicircular to register the electron pairs. The lens method, which possesses a much higher transmission power, cannot immediately be used since this type of focusing ordinarily does not separate negatrons and positrons. It is true that this can be made if a twisted shutter system is introduced.[3] If this is done, however, only one type of particles, i.e., either negatrons or positrons, is transmitted and the important condition for obtaining coincidence lines is lost, namely, the simultaneous transmission and registering of both particles in the pair.

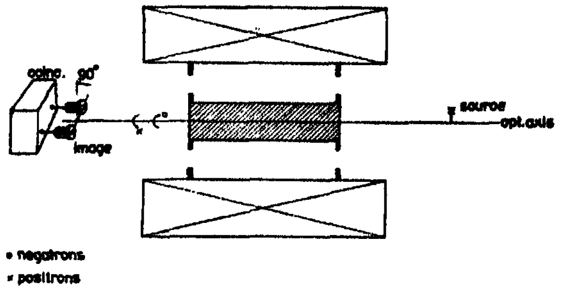

FIG. 1. Principle of the electron pair lens spectrometer.

One can avoid this difficulty in a rather simple way, making use of the property of a short lens of rotating the image. It is well known that a long lens with a homogeneous field has a rotation of image of 360°. A short lens will generally have a rotation of image, which is $\neq 360°$ and it is easy to dimension the lens and the distance between the source and detector so that the angle will be around 90°. If the electron pair converter is placed a little to one side of the optical axis of the lens (see Fig. 1), the negatrons and positrons due to their opposite direction of rotation, will form *two* separated images in a distance from each other, which is twice the distance of the converter from the axis (provided the rotation is 90°). If the rotation is different from 90° the separation will be smaller. Two G-M tubes in coincidence arrangement are then put with their apertures coinciding with the two images.

The correct positions of the two images, when the source was 1.5 cm from the axis, were found experimentally by focusing the ThB *F*-line on to a photographic plate and then changing the direction of the current through the lens. Figure 2 shows the result. As can be seen, the images are fairly well defined on the plate. Due to a small shift in the current during the exposure of the negatron image, this is less sharp. A somewhat better separation can be obtained if the rotation of image were closer to 90°.

The two G-M counters have been designed in one unit with the gas mixture in common. The apertures have a diameter of 10 mm and are situated on the sides of the counters so that the electrons enter the sensitive region directly.

There is especially one important question which has to be considered when further details of the instrument are worked out, i.e., the angular correlation between the photon and the positron and negatron in the pair. This correlation is energy dependent and is approxi-

mately given by the formula by Bethe and Heitler.[4]

$$N(\theta)d\theta=\frac{\theta d\theta}{(\Theta^2+\theta^2)^2};\quad \Theta=\frac{mc^2}{E_0},$$

$N(\theta)$ = number of electrons making the angle θ with the quantum, E_0 = energy of the electron.

In the actual case the γ-emission takes place in the immediate vicinity of the pair converter, i.e., the particle beam from the accelerator should strike the target in close contact with the converter, or the radioactive material should be put directly behind the converter. Independent of γ-energy we will therefore always have, e.g., negatrons emitted from the converter which can pass the diaphragm system and be counted in the one tube. The positron belonging to one of these negatrons may, however, easily get lost in the shutter if the angle between the positron and negatron is too large. The *average* angle between the negatron and positron may be found by differentiating the formula and is approximately given by $\theta_{\text{Av}}\sim mc^2/E_0$. For high energy γ-radiation ($\gtrsim$10 Mev) this angle is seen to be very small, and a substantial part of the electron pairs may go through the diaphragm system.

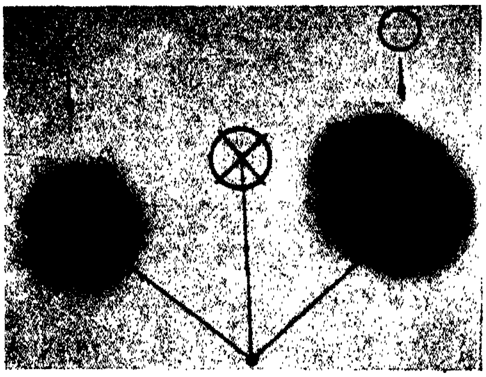

FIG. 2. Photographic investigation of the separation of positrons and negatrons when the sample is placed some distance from the optical axis.

In designing the diaphragm system, attention must be paid to this circumstance. Thus, at lower γ-energies, the shutter system must be rather widely opened, which makes the maximum resolution fairly small. As the γ-energy increases, the number of pairs goes up (a factor of 10 from 2 Mev to 10 Mev), and simultaneously the angle between the negatron and positron makes it possible to increase the resolution by using a more narrow shutter system.

In order to investigate the general properties of the pair spectrometer, its ability of separating and registering positrons and negatrons in the two counters was first studied. In all these measurements the sample was placed 1.5 cm from the axis and with wide-opened shutter system. If the strong F-line of ThB was focused on the one counter, the line could not be observed with the other counter. If the direction of the lens current was changed, the line appeared in the other counter with the same intensity and at the same current as before but could not be observed in the first counter. Next, the continuous spectrum of Na^{24} and Co^{60} was investigated with the two tubes and with different direction of the current. Figures 3(a) and 3(b) show the results for Co^{60}. No window (10 mg/cm^2) correction has been applied. As can be seen from Fig. 3, only a small portion of the spectrum is registered with the "wrong" counter. If the direction of lens current is reversed [Fig. 3(b)], the intensities are almost exactly the same as before when registered with the opposite counters. In all cases the spectra obtained yield Fermi plots, which are straight lines over very large parts of the spectra. The upper limits obtained from these plots agree very well with previously reported values.

Since the ability of registering positrons and electrons is quantitatively known from these experiments, one can also easily use the arrangement to investigate and separate β-spectra consisting of both kinds of particles

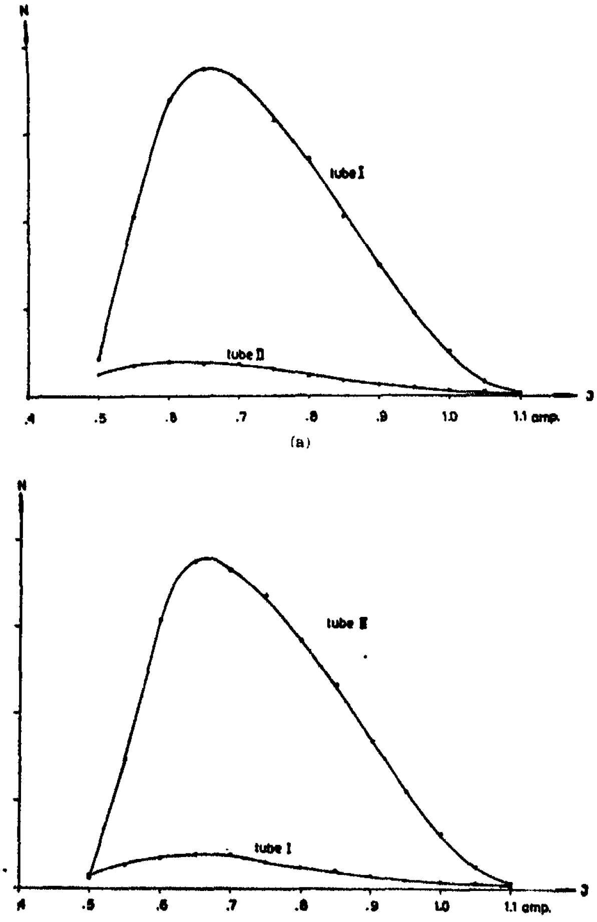

FIG. 3. Co^{60} β-spectrum registered with the two counters. In (b) the current has been reversed compared to (a),

simultaneously, provided the intensity of one of them is more than about five percent of the other. This limit could probably be made much smaller if the sample were put say, 2 cm from the axis and the shutters and G-M-slits were made narrower. If the rotation of image were made closer to 90° than in the present case the separation would also be greater. For the present purpose there is no need for a more complete separation, the only necessary requirement being the ability of registering positrons and negatrons simultaneously in two different tubes.

---

[4] H. Bethe and W. Heitler, Proc. Roy. Soc. 146, 83 (1934).

We have finally tested the pair spectrometer by investigating the electron pairs expelled from a Pb converter by the γ-radiation of ThC'' ($E_\gamma = 2.62$ Mev) and Na^{24} ($E_\gamma = 2.76$ Mev). It should be emphasized that this choice for testing the apparatus is very unfavorable in several respects. Apart from the low pair cross section at these energies, the angle between the positron and negatron is unsuitably large for any kind of pair spectrometer. Furthermore, in order to stop all the primary electrons from the sample the converter had to be chosen thick, which gives rise to pronounced multiple

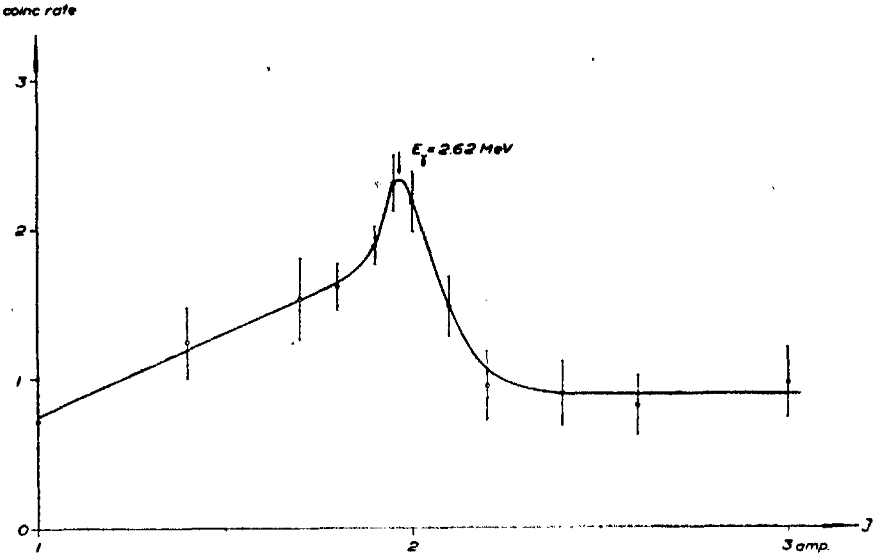

FIG. 4. Coincidence line of the hard γ-ray of ThC''.

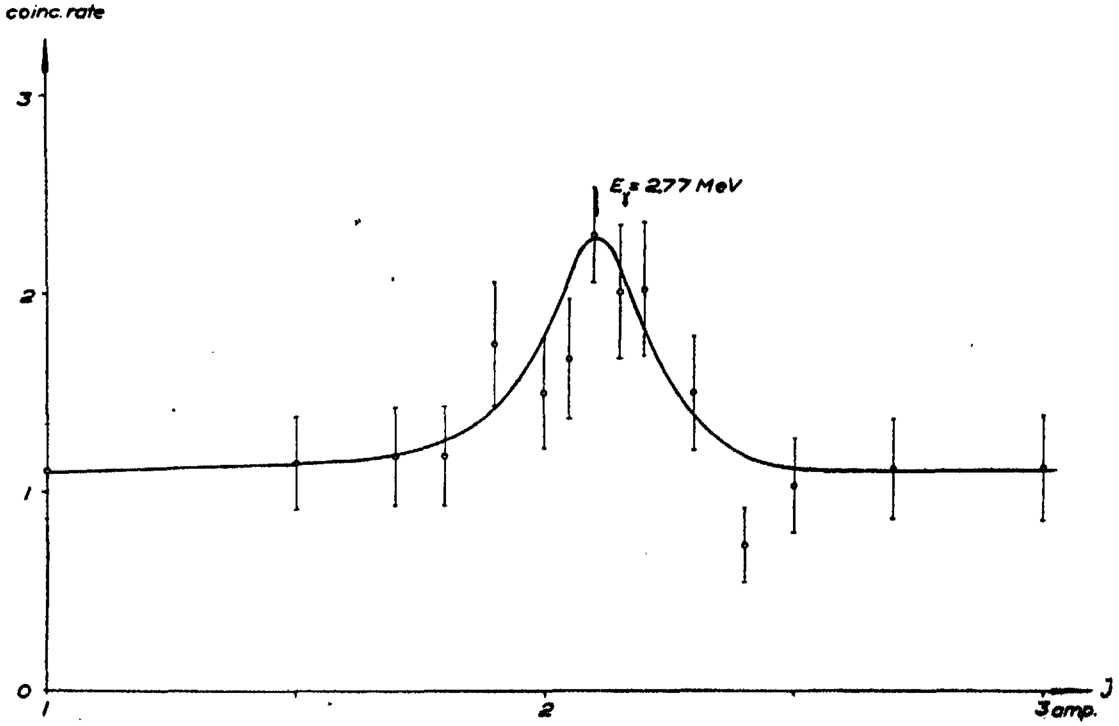

FIG. 5. Coincidence line of the hard γ-ray of Na^{24}.

scattering. The Compton electrons expelled from the thick converter cause a rather high background of the counter registering negatrons and this increases the coincidence background, which otherwise would be very small. Figures 4 and 5 show the coincidence lines obtained for ThC$''$ and Na^{24}. The spectrometer was calibrated by means of some well-known photo-lines in the energy region in question. Using this calibration, the values obtained for the γ-energies of ThC$''$ and Na^{24} from the coincidence lines are 2.62 and 2.77 Mev, i.e., in very good agreement with data obtained by other methods.

Since these experiments in spite of the very unfavorable conditions for a pair spectrometer could give reasonably good results, it seems likely that the instrument may be useful when higher γ-ray energies are available for a similar study.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 5 MAY, 1950

A Focusing Device for the External 350-Mev Proton Beam of the 184-Inch Cyclotron at Berkeley

W. K. H. Panofsky and W. R. Baker
Department of Physics, Radiation Laboratory, University of California, Berkeley, California

(Received January 11, 1950)

A device has been constructed to focus the external beam of the 184-in. cyclotron at Berkeley. The device consists of a cylindrical tube 4 ft. in length and 3 in. in diameter, which contains a longitudinal arc of nearly uniform current density. Such a device will focus any beam of cylindrical symmetry. Owing to the large power requirements of such a device it is applicable only to very short pulsed beams.

The external beam of the 184-in. synchro-cyclotron[1] is produced by a pulsed electrostatic deflector displacing the cyclotron orbits to enter a magnetic shield which channels the beam to the outside of the magnetic field. The beam thus produced covers an area of approximately 8 sq. in. at the bombarding position (about 46 ft. from the center of the cyclotron). Since the total beam attained thus far is only of the order of 10^{-9} amp., the resultant beam density is insufficient for many experiements or at least leads to long runtimes. Since in most experiments beam density rather than total current is the determining factor a focusing device was considered of advantage.

Both horizontal and vertical focusing is possible by means of a wedge-shaped deflecting magnet.[2] The use of such a device, although practical in principle, was rejected here since it involved re-location of the target facilities and also since the physical size of a focusing magnet at this energy and aperture is very considerable. It was therefore decided to study an "in-line" focusing device, i.e., a device focusing without deflection.

The device chosen consists essentially of a current-carrying cylindrical conductor whose axis is parallel to the beam and which is transparent to the passage of the beam. If the current density is uniform, the magnetic field will increase linearly with the radius, and a linear restoring force on the beam will result (Fig. 1). It can easily be shown that if such a device is effectively a "thin" lens, it will give rise to a focal length

$$F=(a/L)(B\rho)/B_o, \tag{1}$$

where $(B\rho)$ is the momentum of the beam, B_o the magnetic induction at the outer edge of the transparent conductor, and the a and L are dimensions defined in Fig. 1.

A current-carrying conductor transparent to the proton beam was realized physically in the form of an arc inside a cylindrical glass tube 3 in. in diameter and 48 in. in length. The arc was struck between two cylindrical aluminum electrodes protruding into the arc tube. The physical layout is shown in Fig. 2. The entrance of the tube is closed by a $1\frac{1}{2}$-mil dural foil; the foil has to be thin enough such that the multiple scattering in the foil will not produce appreciable broadening

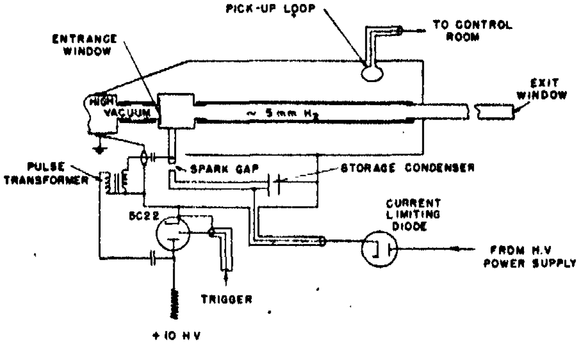

FIG. 3. Diagram of arc lens pulse connections. Note the coaxial connections of the storage condenser in relation to the spark gap and discharge tube.

of the beam. Even at a proton energy of 350 Mev this necessitates the thin foil as indicated owing to the large distances involved. The arc was operated at a pressure of 0.3 to 0.5 mm of hydrogen. The hydrogen was circulated continuously to purify the gas from gases generated from the surfaces of the discharge. The exit foil (0.010 in. Al) which has to stand atmospheric pressure was located near the target to make scattering effects unimportant.

The arc was fed from a condenser bank consisting of sixteen 0.03-μf condensers through a spark gap triggered by a 70-kv pulse transformer. The trigger arrangement is shown in Fig. 3. The arc was operated at a pulse repetition rate of approximately 60 c.p.s., in synchronism with the rotating condenser of the synchrocyclotron. The time sequence of firing the electrostatic deflector and the arc is shown in Fig. 4. At this repetition rate it was found necessary to air-cool the condenser bank and to water-cool the gas discharge tube.

The location of the lens relative to the bombardment position required a focal length of approximately 200 in. and an arc current of 4000 amp. The arc drop under these conditions is 9 kv, principally inductive.

In order to produce a good focal point, two requirements have to be fulfilled: (1) The current density of the arc has to be uniform. (2) The incoming beam must originate from a (real or virtual) point source. Neither of these requirements can be fulfilled accurately in practice. The current distribution in the arc is affected by a number of factors, including the magnetic contraction effect which focuses the beam. There is however, also, at this rate of rise of current, a skin depth effect which tends to keep the arc apart. These and other effects depend on the arc conditions; the arc was thus adjusted empirically to give most uniform current density so judged by end-on photographs of the discharge.

The deflected beam of the 184-in. cyclotron is somewhat astigmatic, i.e., has a different divergence of the

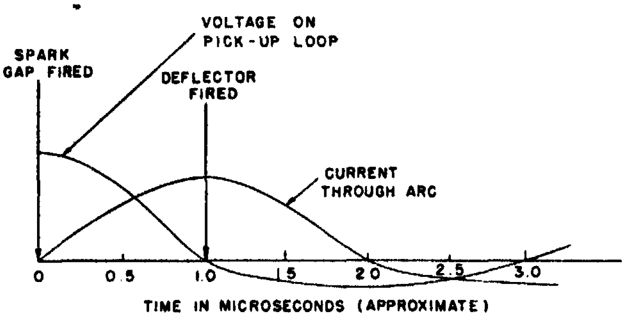

FIG. 4. Time sequence of arc operation. Note the relative firing times of the arc and electrostatic deflector.

FIG. 5. Beam cross sections taken on x-ray film. Operating conditions are as follows: (a). No arc. (b). Arc voltage 7 kv. (c). Arc voltage 12 kv. (d). Arc voltage 8.5 kv; astigmatism corrected. *Note.*—The round marks are fiducial marks and of no significance here.

beam horizontally and vertically. Figure 5(a) shows the cross section of the deflected beam in the external bombardment area of the 184-in. cyclotron with the "arc lens" inoperative. Figure 5(b) shows the beam shape at 7-kv arc voltage and Fig. 5(c) shows the beam shape at 13-kv arc voltage. Note that the optimum focusing conditions for the vertical and horizontal directions are different, indicating astigmatism in the primary beam. An attempt was made to correct the astigmatism with a transverse magnetic field produced by a magnetic quadrupole consisting of two opposed Alnico magnets (see Fig. 6). These magnets, as can be seen by inspection of Fig. 6, produce a vertical focusing and horizontal defocusing force. By choosing magnets of suitable strength (250 gauss at 1½-in. radius for 4-in. depth), the beam astigmatism could be compensated. The resulting beam shape is shown in Fig. 5(d). The ratio in area of Fig. 5(a) (lens not operating) and Fig. 5(d) (lens at optimum) is 8.5. The current density within a central circular area of 1-in. diameter is increased by approximately a factor of five.

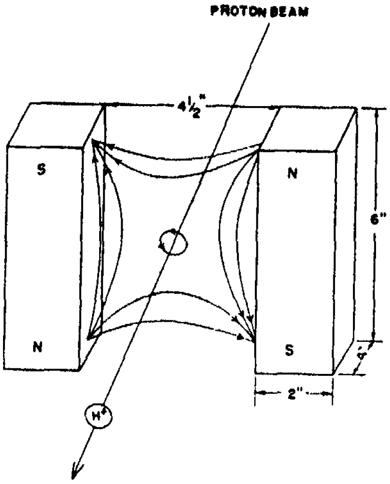

FIG. 6. Geometry of Alnico magnet "quadrupole" to correct astigmatism. Lines of force due to magnets and due to beam are shown to indicate sign of the forces.

The writers are greatly indebted to Messrs. David Vance and Robert Meuser for mechanical design. Mr. Harvey Orrin and Mr. Charles Park aided in the design and installation of the timing and safety circuits. We also owe thanks to Mr. James Vale and Robert Watt and the crew of the 184-in. cyclotron for assisting effectively in these tests. The work was done under the auspices of the AEC.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 5 MAY, 1950

Relation between Apparent Shapes of Monoenergetic Conversion Lines and Continuous Beta-Spectra in a Magnetic Spectrometer. II

GEORGE E. OWEN AND HENRY PRIMAKOFF
Department of Physics, Washington University,[*] *St. Louis, Missouri*

(Received January 30, 1950)

The method worked out previously for correcting distortions which affect the apparent shape of a continuous beta-spectrum has been further extended. A general solution of the integral equation governing the relation between the true and the observed spectra is given, and is applied to the correction of the experimental spectra from a 1-mg/cm^2 source of Cu^{64}. The kernel of the distortion integral equation is determined from a study of the internal conversion lines of I^{131} (47 and 330 kev) using sources of various thicknesses from 0.042 to 0.840 mg/cm^2. It is found that the discrepancy between the experimental Cu^{64} negatron and positron spectra and those predicted by the Fermi ("allowed") theory can be completely understood as a thick source effect.

I. INTRODUCTION

IN a previous paper[1] written sometime ago, a general method was described for compensating source-thickness and instrumental distortions in continuous β-spectra by means of an analysis of monoenergetic conversion lines. Since then, work[2] with S^{35} and H^3 has re-emphasized the importance of source thickness in producing distortions, while an experimental investigation of distortions introduced by spectrometer chamber scattering[3] has shown that these last can be reduced to a minimum by proper chamber design.

Although the experimental data on line shapes used in I was quite rough, it was indicated, as a consequence of the analysis there developed, that the then existing discrepancies between the Fermi theory and experiment for relatively thick source Cu^{64} positron and negatron spectra could well arise from source-thickness and instrumental distortions. Recent work[4] with Cu^{64}, employing extremely thin and uniform sources prepared by thermal evaporation from a hot filament, has confirmed this suggestion, yielding linear Fermi-Kurie (F-K) plots for both positrons and negatrons down to energies as low as 50 kev.

As a further contribution to the clarification of the source-thickness distortion problem in continuous β-spectra, we have (a) made studies of the dependence of conversion line shapes on variation in source thickness for the I^{131} 47- and 330-kev lines, and (b) employed this data and a somewhat more accurate mathematical treatment in order to analyze the discrepancy between Fermi theory and experiment in the continuous positron and negatron spectra from a 1.0-mg/cm² Cu^{64} source. We found that in both cases the discrepancy can be completely understood as a thick source effect.

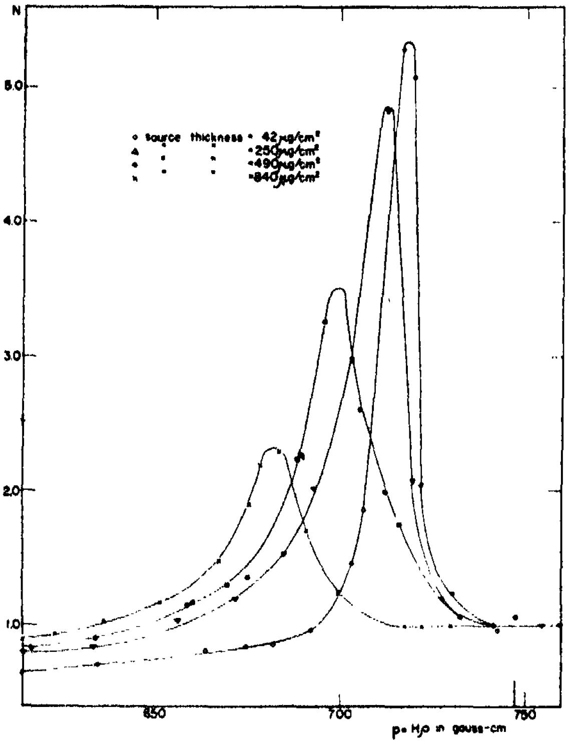

FIG. 1. Line shape at 47 kev (I^{131}) as a function of source thickness.

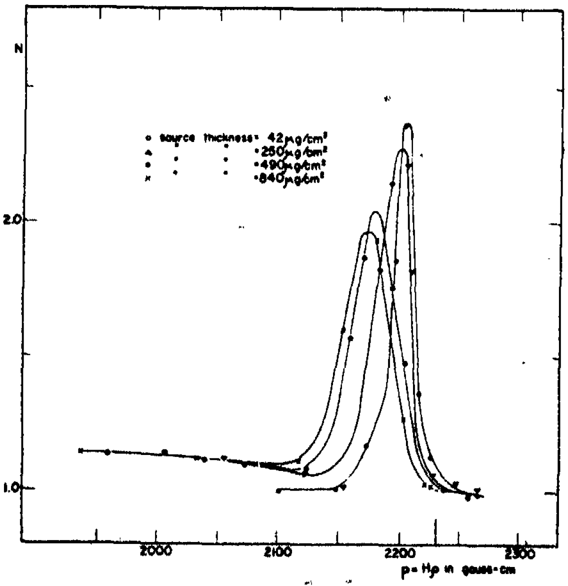

FIG. 2. Line shape at 330 kev (I^{131}) as a function of source thickness.

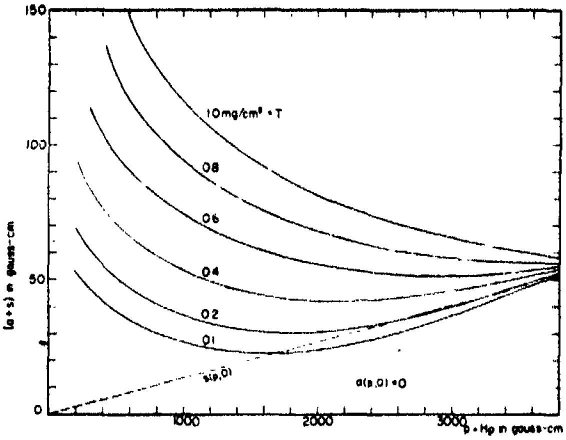

FIG. 3. Coefficient of the first derivative distorting term.

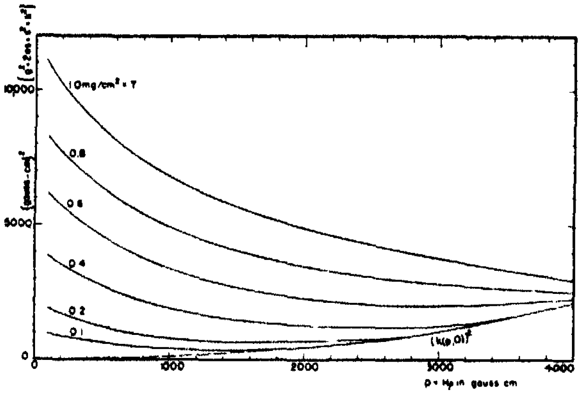

FIG. 4. Coefficient of the second derivative distorting term.

In view of the usefulness of the present technique in the possible analysis of other thick source continuous spectra, the results of the study summarized in (a) and (b) are herewith presented.

II. GENERAL SOLUTION OF THE DISTORTION EQUATION

The distortion problem has been formulated in I, where it has been shown that

$$M(p)=\int_0^\infty N(p')K(p',p)dp', \tag{1}$$

with

$M(p)dp=$ the number of electrons appearing at the spectrometer exit slit with the magnetic field set to admit particles with magnetic rigidity (momentum) lying between p and $p+dp$ (the measured momentum distribution).

$N(p')dp'$ = the number of electrons emitted by the nuclei of the source with an original momentum lying between p' and $p'+dp'$ (the true momentum distribution).

$K(p', p)$, the "kernel" of the distortion (integral) equation; this kernel is determined by the apparent (measured) shape (dependence on p) of a suitably normalized monoenergetic conversion line with a true momentum $= p'$. $K(p', p)$ is therefore a function of the source thickness, T, and the scattering and focusing properties of a given spectrometer.

If $N(p')$ is now expanded in a Taylor series in $p'-p$, the general approximation is obtained

$$M(p)=N(p)\int_0^\infty K(p',p)dp' +\frac{dN(p)}{dp}\int_0^\infty (p'-p)K(p',p)dp' +\frac{1}{2}\frac{d^2N(p)}{dp^2}\int_0^\infty (p'-p)^2\ K(p',p)dp'+\cdots. \quad (2)$$

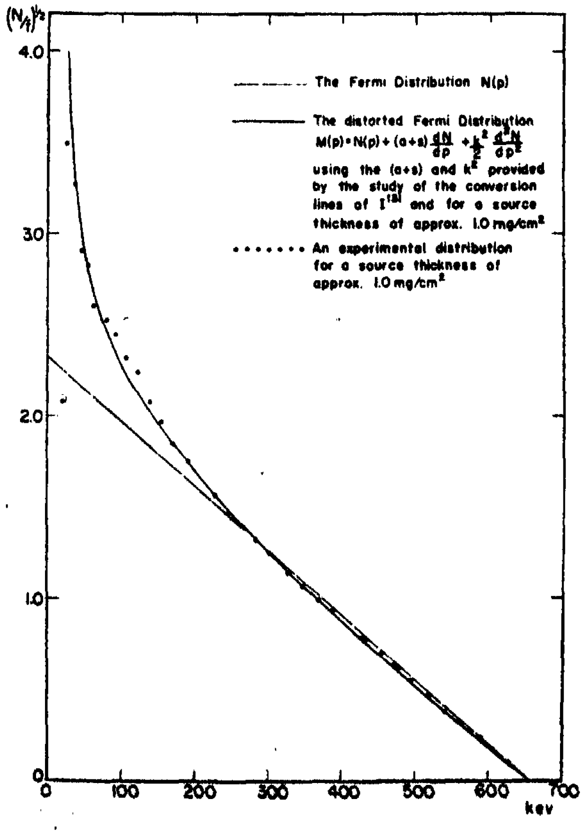

FIG. 5. F-K plot of the positrons from Cu⁶⁴.

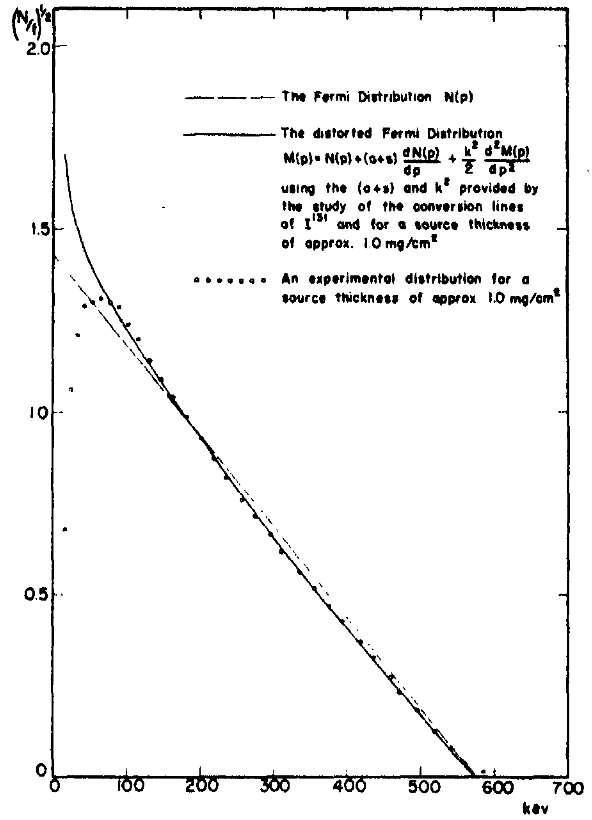

FIG. 6. F-K plot of the negatrons from Cu⁶⁴.

Further, the observed point of maximum intensity of an internal conversion line with a true momentum p' does not lie exactly at p' but rather at $p_m(p', T)$. The quantity $p_m(p', T)$ for a fixed p' decreases with increasing T, i.e., the point of maximum intensity shifts to lower momenta as the source thickness is increased.[5] It is therefore convenient to introduce new variables,

$$s(p', T)=p'-p_m(p', T) \quad (3)$$

and

$$x(p', T)=p_m(p', T)-p=p'-s(p', T)-p\approx p'-p-s(p, T), \quad (4)$$

the last (approximate) equality being a consequence of the relatively slow variation of $s(p', T)$ with p' (compared to the variation of $K(p', p)$). Insertion of Eq. (4) into Eq. (2) then yields,

$$M(p, T)=N(p)+[s(p, T)+a(p, T)][dN(p)]/dp +\tfrac{1}{2}k^2(p, T)[d^2N(p)]/dp^2, \quad (5)$$

where

$$a(p, T)=\int_{-\infty}^{\infty} xK(p+x+s(p, T), p;\ T)dx = \text{the centroid}$$

of the internal conversion line shape about the momentum, p_m, of the maximum intensity. The shape is specified for a given source thickness T by the kernel $K(p', p; T) = K(p+x+s(p, T), p; T)$; also $k^2(p, T) = g^2(p, T) + 2a(p, T)s(p, T) + s^2(p, T)$, with

---

[5] $p_m(p', T)$ will approach a limiting value when T becomes sufficiently thick to stop all electrons originating at the back of the source.

$$g^2(p, T) = \int_{-\infty}^{\infty} x^2 K(p+x+s(p, T), p; T)dx$$

and g^2 = the radius of gyration, squared, of an internal conversion line shape for a source thickness, T, about the momentum, p_m, of the point of maximum intensity.

In general it has been found that the second derivative correction is small and only becomes important near the maximum momentum of the continuous distribution.

III. APPLICATION TO A SMALL 180° SPECTROMETER

The 47- and 330-kev internal conversion lines of I^{131} were studied in a small 180° magnetic spectrometer (5.7-cm radius of curvature).[3] The conversion lines were investigated using four different source thicknesses (42, 250, 490, and 840 μg/sq. cm). The sources were prepared by allowing the solvent containing the I^{131} to evaporate after being placed upon the source backing. This method is known to produce non-uniform crystalization resulting in the actual source thickness for the beta-particles being much larger than the average source thickness as obtained by weighing. In order to minimize non-uniform crystalization small amounts of gelatin were added to the solution. This procedure was found to be quite satisfactory. The average thicknesses of the sources were obtained by weighing.

Figures 1 and 2 show the shapes of the internal conversion lines as a function of the source thickness, T. From the experimental data concerning these lines, values of $s(p, T)$, $a(p, T)$, and $g^2(p, T)$ plus their dependence on source thickness were deduced by interpolation. These values should be accurate to approximately ±20 percent.

Figures 3 and 4 illustrate a summary of this analysis. We have also given, for the sake of comparison, values of $s(p, 0)+a(p, 0)$ and $k^2(p, 0)$ which are to be expected (for an infinitely thin source) from a theoretical analysis of the focusing properties of a 180° magnetic beta-ray spectrometer.[6]

It is significant to note in Fig. 1 that not only does the peak intensity of a line decrease as the source thickness is increased, but that the intensity of the low energy tail grows appreciably with an increase in source thickness. This increase in the intensity of the tail of the line illustrates the degradation of particles to momenta much lower than they originally possessed, and essentially accounts for the type of continuous spectrum distortion which is exhibited as an excess of particles in the low energy region.[7]

To test the accuracy of our method, a comparison was made between the corresponding Fermi allowed shape, $N(p)$, which had been distorted according to Eq. (5) and the values of $a(p, T)+s(p, T)$ and $k^2(p, T)$ for 1.0 mg/cm^2 from Figs. 3 and 4, and, an experimental distribution from a source of approximately 1.0 mg/cm^2 thickness. Experimentally obtained positron and negatron spectra of Cu^{64} were used for this comparison. The $N(p)$ spectra distorted according to Eq. (5), i.e., the $M(p)$, and the experimental spectra were normalized at the value of p where $dN(p)/dp = 0$, since we could expect a minimum distortion at this point.

Figures 5 and 6 present the result of this comparison. The $M(p)$ curve for 1.0 mg/cm^2 obtained from Eq. (5) and Figs. (3) and (4), is represented by the continuous line, and the experimental distributions of positrons and negatrons from a source thickness of approximately 1.0 mg/cm^2 are indicated by the small circles. The agreement is quite good, both in the case of the positrons and in the case of the negatrons.

The greater magnitude of the distortion for positrons as compared to negatrons arises from the higher first derivatives of the positron momentum distribution in the low energy region.[8] In both cases the experimental points at very low energies fall below our $M(p)$ spectra because of absorption in the counter window.

---

[6] G. E. Owen, Rev. Sci. Inst. **20**, 916 (1949).

[7] The line shapes in Figs. 1, 2 were normalized on the high energy side where the thick source distortion is a minimum.

[8] In general because of the sensitive dependence of the corrections to the measured spectrum ($M(p)$) on the derivatives of the true spectral distribution ($dN(p)/dp$, etc.), it is not possible to correct a continuous thick source spectrum by means of a direct comparison with a continuous thin source spectrum, unless the two spectra have the same true shape.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 5 MAY, 1950

Theory of the Capture Process in a Betatron-Injected Synchrotron

David C. de Packh and Milton Birnbaum
Naval Research Laboratory, Washington, D. C.

(Received September 15, 1949)

The investigation of electrons of all possible initial phases and phase velocities at transition between betatron and synchrotron phases of an electron synchrotron has been undertaken with a view toward determining the effect of different ways of applying the r-f. It has been found that for an average accelerator there is an advantage in a moderately slow increase of the voltage from zero to its final value, while for the extreme case where particles enter the transition region with large phase velocity, an asymptotic final radial oscillation amplitude is reached which is independent of the manner in which the voltage is applied, provided only that it is applied adiabatically.

I. INTRODUCTION

It has been shown by Bohm and Foldy[1] and others that the differential equation governing the phase oscillation in a synchrotron is

$$d/dt(H\dot{\phi})+a^2V\sin\phi=a^2V\sin\phi_s, \tag{1}$$

where H is the orbital magnetic field, V is the r-f voltage envelope, ϕ is the phase of the electron with respect to the rotating wave, and $a^2=\omega_0^2/2\pi R(1-n)$. As usual, R is the stable orbit radius, ω_0 is the angular velocity of the electron in its orbit, and $n=-R\partial H/H\partial R$. ϕ_s is the equilibrium angle of the bunch. Following reference 1, we may take the right-hand side of (1) to be negligible at the transition between betatron and synchrotron phases, since the betatron flux condition is satisfied and since the energy of the electron at transition, W_1, is large in comparison with the rest energy, W_0. The rate at which energy is being added to the particle due to betatron action is assumed to be slow. As a consequence of this assumption, one may divide out the H from the first term of the left-hand side; that is, the percentage change of H during one cycle of the phase oscillation is taken to be small. Consequently, the differential equation is to a sufficient approximation of the form

$$d^2\phi/dt^2+f(t)\sin\phi=0;$$

to make matters more precise, $f(t)$ can be taken as a power of the time and the equation written

$$d^2\phi/dt^2+b^2(t/T)^s\sin\phi=0. \tag{2}$$

The bunching process is taken to be over in a time T dating from the instant of application of the r-f. Accordingly, the power s is a design parameter (a quantity $p=1/(s+2)$ will be used frequently in preference to s for convenience in the analysis), and $b^2=a^2V_T/H_T$, where V_T/H_T is the value of V/H at $t=T$. For the most part T will be sufficiently short so that H can be considered constant, meaning that the voltage envelope increases as the sth power of the time. V_T is supposed to be enough larger than $2\pi c\dot{H}/\omega_0^2$ so that the equilibrium angle of the bunch shifts by a negligible amount after the betatron flux is removed.

In general one can distinguish two limiting types of behavior of the particles subject to (2) according as their initial phase velocity, $\dot{\phi}_0$, is large or small in comparison with the quantity $b\phi_0$, where ϕ_0 is the initial phase displacement. To explain the difference between these two, let us for the moment suppose that the angles involved are small and consequently that $\sin\phi$ can be replaced by ϕ. This is then the equation of a harmonic oscillator of displacement ϕ whose restoring force varies with the time. If the particle is given a large initial velocity, it is plainly of advantage to increase the restoring force as rapidly as possible if the amplitude of oscillation is not to become excessive. If, on the other hand, the particle has an initial displacement but no initial velocity, it is desirable to increase the restoring force slowly in order not to bestow too great a velocity on the particle by the time it first passes through the equilibrium position. If there is a group of particles, all subject to the same restoring force but having varying conditions of initial displacement and velocity, it then appears that there is a certain optimum way of applying the restoring force in order to keep the maximum number of this group confined within a given range of final amplitudes of oscillation.

This qualitative argument fails to do justice to those particles whose initial phase velocities are high because the restoring force is in fact not linear with ϕ but sinusoidal. It will be shown for this type of particle that its final velocity is, in the main, independent of the manner of application of the r-f, provided it is applied slowly; it depends only on the final voltage and the initial phase velocity of the particle.

II. THE "LINEARIZED" EQUATION AND ITS GENERAL SOLUTION

In order to explore the distribution of amplitudes arising from the initial velocity and displacement components, we may examine the "linearized" equation in which $\sin\phi$ is replaced by ϕ; this is of course

$$d^2\phi/dt^2+b^2(t/T)^s\phi=0. \tag{3}$$

---

[1] D. Bohm and L. Foldy, Phys. Rev. 70, 249 (1946).

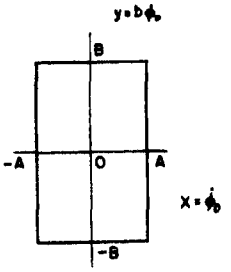

FIG. 1. Rectangle representing possible starting conditions.

The solution of this[2] is

$$\phi=t^{\frac{1}{2}}[a_1J_p(u)+a_2J_{-p}(u)]$$
$$\dot\phi=bt^{\frac{1}{2}}(t/T)^{s/2}[a_1J_{p-1}(u)-a_2J_{1-p}(u)] \qquad (4)$$

in which

$$u=2pTb(t/T)^{\frac{1}{2}p},\quad p=1/(s+2),\quad a_1=\phi_0p!(pTb)^{-p}T^{\frac{1}{2}},$$

and

$$a_2=\phi_0(-p)!(pTb)^{+p}T^{-\frac{1}{2}}.$$

The simplified notation $p!=\Gamma(p+1)$ is used throughout.

We are interested in rise times appreciably greater than one cycle of phase oscillation, so that we may use the asymptotic approximations for the Bessel functions. Since what determines the loss or capture of a particle is whether or not its radial oscillation amplitude exceeds the available aperture, the amplitude in turn depending on the final phase velocity, we accordingly find the asymptotic value of this quantity, using the relation

$$[\dot\phi_a(T)]^2=[b\phi_0\pi^{-\frac{1}{2}}(-p)!(pTb)^{p-\frac{1}{2}}]^2$$
$$+[\dot\phi_0\pi^{-\frac{1}{2}}(p-1)!(pTb)^{\frac{1}{2}-p}]^2+2b\phi_0\dot\phi_0\cot p\pi, \qquad (5)$$

where the subscript a indicates the amplitude of the quantity it follows. The amplitude of the phase velocity is greatest at $t=T$. The two opposing trends mentioned above are clearly in evidence in this expression; the first term vanishes while the second becomes infinite with increasing T.

In order to determine the best way of applying the voltage, one must consider the prior distribution of phase amplitudes and velocities at the instant when the r-f is first turned on. It is apparent that all phases from $\phi=\pi$ to $\phi=-\pi$ are equally probable for a given particle. Following reference 1, we take the energy spread of the beam to be

$$\Delta W=(1-n)(2W_0W_I)^{\frac{1}{2}}(x_1/R),$$

where W_I is the kinetic energy of injection and x_1/R is the relative aperture. The phase velocity at energy $W_I \gg W_0$ is, from (15),[1]

$$[\omega_0(2W_0W_I)^{\frac{1}{2}}/2W_I](x_1/R), \qquad (6)$$

since the energy spread is equally divided about a mean. We may take (6) to be the limit of possible phase velocities and assume that any phase velocity between $-A$ and A, where A is the value of (6), is as probable as any other for a given particle.

We may now construct a rectangle as shown in Fig. 1, taking $y=b\phi_0$ and $x=\dot\phi_0$, extending between the limits $-A$ and A as regards x and between $-B$ and B as regards y; here $B=\pi b$. As indicated in the preceding paragraph, the area of this rectangle has been taken to be everywhere equally densely populated with particles.

The error incurred in extending the linear solution to $\phi=\pi$ and thus of taking the limit B simply as πb in the face of the non-linear character of the original Eq. (2) is not as great as might be supposed. The smallest value of B/A for a conceivable machine is about 20, and the value is usually higher, so that particles having large initial displacements derive most of their energy of oscillation from initial potential rather than kinetic energy. Now one can form a good idea of the behavior of a particle with zero initial phase velocity without making the linearizing approximation (see Appendix I); such a calculation indicates that for $p=\frac{1}{3}$, for example, the ratio of $\dot\phi_a(T)$ as computed in this more accurate way to the approximate "linearized" value from (5) is between 0.91 and 1.00 for any starting angle up to 178°.

In the notation adopted for the rectangle one can put (5) as

$$z=fx^2+gy^2+hxy, \qquad (7)$$

where z is the square of the final phase velocity amplitude and f, g, and h are the corresponding coefficients depending on p and T. An examination of (5) indicates that the discriminant of this expression, h^2-4fg, is constant and equal to -4. Thus it follows that the lines of equal z and consequently of equal final radial oscillation amplitude are ellipses symmetric about the origin.

The greatest interest is in the ellipse $z=z_1$, where z_1 is the particular value of z corresponding to the available aperture; one has $z_1=\omega_0^2(x_1/R)^2$ [see, for example, Saxon and Schwinger,[8] relation (21)]. If a particle lies within the rectangle but outside the ellipse $z=z_1$, then its radial oscillation is greater than the aperture and it is lost. It therefore becomes desirable as nearly as possible to fit the ellipse to the rectangle. In this con-

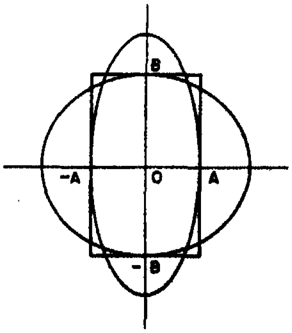

FIG. 2. Ellipses representing approximate limiting values of g.

---

[2] E. Jahnke and F. Emde, *Tables of Functions* (Dover Publications, New York, 1943), p. 147.

[8] D. Saxon and J. Schwinger, "Orbits in magnetic resonance accelerators" (unpublished).

nection it is also desirable that $z=z_1$ be as little tilted as possible, since any dissymmetry with respect to the axes cannot but reduce the area common to the rectangle and the ellipse. In view of the large value of B/A, it is easy to verify that the xy term in (7) can be overlooked, so that this requirement is automatically satisfied. From (5), $fg=\csc^2 p\pi$; thus the equation of the ellipse becomes approximately

$$x^2\csc^2 p\pi/g+gy^2=z_1. \qquad (8)$$

Now one can see (Fig. 2) that there are two approximate limits on g for $z=z_1$; these are tangency at the sides $(x=\pm A)$ and tangency at the top $(y=\pm B)$. Going beyond these limits cuts off particles at the sides and top, respectively, of the rectangle. Tangency at the sides means $g=A^2\csc^2 p\pi/z_1$; tangency at the top gives $g=z_1/B^2$. The best value lies between these limits. Now

$$A=\omega_0[(2W_0W_I)^{\frac{1}{2}}/2W_1](x_1/R)$$

and $B=\pi b=\pi\omega_0(V_T/2\pi RH_T(1-n))^{\frac{1}{2}}$ [see (1), (2), and (6)], so that

$$\csc^2 p\pi W_0W_I/2W_1^2<g<(1/\pi)^2(x_1/R)^2 \times[2\pi RH_T(1-n)/V_T], \qquad (9)$$

unless of course the rectangle is such that $z_1/B^2 \leqq A^2\csc^2 p\pi/z_1$, in which case the common area is greatest if one keeps the ellipse tangent at the sides, its area being contained entirely within that of the rectangle.

The best possible value of g in the range (9) can be found by choosing it such that one of the ellipses of the family, say $z=z'<z_1$, is tangent to the rectangle at both top and sides; this is the value of g which concentrates the greatest number of particles in the amplitude z'. Substituting in (8) gives the best value of g, say g_0, as

$$g_0=A\csc p\pi/B,\text{ from which } z'=AB\csc p\pi. \qquad (10)$$

Remembering (5), we have $g=(-p!)^2(pTb)^{2p-1}/\pi$, whence one finds the rise time corresponding to g_0 to be

$$T_0=(1/pb)[(-p)!^2/\pi g_0]^{1/(1-2p)}, \qquad (11)$$

which is valid only if pT_0b turns out large compared with 1.

The distance along the normal to the two curves z and $z+dz$ is $dz/|\nabla z|$; consequently the area between them is $dz\int ds/|\nabla z|$, the integral being along the curve z. In Cartesian coordinates this becomes $dz\int dx/(\partial z/\partial y)$; in polar coordinates it is $dz\int rd\theta/(\partial z/\partial r)$. If the total number of electrons in the rectangle is taken as unity, then the number dN having oscillation amplitudes between z and $z+dz$ is

$$dN=(dz/4AB)\int dx/(\partial z/\partial y)$$
$$=(dz/4AB)\int rd\theta/(\partial z/\partial r).$$

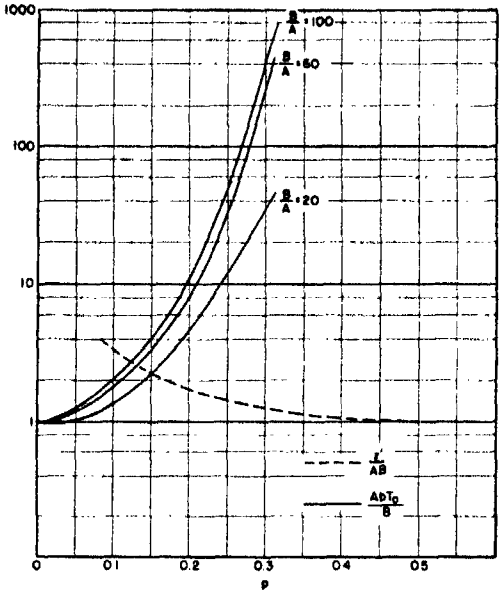

FIG. 3. Variation with p and B/A of the quantities z'/AB and AbT_0/B. The former is proportional to the square of the required aperture and the latter to the rise time.

In order to determine the distribution of amplitudes when the optimum value of g is used, one divides the region into two parts, namely, $0<z<z'$ and $z'<z<2z'$, since $2z'=A^2\csc^2 p\pi/g_0+g_0B^2$ is the largest possible value of z within the rectangle, assuming that z_1 is outside the rectangle. All the ellipses in the first region are complete and lie inside the rectangle; hence, polar coordinates are used, the integration extending from 0 to 2π. This gives

$$dN=\pi\sin p\pi dz/4AB,\quad 0<z<AB\csc p\pi. \qquad (12)$$

This means that the squares of all radial oscillation amplitudes up to

$$x_0/R=\{\pi[(2W_0W_I)^{\frac{1}{2}}/2W_1] \times[V_T/2\pi RH_T(1-n)]^{\frac{1}{2}}\csc p\pi(x_1/R)\}^{\frac{1}{2}}$$

are equally probable and that $\pi/4$ of the total number of particles are in this group. The remainder of the electrons are between x_0/R and $(x_0/R)\sqrt{2}$; by using Cartesian coordinates one can verify without difficulty that the distribution is

$$dN=(dz\sin p\pi/2AB)[\arcsin(z'/z)^{\frac{1}{2}} -\arcsin(1-z'/z)^{\frac{1}{2}}]. \qquad (13)$$

If $z=z_1$ lies wholly within the rectangle, one has again

$$dN=\pi\sin p\pi dz/4AB,$$

where, however, the limits of application are $0<z<z_1$; the distribution is uniform over all amplitudes within the aperture, and the fraction of particles captured is $\pi\sin p\pi z_1/4AB$. The intermediate case in which $z=z_1$ is partly inside the rectangle and partly outside can be worked out without difficulty by the methods already outlined.

To estimate the amplitude if the r-f is applied suddenly one may return to Eq. (3), taking $s=0$. From this it can be seen that if the voltage is applied in one step, the lines of equal oscillation amplitude will be the circles $z=x^2+y^2$; further, if, as before, we impose the circle $z_1=x^2+y^2$ on the rectangle, we can form an idea of the number of particles lost. Two cases can be distinguished: (1) the circle is within the rectangle, under which conditions the fraction saved is simply $\pi z_1/4AB$; (2) the circle is partly outside the rectangle, in which case the number saved is $(z_1/2AB)[q(1-q^2)^{\frac{1}{2}}+\text{arc}\sin q]$ where $q=A/z_1^{\frac{1}{2}}=(2W_0W_I)^{\frac{1}{2}}/2W_1$. This fraction cannot of course exceed 1.

It may be profitable to discuss a numerical example in order to fix these concepts. Consider a machine of the following specifications: $\omega_0=3\times10^8/\text{sec.}$, $V_T=10$ kv, $n=\frac{2}{3}$, $W_I=50$ kev, $x_1/R=3$ percent, $W_1=1.5$ Mev; tentatively we take $p=\frac{1}{3}$, that is, the voltage rises linearly with the time. From (9) we learn that $7.41\times10^{-3}<g<3.70\times10^{-2}$; from (10) $g_0=1.66\times10^{-2}$. It is apparent, however, that the linear rise leads to an excessive rise time; (11) gives $bT_0=1.3\times10^5$ and $T_0=8800$ μsec. The importance of choosing the law of rise so as to keep the rise time within reason is here made clear. Under these conditions it is desirable to form an idea of the dependence of T_0 and the required aperture on p. Figure 3 shows graphs of AbT_0/B and z'/AB as functions of p. From these it may be inferred that the best value of p for most machines lies somewhere between 0.1 and 0.2, somewhat favoring the larger value. Smaller values of p lead to excessive apertures; larger ones to excessive rise times. In this example, one might take $p=\frac{1}{6}$, corresponding to a fourth power law of rise, giving a rise time of 21.3 μsec. Equation (12) indicates that the distribution is uniform up to a relative aperture of 2.64 percent and that 79 percent of the particles are in this group; if the electrons could do so, they would occupy an aperture of 3.74 percent, which exceeds the available space, so that a small number are lost. This number might be computed by integrating (13) between apertures of 3.0 and 3.74 percent; however, it is easier to compute the difference between the area of the rectangle and the portion of $z=z_1$ contained within it; the fraction of particles lost amounts to about 8 percent of the total. Finally, to estimate the number retained if the voltage is applied suddenly, one finds $q=0.075$, so that the total fraction saved is 30 percent.

In general, it may be remarked that any factors in the design which limit the range over which g can vary in (9) are detrimental to the efficiency of capture. This consideration favors values of p not too near zero, high transition energies, and large apertures. The degree to which this affects the ultimate design of the machine must, of course, be weighed against other factors not mentioned here.

III. THE LIMITING CASE FOR PARTICLES OF HIGH INITIAL PHASE VELOCITY

One is justified in applying the results of the last section only because in actual machines the rectangle describing the distribution of initial conditions is tall and narrow. The linear solution is otherwise quite inaccurate. It is therefore of interest to determine the upper limit of oscillation possible in a machine in which, for one reason or another, particles may enter the transition region with large phase velocities. One can immediately see that the prediction arising from the linearized theory of infinite amplitude for an infinite rise time is in error because of the sinusoidal character of the restoring force; in fact, if the rise time is long enough so that the process is truly adiabatic, it would appear probable that the final oscillation amplitude will be independent of the manner of application of the voltage since in this case there is no dependence on the initial phase of the particle; the angular velocity depends merely on the magnitude of the applied voltage and the initial phase velocity.

To show this, let us consider the analogous pendulum of unit length in a slowly varying gravitational field; if the displacement is ϕ as before, then

$$d^2\phi/dt^2+g\sin\phi=0. \tag{15}$$

Two forms of solution for this equation are available according as the pendulum is rotating or vibrating.[4] These are

$$\phi=2\,\text{arc}\sin\begin{cases}k\,\text{sn}(u,k)\\ \text{sn}\left(K\int_0^u kdu/K,\,1/k\right)\end{cases}$$
$$\phi=2kg^{\frac{1}{2}}\begin{cases}\text{cn}(u,k)\\ \text{dn}\left(K\int_0^u kdu/K,\,1/k\right),\end{cases} \tag{16}$$

where the upper quantities refer to the vibrating and the lower to the rotating pendulum. If ϕ_a is the amplitude of the velocity variation, then $k=\phi_a/2g^{\frac{1}{2}}$, $u=\int_0^t g^{\frac{1}{2}}dt$, and K is the complete elliptic integral of the first kind and the appropriate modulus (k or $1/k$). The two cases are thus differentiated according as k is less or greater than one. The integral form of the argument in the rotating case is necessitated by the variation of the period of the function during the course of the motion.

The action integral for the rotating pendulum is readily found to be

$$J=kg^{\frac{1}{2}}E(1/k)=a\phi_0, \tag{17}$$

where a is a constant, since the motion is adiabatic at $t=0$. $E(1/k)$ is the complete elliptic integral of the second kind of modulus $1/k$. Since the total energy at $t=0$ is kinetic and $E(0)=\pi/2$, the constant a is seen to be $\pi/4$ and consequently $\dot{\phi}_a$ can be obtained at any time during the motion of the rotating pendulum from the transcendental equation

---

[4] E. T. Whittaker, *Analytical Dynamics*, 4th ed. (Cambridge University Press, London, 1937), pp. 72–74.

$$kE(1/k)=\pi\phi_0/4g^{\frac{1}{4}}. \tag{18}$$

If g continues to increase, there will eventually be a crossover point at which the pendulum passes from a rotating to a vibrating mode. This of course corresponds to particles which are slipping over the crests of the potential function but which are finally trapped in a valley because of the increase in the height of the crests with time. Accordingly, we must have $\dot{\phi}_c/\phi_0=\pi/2$, where ϕ_c is the amplitude of ϕ at the crossover.

Moreover it has been shown [1, 3] that the solution for the vibrating pendulum can be put in the form

$$\phi=2k_1g_1{}^{\frac{1}{4}}g^{\frac{1}{4}}\mathrm{cn}(u,\, k), \tag{19}$$

where k_1 and g_1 are values of these quantities at some specific time, say t_1. One can now estimate the amplitude at the time T, assuming that the crossover has occurred before this time, by taking $t_1=t_c$, the crossover time. At this instant $k_1=1$ and $g_1=\pi^2\dot{\phi}_0{}^2/16$, so that

$$\phi_a(T)=(\pi\phi_0 g_T{}^{\frac{1}{4}})^{\frac{1}{2}}=(\pi b\phi_0)^{\frac{1}{2}} \tag{20}$$

in the notation of Eq. (2). The condition that the crossover occur in the interval $\frac{1}{2}<t<T$ is $\phi_0<4b/\pi$.

This analysis of course neglects those singular regions in which the crossover occurs when the particle is very near the unstable point $\phi=\pi$. Accordingly, there are certain specific values of ϕ_0 which give rise to these singularities and impose a fine structure on the general behavior indicated by (20). These singularities have been investigated both numerically, by means of a computing machine, and analytically, by joining the adiabatic solution to one in which the restoring force is a triangular rather than a sine wave. The singularities are of a very low order (see Appendix II). It is thus reasonable to suppose that only a very small percentage of the totality of particles of large velocity are affected by this fine structure and that the behavior indicated by (20) is essentially that followed by the great majority of the particles. It is a pleasure to acknowledge the assistance of Mr. C. H. Chrisman in connection with the numerical work performed on the BTL relay computer.

APPENDIX I

To arrive at the solution for the general Eq. (2) for a particle with an initial displacement ϕ_0 but no initial phase velocity, one must investigate the differential equation near $t=0$, where the adiabatic solution previously obtained is no longer valid. An exact solution already exists for the linearized Eq. (3), and consequently a simple way to proceed is to determine the effect on the solution (4) of putting $\sin\phi$ for ϕ for large phase displacements. We do this by considering Eq. (2) as that of a modified harmonic oscillator, in which the "period" of the motion is modified in the same way as the period of a pendulum is changed with large oscillation amplitudes. That is, the period is multiplied by a factor $2K(k)/\pi$, where K is the complete elliptic integral of the first kind of modulus $k=\sin\phi_a/2$, ϕ_a being the amplitude of oscillation; thus one makes the transformation

$$u=\frac{\pi b}{2}\int_0^t (1/K)(t/T)^{s/2}dt$$

instead of

$$u=b\int_0^t (t/T)^{s/2}dt$$

in (3). We shall use this relation to establish the time of the first zero of the displacement, at which time it will be assumed that the motion is adiabatic so that a juncture can be made to the solution (16). If t_0 is the time of the first zero and if we assume that $\phi_0=\phi_a$ for $0<t<t_0$, then one can establish that

$$t_0/T=[K(\sin\phi_0/2)u_0(-p)/\pi pTb]^{2p},$$

where $u_0(-p)$ is the first zero of $J_{-p}(u)$. We can also get the value of the amplitude of the function at the first zero to a reasonable approximation by recalling that at this time the motion is supposed to be adiabatic and of constant frequency with respect to u and therefore that the value of the "amplitude" is equal to the value of the derivative. Using these concepts and (16) one obtains the result

$$\dot{\phi}_a(T)=\sin\{(\phi_0/2)\Lambda'_{-p}[u_0(-p)]\}(\pi pTb/K(\sin\phi_0/2)u_0)^{p-\frac{1}{2}},$$

where $\Lambda_p(u)=p!(u/2)^{-p}J_p(u)$.[5] Λ' is the derivative of this function with respect to its argument. The values for $u_0(-p)$ and $\Lambda_{-p}'[u_0(-p)]$ can be computed from existing tables and formulas.[2] The results obtained from the above expression are in excellent agreement with numerical solutions of (2) obtained from the digital computer.

APPENDIX II

An approximate form of (2) which furnishes a reasonable idea of the behavior of the particles near $\phi=0$ and $\phi=\pi$ is furnished by the two linearized equations $d^2\phi/d^2t+b^2(t/T)^s\phi=0$ and $d^2\theta/dt^2-b^2(t/T)^s\theta=0$, where $\theta=\phi-(2m+1)\pi$, m an integer. The former equation holds for ϕ near $2m\pi$, the latter for θ near zero, the transitions between the domains of application of the two equations being at $\theta=\pm\pi/2$. It is apparent that, by the use of these equations and the indicated boundary conditions, the original motion described by (2) is changed into a motion in which the restoring force as a function of the displacement is in the form of a symmetrical triangular wave with period 2π and a slope of ± 1. This modification preserves the qualitative features of the motion, particularly near $\phi=0$ and $\phi=\pi$.

For the purpose of investigating the crossover in the neighborhood of the singularity at $\phi=\pi$ the second equation is sufficient. If u is defined as in (4) and u_0 corresponds to the value of u at which $\theta=-\pi/2$ and such that the crossover occurs in the immediately following quarter-cycle $(-\pi/2<\theta<0)$, then one may write $\delta=u-u_0$ and form the asymptotic solution to the equation thus:

$$\theta/\theta_0=(1+\delta/u_0)^{p-\frac{1}{2}}[\cosh\delta+(\dot{\theta}_0/\theta_0 b)(u_0/2pTb)^{2p-1}\sinh\delta]$$

$$\dot{\theta}/\theta_0=b(2pTb/u_0)^{2p-1}(1+\delta/u_0)^{\frac{1}{2}-p}$$
$$\times[\sinh\delta+(\dot{\theta}_0/\theta_0 b)(u_0/2pTb)^{2p-1}\cosh\delta],$$

from which one concludes immediately that at the crossover

$$\tanh\delta=(2\dot{\theta}_0/\pi b)(u_0/2pTb)^{2p-1},$$

where θ_0 has been put equal to $-\pi/2$, or $u_c=u_0+\mathrm{arc\ tanh}(2\dot{\theta}_0/\pi b)\times(u_0/2pTb)^{2p-1}$, u_c being the value of u at the instant of crossover. Now from (19)

$$\phi_a(T)\propto g_c{}^{\frac{1}{4}}=\{(\tfrac{1}{2}pTb)[u_0+\mathrm{arc\ tanh}(2\dot{\theta}_0/\pi b)(u_0/2pTb)^{2p-1}]\}^{\frac{1}{2}-p}.$$

Also $\mathrm{arc\ tanh}\,y=\frac{1}{2}\log(1+y)/(1-y)$; if we take y very near 1, we can neglect additive constants, so that in this region

$$\phi_a(T)\propto[-\log(1-h\dot{\theta}_0t_0{}^{-s/2})]^{\frac{1}{2}-p},$$

---

[5] See reference 2, p. 128ff.

where h is a constant depending on p, T, and b, and t_0 is the time corresponding to u_0. The relation of $\dot{\theta}_0 t_0^{-s/2}$ to the initial conditions can be established by recalling the adiabatic theorem in the form $J=\bar{T}\tau=a\phi_0$, where $\bar{T}$ is the mean kinetic energy over one cycle, τ is the duration of that cycle, and a is a constant. Since $\bar{T}\tau\propto\phi_0$ while $\bar{T}\propto\dot{\phi}_0^2$ for a small change in ϕ_0, it follows that $\tau\propto 1/\dot{\phi}_0$, while if the number of cycles is constant, the whole elapsed time t_0 must also be proportional to $1/\dot{\phi}_0$. Now $\dot{\theta}_0\propto\dot{\phi}_0$, and since $t_0\propto 1/\dot{\phi}_0$, one has $\dot{\theta}_0 t_0^{-s/2}\propto\dot{\phi}_0^{\frac{1}{2}p}$, so that

$$\phi_a(T)\propto[-\log(1-h\dot{\phi}_0^{\frac{1}{2}p})]^{1-p}.$$

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 5 MAY, 1950

Apparatus for Recording Fluctuations in the Refractive Index of the Atmosphere at 3.2 Centimeters Wave-Length*

C. M. Crain
Electrical Engineering Research Laboratory, The University of Texas, Austin, Texas

(Received January 16, 1950)

This article describes equipment which is being used for measuring and recording rapid fluctuations in the refractive index of the atmosphere.

RECENT studies[1,2] in microwave propagation have indicated the need for a device which will accurately record small changes in the refractive index of the atmosphere. A block diagram of the equipment which has been used by the Electrical Engineering Research Laboratory at The University of Texas for recording such changes is shown in Fig. 1. The equipment is a modification of that previously used for measuring the dielectric constants of several gases under controlled conditions.[3] The frequency of each of two microwave oscillators is controlled by the resonant frequency of its associated cavity resonator by the method previously described by Pound.[4] The outputs of the two stabilized oscillators are mixed in a crystal detector as shown. The output of the crystal is amplified by a two-stage conventional 10.7-megacycle amplifier and then applied to a limiter and discriminator. The output of the discriminator is used in conjunction with a differential amplifier to deflect a recording milliammeter. Thus, the deflection of the milliammeter is made proportional to the change in resonant frequency of one of the cavity resonators if the resonant frequency of the other cavity remains fixed. TFX-30EC wave meters were used for the cavity resonators. One cavity was sealed off so that its resonant frequency would not change with atmospheric refractive index changes. The second cavity was modified by drilling holes in one end plate as shown in Fig. 2, making about 20 percent of the end plate open. The plunger was reduced in diameter to give approximately the same open area on the other end of the cavity. A small blower was coupled to the cavity by means of a thin rubber hose so that air could be pulled through it. Thus, a change in the dielectric properties of the air being pulled through the cavity causes the output frequency of the oscillator to change accordingly. The 10.7-megacycle amplifier, limiter, and discriminator were built such that the recording milliammeter would be deflected linearly from its normal mid-scale position to either zero or full scale by a frequency change from

10.7 megacycles of ±100 kc. It can be shown that the change in resonant frequency of the cavity resonator in kilocycles is 9.34 $(\Delta N)10^6$, where ΔN is the change in index of refraction of the gas in the cavity resonator, and the normal resonant frequency of the cavity is 9,340 megacycles. Thus, if the index of refraction varies one part in a million, the resonant frequency of the cavity resonator will change 9.34 kc and the recording milliammeter will change deflection approximately 4.7 percent of full scale deflection. The equipment then records changes in the refractive index about a mean value of ±100/9.34 or 10.7 parts in a million or simply 10.7 N units. Changes in one direction only as large as 21.4 N units can be recorded by adjusting the micrometer of the cavity wave meter such that operation is at one end of the discriminator curve. Measurements which have been made to date indicate that such a range is adequate for recording the maximum fluctuations which occur in the refractive index at a fixed point in time intervals less than a minute. The stability of the equipment was such that when both cavities were sealed off, the variation in the indicated index of refraction was never greater than 0.25 N unit in a minute.

Most of the measurements to date have been made from two to ten feet above the ground and surprising results have been obtained. Variations over a period of a fraction of a second greater than 10 N units were recorded when the ground was wet. For drier ground conditions, the variations have been less. A detailed study of these fluctuations for heights above the ground up to 300 feet and for various meteorological conditions is now being made.

The actual changes in refractive index are greater than those recorded as the nature of the equipment is such as to smooth out the peaks in the variations. Obviously the cavity itself will have some smoothing effect due to its volume. In many cases, as is apparent from examining the milliammeter recording, the time response of the meter has limited the magnitude of the change indicated. Changes in refractive index due to changes in the temperature of the air are smoothed out to some extent since air entering the cavity tends to assume the temperature of the walls of the cavity. However, the rate of flow of air has been such as to make this smoothing effect small. Another error can arise from the dimensions of the cavity varying because of fluctuations in temperature. However, since the invar cavity walls are 0.15 inch thick, the temperature time constant of the cavity will be such as to practically eliminate all erratic fluctuations about a mean temperature. The long time variations in temperature will be fairly well compensated for since both cavities will change dimensions approximately the same. Corrections as necessary could be made by recording the temperature difference between the cavity walls. This has not been done in the equipment described as this error has been negligible in the study of rapid fluctuations.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 5 MAY, 1950

Combination Two-Circle Goniometer and X-Ray Spectrometer

MORTON L. BARON AND A. DEBRETTEVILLE, JR.
Signal Corps Engineering Laboratories, Fort Monmouth, New Jersey

(Received January 16, 1950)

A combination instrument consisting of a two-circle goniometer and x-ray spectrometer suitable for the study of crystals was designed and fabricated in Squier Signal Laboratory. A crystal can be oriented optically by using the instrument as a goniometer. X-ray techniques can then be used to study the crystal by replacing the collimator and telescope with an x-ray slit system and a Geiger counter. Absolute intensity measurements can be made by fixing the Geiger counter at twice the Bragg angle and rotating the crystal at 8° per hour from $\theta_{\text{Bragg}}-\Delta\theta$ to $\theta_{\text{Bragg}}+\Delta\theta$. Back reflection angles of up to 160° are obtainable. The result of a test on synthetic halite (400) reflection, gave a structure factor 12.7 compared with Max Renniger's value of 12.67. No absorption corrections are required with this technique of measuring intensities.

I. INTRODUCTION

IN the study of single crystals by x-ray diffraction, an instrument was required which could be used for many purposes. To study the mosaic structure, the instrument should be capable of receiving the total reflected intensity. In making absolute intensity measurements, the crystal must be rotated at a low constant angular velocity and the Geiger counter must intercept a large solid angle of reflection; also monochromatic radiation must be used. To obtain high resolution, the instrument must be capable of large back-reflection angles in order to work with the higher orders, although this factor is subsidiary to intensity demands. These requirements are fulfilled by using an optical two-circle goniometer designed for easy conversion to an x-ray spectrometer. Brill *et al.* describe a similar instrument.[1] This is accomplished in this instrument by substituting a Geiger counter for the telescope and an x-ray incident slit system for the light collimator. The counter subtends an angle of 14°, the crystal is rotated at a constant rate of 8° per hour and back-reflection angles of up to 160° are possible. The instrument's inherent characteristics obviate time-consuming x-ray crystal alignment by first pre-aligning the crystal optically and then converting the machine for x-ray work. Time and budget limitations made it necessary to construct the apparatus in an ordinary machine shop using commercially available components; but in so doing, the high degree of accuracy required must not be impaired. For example, we employed camera lenses as our objectives in the collimator and telescope. We also used precision ball bearings in the rotating parts, instead of the conventional instrument design of a conical shaft ending in an optically flat hardened steel block, the thrust being transmitted through a sapphire whose curved surface rests on the steel block. Intensity tests on the instrument proved to be satisfactory, indicating that the required accuracy can be obtained in an apparatus of this type and can be constructed in a machine shop at a labor cost of approximately 500 man-hours.

II. GENERAL DESCRIPTION OF THE INSTRUMENT

Referring to Fig. 1 (some parts referenced appear only in Fig. 2 and/or Fig. 3) the instrument is supported on the leveling screws (1) which are also used to adjust the height of the instrument for alignment with the x-ray beam. The base (2) of the instrument is a heavy bronze casting in which are located the Geiger counter preamplifier, the rheostat (3) for varying the light intensity, the motor and collimator switch (4), the collimator jack (5) and the power cord. The main shaft (6) is a hardened and ground steel shaft firmly affixed to the base. The vertical circle bracket (7) and the telescope or Geiger counter bracket (8) are sturdy annealed aluminum castings. These rotating brackets are supported on the main shaft by means of angular contact precision ball bearings (9) and (10) mounted in tandem. These bearings are preloaded by means of lock nuts (11) and (12). The brackets may be locked in position by means of lock screws (13) and (14). The lock screws pass through tangent clamps (15) and (16) which are conveniently located between the legs of the collimator bracket (17). Tangent screws (18) and (19) acting on these tangent clamps produce slow motion angular adjustment of the two rotatable brackets. The vertical circle bracket (7) contains a housing (20) which is fitted with precision ball bearings (21), and a horizontal hardened and ground steel shaft (22). On this shaft are mounted the vertical circle (23) which is 6 inches in diameter, and the goniometer head (24). The goniometer head is provided with all the usual movements, namely, two perpendicular sliding motions, two rocking motions and a translation along the axis by means of rack (25) and gear (26). This latter motion is locked by means of lock screw (27). The vernier (28) permits the angular setting to be read to 1 minute of arc. The vernier body supports the vertical circle clamp screw (29) and tangent screw (30) for slow motion adjustment. The second rotating bracket (8) may be fitted with either a telescope (31) or a Geiger tube (32).

---

[1] Brill, Grimm, Hermann, and Peters, Ann. d. Phys. 34, 408–409 (1939). These authors describe a similar apparatus but there are no provisions for optical alignment on the instrument itself. The crystal is pre-aligned on an optical two-circle goniometer and then the goniometer head is transferred to their x-ray spectrometer.

The telescope is focused by means of knob (33) and is locked in position by screw (34). The telescope lens system consists of a Zeiss Tessar *f* 3.5 cm, *f*/3.5 objective (35) and a 5× eyepiece. This system has a magnification of 2×. The telescope is focused for infinity and contains an adjustable slit system (36) located in the focal plane of the objective to mask any spurious reflections. By replacing the eyepiece with an adapter and a 10× eyepiece (37), the telescope may be used as a 30 power microscope for examining the surface of the crystal. The telescope orientation is adjustable by means of two groups of three set screws located radially about the telescope 120° apart. After final orientation, these set screws are securely locked. To replace the telescope with the Geiger tube, it is merely necessary to release lock screw (34), slide the telescope out and insert the commercial Geiger tube which is retained in a steel adapter of the same diameter as the telescope tube for interchangeability. The angular relation between the two rotating brackets and/or the collimator is read on the 8-inch horizontal circle (38) in conjunction with the brackets' verniers (39) and (40) to one minute of arc. The stationary collimator bracket (17) is fastened to the base and is a sturdy annealed aluminum casting. It may be fitted with either a light collimator (41) or an x-ray collimator (42). The light collimator is moved forward or back by hand and locked in position by lock screw (43). The lens system consists of a Zeiss Tessar *f* 10.5 cm, *f*/4.5 objective (44) which is focused, for infinity, by turning threaded retainer (45). The aperture system (46) is located at the focal plane of the lens. The apertures consist of the following: pin hole, large and small Maltese crosses, vertical line and horizontal line. They are interchanged by rotating the

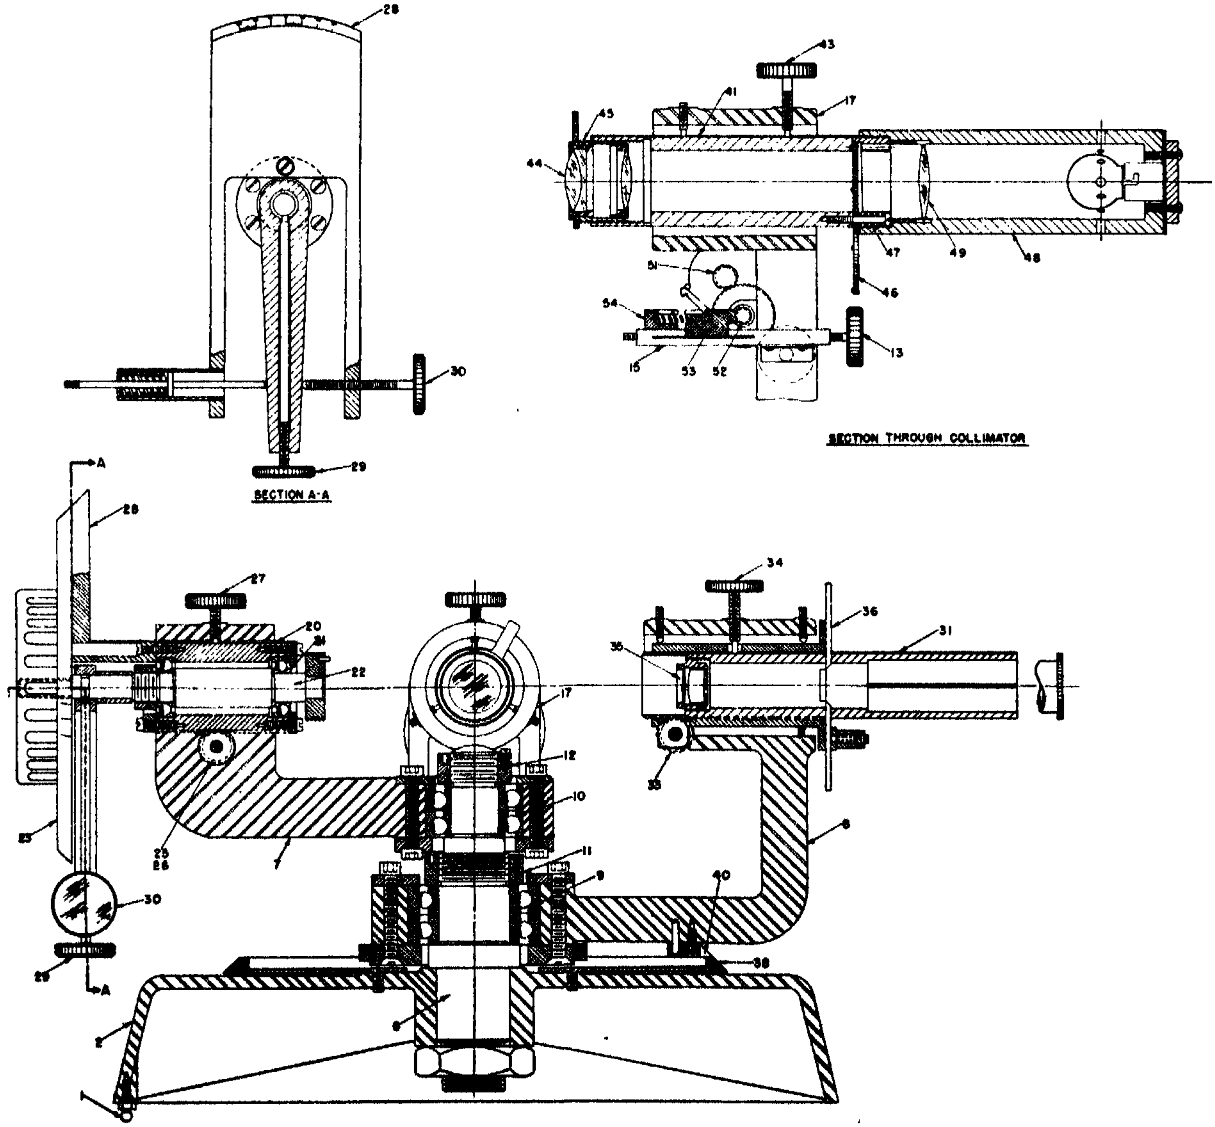

FIG. 1. Cross-sectional drawing of the two-circle goniometer and spectrometer.

holder. A spring device (47) snaps into position when the aperture is correctly located in the center of the tube. The light house (48) is built in and contains a simple condensing lens (49). Current for illuminating the lamp is provided through a transformer and the rheostat (3) located in the base. The lead terminates in a plug which may be inserted in the jack (5) located in the base. The collimator orientation is adjustable by the set screws 120° apart as heretofore.

To replace the light collimator with the x-ray collimator, it is necessary to release lock screw (43), unscrew the lens mounting (45), slide the assembly out and replace it with the x-ray collimator (42). This collimator is made of steel and is fitted with four adjustable shields (50) to produce rectangular windows. These shields are made of Babbitt metal which contains a high percentage of lead and which have the desirable features of being easily machined, relatively sturdy and show little or no wear due to friction. A one-r.p.m. clock motor with a 3 to 1 spur gear reducing train (51) is mounted on one leg of the collimator. A 20 pitch worm (52) is mounted in ball bearings between the legs and is driven by this combination. A segment of a 20-pitch, 10½-inch diameter worm wheel (53) is mounted on a slide on the vertical circle tangent clamp (15). This segment is engaged in the worm by the spring-loaded thumb-latch (54) thus causing the vertical circle bracket and the goniometer head, presenting the crystal, to move across the x-ray beam at a rate of 8° per hour. Back lash or lost motion between the worm and wheel is obviated by constraining the drive to operate against the spring and plunger of the tangent screw slow motion system.

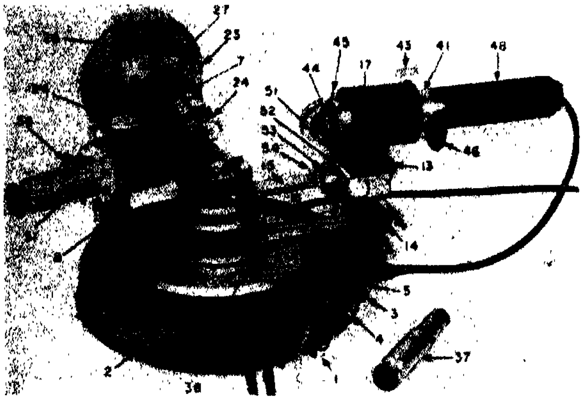

FIG. 2. Over-all view of the two-circle goniometer set up for use as an optical goniometer.

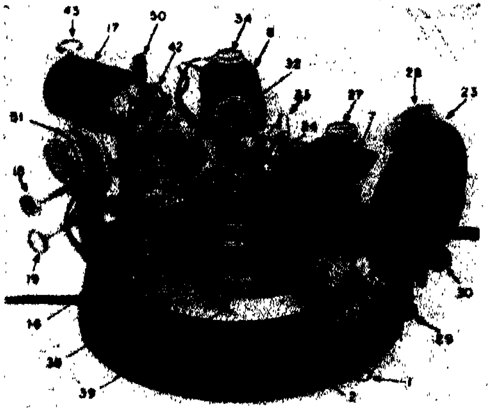

FIG. 3. Over-all view of the two-circle goniometer and spectrometer set up for use as an x-ray diffraction spectrometer.

III. OPERATION

Referring to Fig. 2 it is seen that for operation as an optical goniometer, the instrument is fitted with the light collimator and the telescope. The collimator lead is plugged into its receptacle and the switch thrown to the "collimator" position. The desired aperture is selected and the light intensity is adjusted with the rheostat, while viewing the aperture with the telescope, until the signal is bright with no attendant glare. The crystal is mounted with plasticine or wax on the goniometer head with one face, called the pole face, in a position as nearly perpendicular to the horizontal axis as can be arranged by eye. The vertical circle bracket is placed approximately in an angular position where a reflection from the crystal to the telescope is possible, then locked in position. The telescope is rotated until a reflection is observed and clamp (14) is drawn up. Slow motion tangent screw (18) is then turned until the aperture image is centered in the field of the telescope. The horizontal axis of the crystal is then adjusted with the goniometer head until it lies in the plane of the collimator and telescope. This can be achieved by observing the aperture image reflected from the pole face and rotating the crystal by the hand wheel mounted on the vertical circle. When the image describes a circle with the intersection of the telescope's cross-hairs as a center, the horizontal axis then lies in the plane of the telescope and collimator. The pole face is then adjusted so that the diameter of the circle described on rotating the crystal is as small as possible. When this circle is reduced to the vanishing point, the pole face is then perpendicular to the horizontal axis. The readings of the circles now obtained are the zero readings, denoted by π for the polar angles and ϕ for angles obtained from the vertical circle. The vertical circle and the vertical circle bracket are rotated until the image giving the desired face is received in the telescope. This procedure is repeated for each face in turn and a table of π- and ϕ-angles represents the full data obtained.

For operation as an x-ray spectrometer see Fig. 3. The telescope is removed and replaced with a Geiger counter which is connected to the shielded lead provided. The Geiger counter is used without slits and thus subtends a solid angle of reflection of 14°. The light collimator is removed, its lead to the base jack disconnected and the x-ray collimator is inserted into the housing. The two leads are connected to the electronic recorder and the power supply. The crystal is mounted and adjusted as in the foregoing description. The Geiger counter bracket is then located at θ_{Bragg}, the vertical circle bracket at $\theta_{\mathrm{Bragg}}+\Delta\theta$ and the worm wheel segment is then released from its detent. Upon throwing the switch to the "motor" position and actuating the x-ray beam, the crystal will move across the beam at a rate of 8° per hour. The reflections will be received in the Geiger counter and the integrated output impressed on an electronic recorder or the impulses may be fed to a scaling circuit and counted on an impulse counter.[2]

IV. PERFORMANCE AND TESTS

The results of several tests indicate that the instrument is accurate, capable of obtaining back reflection angles of up to 160°, operates with facility and has good resolution. For example, a test run on synthetic halite (400) reflection, gave a structure factor of 12.70 as compared with Max Renninger's value of 12.67. In Fig. 4 we can see the resolution possible. This is a test run on the 12th-order basal reflection of aluminum phosphate using a penta-erythritrol monochromator. The K alpha-one and the K alpha-two lines, separated by 0.004A, were resolved at a distance of approximately ½ inch on the chart, running at a speed of 20 inches per hour. In Fig. 5 are shown the results of another test which was run to determine the reproducibility. This test was made on the sixth-order basal reflection of aluminum phosphate using the same monochromator. The run was repeated and the resulting curves are shown. They are symmetrical; and using an impulse counter it was found that the difference in the areas under the curves was less than one-half of one percent. (The area is considered proportional to the energy or number of quanta reflected.)

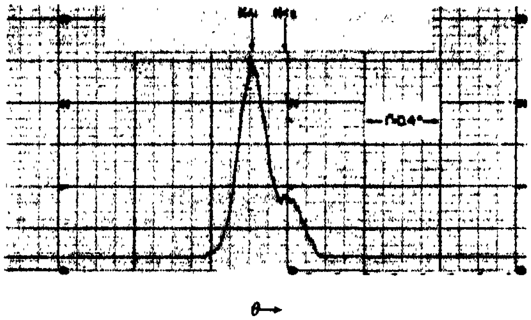

FIG. 4. Curve obtained from basal plane reflection from aluminum phosphate in the 12th order, as a function of the crystal angle. Geiger counter fixed at twice the Bragg angle for the 12th order. (Resolution Run 0012 ALPO$_4$ using penta-erythritrol monochromator.)

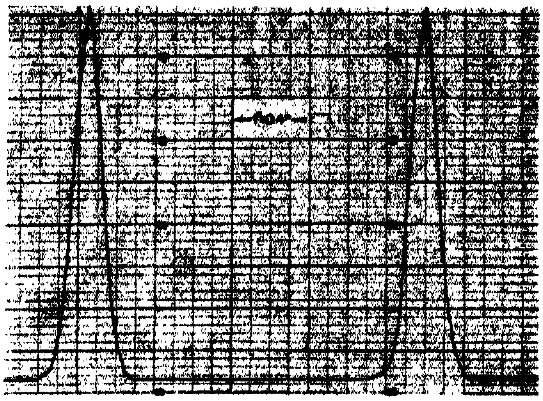

FIG. 5. Curves obtained from basal plane reflection from aluminum phosphate in the sixth order, showing reproducibility. (Run 006 ALPO$_4$ using penta-erythritrol monochromator.)

V. ACKNOWLEDGMENTS

We are indebted to Dr. R. Brill of the Phillips Petroleum Company for his stimulating and helpful interest. We are also indebted to Fred Richardson and Andrew Misko of the Squier Signal Laboratory Shop Section for their skill and careful craftmanship in the construction of the instrument.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 5 MAY, 1950

An 80-Mev Model of a 300-Mev Betatron[*][†]

D. W. KERST, G. D. ADAMS, H. W. KOCH,[‡] AND C. S. ROBINSON
Physics Department, University of Illinois, Urbana, Illinois

(Received January 16, 1950)

The construction and operation of a flux-biased 80-Mev betatron is described. This betatron was built as a model to test design features later to be incorporated in a 300-Mev betatron. Particular attention is paid to factors influencing design and to considerations of magnetic problems which are common to betatrons and synchrotrons such as the construction of field magnets which are uniform, the testing of fields at injection time, the mechanism of electron capture, and the influence of field inhomogeneities. The dimensions and operating characteristics are included together with many comparisons with the 300-Mev betatron.

I. INTRODUCTION

SINCE the completion of the first betatron in 1940, the University of Illinois has looked toward the construction of an accelerator large enough to produce mesons. By July, 1945, the necessary techniques and ideas were available, and a project was established for building a betatron of about 300-Mev energy. At that time this energy was believed ample to produce meson pairs. The General Assembly of the State of Illinois granted a special appropriation for this project. This paper will describe an 80-Mev model constructed to test the important design features of the 300-Mev betatron.

II. FACTORS INFLUENCING DESIGN

A. Earlier Betatrons

In the design of a large betatron for 300 Mev many improvements can be employed which reduce the size and cost. In the early betatrons the field strength at the orbit was much less than that which can be supplied by iron pole faces. In the first design a flux density of about 1200 gausses was used at the orbit so that the iron structure would not overheat when operated at 600 cycles per second.

In the second machine the flux density is around 3600 gausses at 20 Mev. With this flux density at the orbit, the flux density in the central iron of this betatron exceeds 11,000 gausses and is approaching a magnitude at which the changing permeability of the iron will cause the orbit to shrink in radius.

If the volume of the gap containing the vacuum tube could be reduced in such a machine and the orbit kept close to the central iron, the flux density in the orbit could be increased somewhat above that used in the 22-Mev betatron. This improvement in proportions was incorporated in the 100-Mev conventional betatron at Schenectady.

B. Flux Forcing

The expense of a machine can be greatly reduced by eliminating the air gap in the magnetic circuit which carries the central flux. This saving results from the elimination of the magnetic energy stored in the air gap, and a several fold reduction in size of the capacitor bank. Closing the air gap also simplifies the problem of controlling leakage flux from the central magnetic circuit.

In order to make the central iron of the betatron a closed magnetic circuit with no air gaps, it is necessary to devise some means of insuring that the flux within the orbit and the field at the orbit are always kept proportional in spite of the variable reluctance of iron and the constant reluctance of the air gap. The flux change within the orbit and the field at the orbit must satisfy the equation:

$$\Delta\phi = 2\pi r^2 B, \qquad (1)$$

where $\Delta\phi$ is the change in flux during the time in which the field, B, rises from zero, and r is the orbital radius. This is achieved by "flux forcing," that is, connecting the coil containing the flux linkage of the iron magnetic circuit in parallel with the coil containing the flux in the air gap magnetic circuit (Fig. 2). The number of turns and the geometry of the coils about the poles must be such that these two sets of coils can be placed in parallel and fulfill the relation in Eq. (1) at some usable position in the magnet gap. A fine adjustment of this voltage and hence of the orbit radius can be made by a small auto-transformer on one of the coils.

C. Biased Betatrons

An increase by a factor of two in the flux density allowed at the orbit can be achieved by having the flux in the central iron reversed at the time the field at the orbit is zero. Then during acceleration, the flux in the central iron reverses direction while the flux density at the orbit rises from zero to approximately 9000 gausses. Such a betatron is called a biased betatron.

There are two different types of biasing which allow this increase in energy.[1,2] One is field biasing, and the other is flux biasing. In a field biased machine the magnetic field at the orbit has an alternating and a steady component while the flux in the central iron has only an alternating component. The steady superimposed unidirectional magnetic field at the orbit requires gap windings carrying direct current (Fig. 1a). A flux biased machine requires direct current bias winding on the central iron. A flux biased machine cannot be run on alternating current without seriously saturating the central iron which is already biased nearly to saturation. Consequently such a machine must be excited by unidirectional pulses of current (Fig. 1b).

---

[*] Certain phases of this development were assisted by the joint program of ONR and AEC.

[‡] Present Address: X-Ray Section, National Bureau of Standards, Washington, D. C.

[1] D. W. Kerst, Phys. Rev. 68, 233–234 (1945).

[2] W. F. Westendorp, J. App. Phys. 16, 657–660 (1945).

Flux biasing was chosen for the 300-Mev betatron for two reasons.

(1) Fewer bias ampere turns are required because of the complete elimination of the air gap in the central iron core. This advantage is somewhat offset by the fact that the induced voltage in a bias turn around the central iron is approximately three times greater than the induced voltage in one bias turn around the field region. Nevertheless, the choke coil used to prevent a large induced current from flowing in the bias system during the period of changing flux is approximately ten times smaller for flux biasing.

(2) Intermittent unidirectional excitation of the magnet at a low repetition rate is possible with mercury pool tubes and is desirable in order to keep the power consumption low and to reduce the heating of the coils so that coils occupying a small space can be used. By minimizing the space occupied by the coils, useless leakage flux is minimized. The energy stored in this useless leakage flux of an alternating magnet must also be stored in capacitors, and the capacitor cost for a betatron such as we will describe is almost as great as the cost of the iron lamination stock.

It is expected that the yield of the 300-Mev betatron will be sufficiently great that it will be satisfactory to pulse it at a low repetition rate to get integrated results such as those observed in photographic emulsions. Intermittent operation is also needed for cloud-chamber experiments. Although high speed counting techniques which we now have were not yet devised when the repetition rate for our betatron was chosen, it was hoped that improvements in resolving powers of counters would allow one to count several events produced by the same burst of radiation from the accelerator. This hope depended not only upon the development of high resolving power counting techniques but also on the possibility of lengthening the duration of the burst of radiation from the betatron. This lengthening is possible by slightly agitating the beam so that it is intercepted bit by bit by the target. Pulses lasting more than 10 microseconds have been observed from the 22-Mev betatron when this agitation method is used, whereas the normal duration of the x-ray burst can be as small as $\frac{1}{3}$ microsecond.

The repetition rate chosen for the 300-Mev betatron is six pulses per second. The repetition rate of the model described here cannot be this high because of the scaled-down current carrying capacity of the wires. The pulse for each machine is a half of a sixty cycle per second sine wave. The model can run continuously at only one pulse every three seconds.

D. Radiation Loss

One of the important problems which must be faced in high energy accelerators is the energy loss of charged particles by radiation resulting from their acceleration toward the center of a circular orbit.[3] For a particle at radius r (cm) whose energy is proportional to $\sin\omega t$, the fraction of energy which has been lost when the maximum magnetic field has been reached is

$$\Delta E/E = E^3/(300r^2\omega), \qquad (2)$$

where E is the maximum energy of the particle in units of mc^2 and $\omega/2\pi$ is the frequency of the magnetic field in cycles per second. To compensate for this energy loss extra flux must be supplied within the orbit. The fractional increase in the flux needed to hold the orbit at a fixed radius is equal to the fractional energy loss from the orbit at radius r.

In the original betatron, operating at 2.5 Mev and 600 cycles per second, the energy loss according to Eq. (2) is only of the order of five volts. This was not large enough to cause a significant shift or decrease in the orbital radius. The equation is for a single charge, e, in the orbit; but before this early machine was constructed, R. Serber calculated that the energy loss for an isolated electron was in fact the same energy loss that an individual electron would experience although

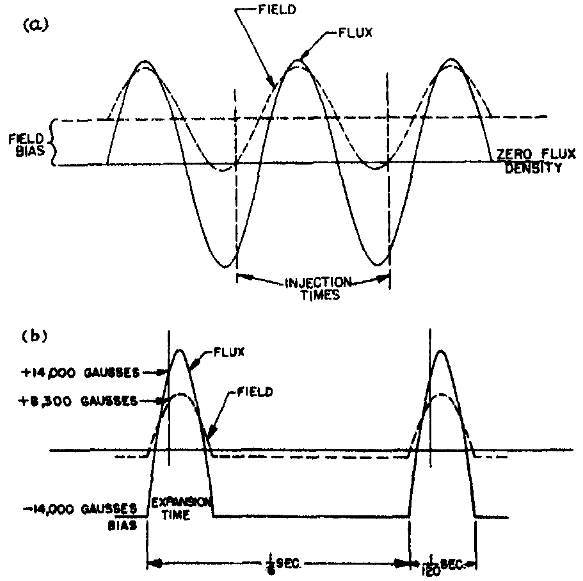

FIG. 1. Field and flux wave forms. (a) Field biased betatron. (b) Flux biased betatron.

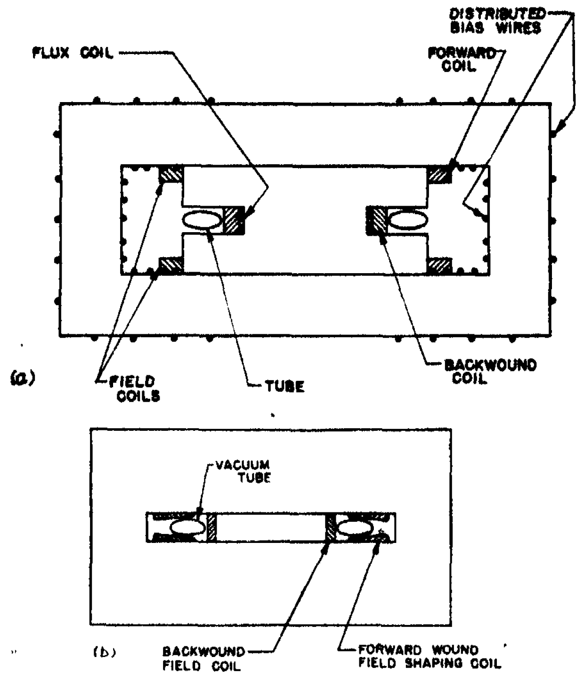

FIG. 3. (a) Single magnetic circuit flux biased betatron. (b) "Poleless" betatron.

accompanied by many other electrons randomly spaced around the circular orbit. It was recognized at that time that a conventional betatron for about 200 Mev would have a serious loss of energy due to orbital radiation. However, the small orbital radius permitted in biased betatrons causes the radiation loss to be serious at a much lower energy. For example, the 80-Mev model discussed here has a computed fractional energy loss, $\Delta E/E = 0.053$. This loss would contract the orbit in about eight percent or two centimeters in radius which would bring the orbit very close to the inner wall of the vacuum tube. This large shift in orbit radius has given an opportunity to experiment with methods of compensating for the radiation loss.

In the case of the 300-Mev betatron the fractional radiation loss will be held to about eight percent by allowing the electrons to remain in the machine for only 75 electrical degrees. The magnetic field at this phase is about 3.5 percent less than the peak field; but removal of the beam at this time results in the maximum energy output of the machine. Retaining the beam longer would require increasing the amount of flux to compensate for radiation loss and consequently this would decrease the amount which is available for acceleration.

In the flux forced betatron the addition of the radiation compensating flux within the orbit can be accomplished by supplying flux which does not link the flux forcing circuit or by destroying the rigid relation between field at the orbit and the flux change within the orbit which is established by the flux forcing circuit. Both of these general methods have been used with the 80-Mev model.

E. X-Ray Production

Moving the high energy beam to the target so that it produces x-rays has been accomplished in two ways. We have used an injector placed at a radius larger than the equilibrium orbit. The beam can be expanded symmetrically to this target by supplying extra flux within the orbit or it can be displaced sideways by decreasing the magnetic field on one-half of the orbital circle and increasing the magnetic field on the other half of the orbital circle.[4] However, the beam does not simply move sideways toward the target when this azimuthal variation in field strength is applied,[5] and with the 80-Mev model it has not been a very satisfactory method for striking the target.

III. MAGNET STRUCTURE

Two magnetic structures were considered in the early design work. One type of structure had one magnetic circuit which carried both the biasing flux and all of the time varying flux. The other structure was composed of two separate magnetic circuits. In the latter case one magnetic circuit carried the central accelerating flux and the biasing flux, while the other magnetic circuit carried only the flux necessary for the field at the orbit. Figure 3 shows two varieties of the one-circuit design, and Fig. 5b shows the separated betatron with two magnetic circuits. Figure 3b might be called a "pole-less" betatron in which the shape of the magnetic field at the orbit was determined by the configuration of the current-carrying coils.

The ampere turns in coil B must be completely cancelled by the ampere turns in coil A (Fig. 5b) so that the large magnetomotive force (mmf) produced by these field coils does not appear across the closed iron core. Coil C of a relatively small number of ampere turns supplies the relatively small mmf for the flux in the central closed core. With an orbital region as large as that necessary for a 300-Mev machine it is possible to put the backwound coil, A, within the air gap. This has the advantage of terminating the mmf planes from coil B in a very uniform way as shown in Fig. 16. Coil A might be said to terminate the field in the air gap with no edge effect, while there is a strong edge effect at the outside pole rim. This position of coil A minimizes the amount of pole rim flux or leakage flux that must be supplied from energy stored in a capacitor bank.

The structures shown in Fig. 3 had the disadvantage of carrying a strong bias flux radially outward under the pole surface. This required a radial mmf drop which seriously distorted the weak magnetic field between poles at the time of injection. If the biasing flux were taken out radially in all directions, it might be possible to shape the iron surfaces or the coils in a way which would compensate for the distorting effect of the strong bias flux.

[5] D. W. Kerst and H. W. Koch, Rev. Sci. Inst. 18, 681 (1947).

Tests on d.c. models in 1946 led us to believe that the structures shown in Fig. 3 would be practically hopeless for a 300-Mev betatron, although it might be successful for an 80-Mev betatron. The reason is that at the present stage of development of electron accelerators it is convenient to inject electrons at voltages of about 50 to 100 kilovolts, whatever the size of the instrument. This means that with the usual injection equipment the electrons must be injected into a large betatron when the magnetic field is far smaller than the field at injection time in small betatrons. For this reason the uniformity of the magnetic field must be better for large instruments. Small asymmetries of the field due to the d.c. bias flux would be relatively more serious for large machines. For example, we inject into the 80-Mev betatron at the time the magnetic induction at the orbit is 22 gausses. On the other hand we expect to inject into the 300-Mev betatron at about 7 gausses. The tests with direct current models were sufficiently discouraging with the single magnetic circuit betatron to cause the choice of the separated betatron. This separated structure in Fig. 5 can be thought of as composed of field magnets the same as those necessary for a synchrotron but with a biased pulse transformer passing through the ring of field magnets to supply the accelerating voltage for each revolution of the particles.

Perhaps the most important improvement in magnet design is the structure of the field pieces, or "C's." The structure was devised to carry all laminations through the same magnetic cycle. The path length in iron for the air gap flux is identical at all azimuths around the betatron. Likewise there is no variation in the cross section of the iron flux path at any azimuth in the betatron. This is achieved by punching all laminations with the same die except for a fraction of the laminations which have their ends cut off at different radii on the pole face. They are stacked to form tapered sectors of laminations in a circular pole structure. This radial arrangement of laminations is essentially the same as that used in the earlier betatrons. The back legs of the "*C*" laminations are pulled together into six bundles around the machine (Figs. 4 and 5). These are clamped to form six "*C*'s" with V-shaped crotches between them. By bundling into six "*C*'s" the crotches are wide enough to allow the free passage of an x-ray beam out of the machine without any distortion of the flux path in iron. The size of the window in the "*C*'s" was determined so that on the 300-million volt scale it would be possible for a man to reach any azimuth inside of the "*C*'s" for purposes of experiment or field correction, if this should be necessary.

In order to make six well-constructed "*C*'s" the laminations were bent in a brake so that they fitted closely together. This scheme of having the entire pole face supplied with flux by laminations which are identical (except for the few mixed in whose ends are clipped) insures that residual magnetism distributed over the pole face after a pulse will be precisely the same at all

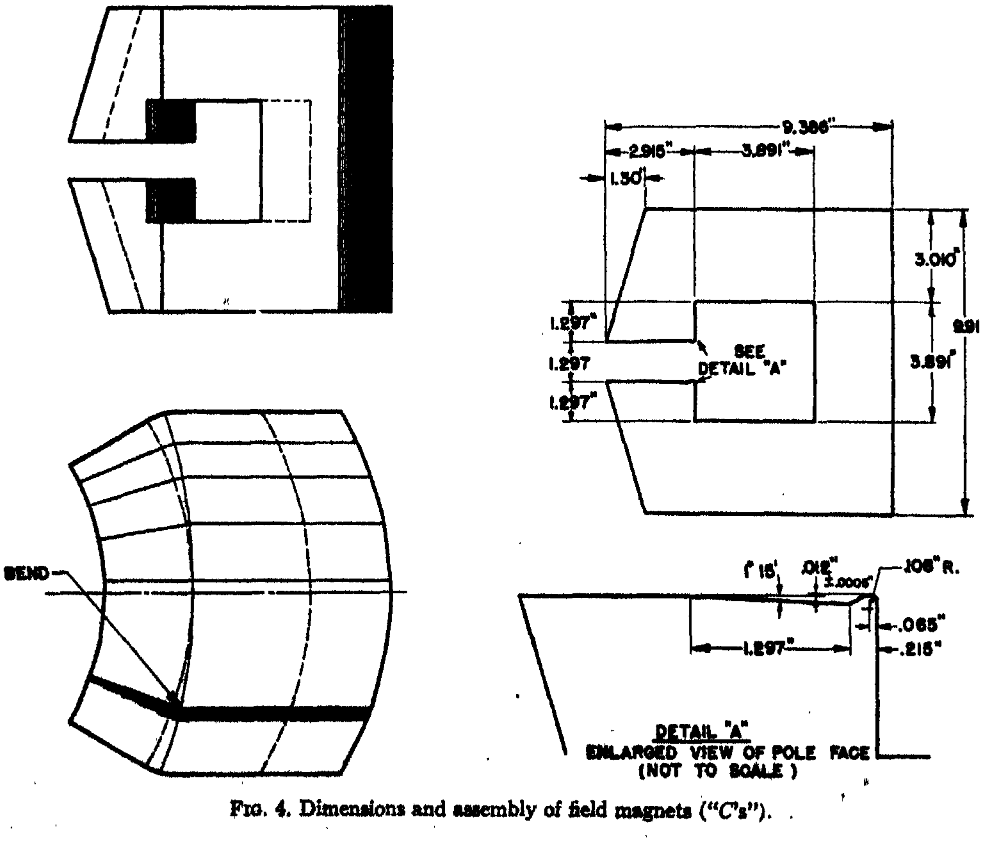

FIG. 4. Dimensions and assembly of field magnets ("*C*'s").

azimuths. It also insures that the time lag of the flux for all azimuths around the pole will be precisely the same at the start of the pulse because the same number of eddy-current ampere turns is required for all flux paths. In addition, the six "C's" fit together snugly so that there is no break in the circular pole piece except a sheet of insulation between "C's." Thus we have avoided a gap between adjacent "C's" which would allow flux to come out of the sides of laminations and which would cause an out-of-phase or lagging flux at the orbit between "C's." Separated pole sections are used in the "race track" type of accelerator, but the ends of each field piece may have to be specially shielded or laminated so that out-of-phase flux sufficient to eject particles will not be produced. The hard problems of field correction are avoided with this magnetic structure; and, as will be described later in the section on field tests, the "C's" produce a field which was two orders of magnitude smoother than the fields of earlier conventional betatrons.

A section of the pulse transformer core is reserved for expansion of the orbit radius when it is desired to cause the beam to strike the target. This section is provided with enough iron so that it can not only move the orbit from its equilibrium position out to the target, but it can also supply the energy lost in the form of central acceleration radiation. In the model about 7 percent of the cross section of the central core is excited late in the acceleration period. In the 300-Mev betatron about 9 percent of the central core is reserved for compensation and expansion.

Figures 4 and 5 show the dimensions of the magnetic circuits. The iron for orbit expansion and radiation compensation is in the sides of the core and it does not link the flux forcing circuit. Except where it passes through the ring of field pieces, this iron is bent away from the central core so that separate windings can be put around this portion of the magnetic circuit. These side packages of iron are wrapped in copper shields to minimize flux leakage into them from the central core throughout the acceleration period. Shielding is also provided on the central part of the pulse transformer to eliminate flux leakage into the space in which the field magnets are installed. Such leakage flux could produce field irregularities at the orbit which might be serious at injection time. The design of these shields will be explained in Section X.

IV. THE FLUX FORCING CIRCUIT

Figure 6 shows the connections of a flux forcing circuit. Coils A and B are in series so that coil A exactly backwinds coil B, while coils C, which are essentially in parallel with the combination of coils A and B, excite the pulse transformer within the orbit. A small transformer, O.P.T., is used for positioning the orbit. Ignoring the effect of this orbit positioning transformer, since it changes the voltage on the core only a small amount, we have equality between the voltage across

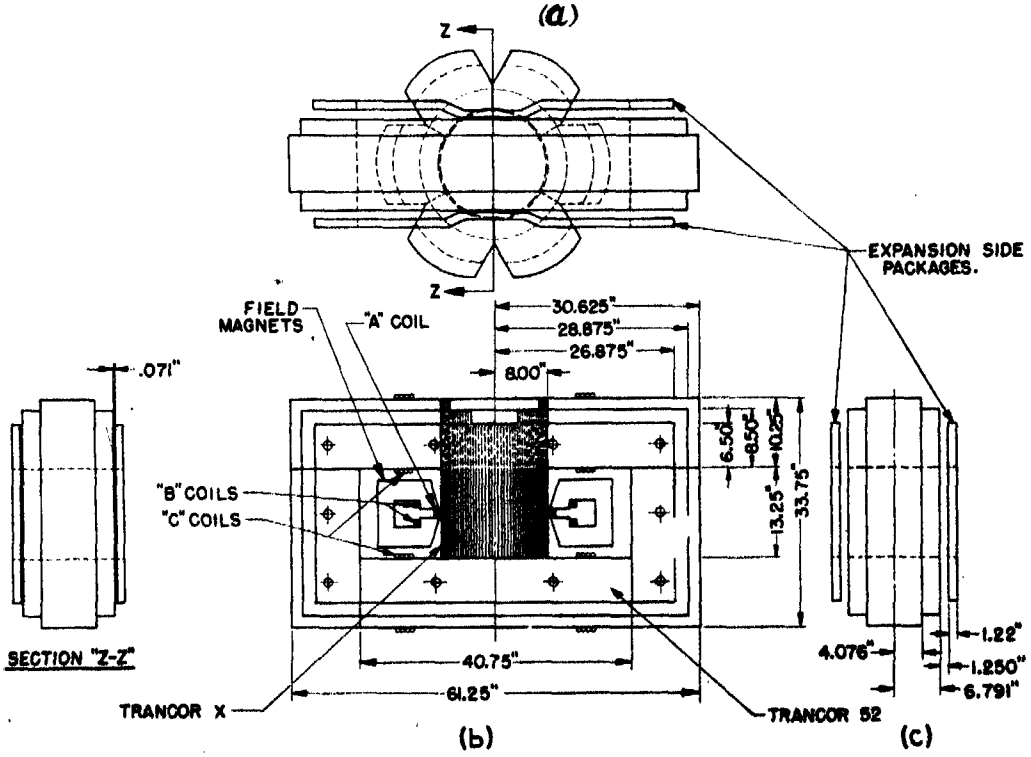

FIG. 5. Assembly of magnetic circuits for 80-Mev model. Coil A is the backwound field magnet coil. Coils B are the forward field magnet coils. Coils C are the excitation coils for the acceleration core.

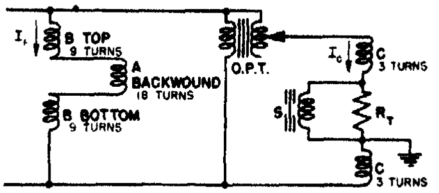

FIG. 6. Pulsed coils and flux forcing connections used. *A*, 19 strands No. 20 enameled. *B*, 19 strands No. 18 enameled. *C*, acceleration core coils, two No. 10 *SN* in parallel. O.P.T., orbit positioning transformer. R_T, trimming resistance for equalizing fundamental I R drop. *S*, saturating reactor which short-circuits R_T at peak current.

the field coils and the voltage across the core coils; thus,

$$N_F\phi_F\times10^{-8}+I_FR_F=N_C\phi_C\times10^{-8}+I_CR_C. \qquad (3)$$

If $I_FR_F=I_CR_C$ at all times, it is clear that flux changes within the orbit are always proportional to field changes at the orbit, and consequently the orbit would remain at a fixed radius except for central acceleration radiation of energy. The current, I_F, through the field coils has almost completely the fundamental frequency of the exciting pulse since the field coils represent a constant inductance and since I_F is large compared to I_C. However, the current passing through the core coils, I_C, has a strong harmonic content. Adjustments of R_T enables the fundamental *IR* drop in the circuit of coil *C* to be made equal to I_FR_F, but the remaining voltage drops in the resistance due to higher harmonics of the current through coils *C* will cause variations in the orbit position. For example, in the 80-Mev betatron, the inductive voltage is close to 1000 volts, whereas I_FR_F reaches a maximum of 1300 amperes $\times R_F$, or 123.0 volts. If the error due to resistive voltage drop were not partially compensated by R_T, then the fractional error in flux within the orbit would be

$$\int_0^t I_FR_Fdt\Big/\int_0^t Vdt$$

where *V* is the voltage across the flux forcing circuit. This is about 12.3 percent in our case at 90 degrees for the 80-Mev model. To supply a compensating voltage drop we set R_C equal to 0.65 ohm. Since the fundamental current through R_C is about 200 amperes peak, the compensating voltage is about 130 volts. Higher harmonic IR drops which cause the variation in orbit position produce about 0.5 percent error in the flux at 75°. This troublesome effect we have eliminated quite well by connecting a saturating reactor, *S*, in parallel with the resistance which balances the first harmonic IR drop. When the large current passes through the core windings, the voltage drop in R_T (Fig. 6) is decreased because the current flows through the saturating reactor. Since the linear scale factor between the 80-Mev and the 300-Mev machines is 4.63, we would expect the flux error without a saturating reactor in the 300-Mev machine to be 0.5 percent $\times 1/(4.63)^2=0.024$ percent. This is a negligible error.

V. PULSE POWER SUPPLY

The pulse power supply, except for some of the auxiliary circuits, is shown in Fig. 7a and the sequence of operations in Fig. 7b. The magnet current pulse is obtained by discharging a capacitor bank through the magnet coils by means of an ignitron. For operation of the model at 80 Mev a capacity of 5000 microfarads is used at an initial voltage of 1130 volts. The pulse is very closely a slightly damped half-sine wave lasting 1/120 second and having a peak current of 1850 amperes. The voltage across the bank reverses during the discharge. Because of dissipation, principally in the coil windings and the ignitron, the final voltage is about 25 percent smaller in magnitude than the initial voltage. This voltage decrease is much larger than that which will be found in the 300-Mev betatron.

After each discharge a mechanical switch is operated to reverse the connections to the capacitor bank. Then, before the next discharge, the 25 percent loss is made up by recharging the bank through a choke coil from a grid-controlled 6-phase rectifier.

Wherever it has been practical, the sequence of operations and the circuits used have been made the same as planned for the 300-Mev machine although many simplifications could have been made in the model. Operation of the model is limited to a rate of about three pulses per second or slower by the speed of the reversing switch. As explained in Section II-C, continuous operation for long periods is limited by heating to one pulse every three seconds. In the 300-Mev design approximately half of the one-sixth second (10-cycle) interval between pulses is available for operation of the reversing switch, and the other half for recharging. In the model the reversing switch takes about 10 cycles, but recharging is accomplished in 5 cycles.

A trigger pulse synchronized with the 60-cycle line is obtained from a frequency subdividing circuit producing 3, 1, or ⅓ pulses per second. This pulse initiates the discharge through the betatron coils. The negative voltage appearing across the capacitors after the discharge actuates the reversing switch. When the reversal is completed, an auxiliary contact triggers two multivibrator gate circuits which allow trigger pulses to reach the grid-controlled rectifier tubes for the following five cycles. During these five cycles the rectifier passes a 1/12-second half-sine-wave current pulse of about 30 amperes peak into the capacitor bank through a 120 millihenry choke chosen to resonate with the capacitor bank at 6 cycles per second. There is a 360-cycle ripple superimposed on this charging pulse, but the 6-phase rectification and the inductance of the charging choke reduce this to about 5 percent peak. If there were no losses in the charging circuit the d.c. power supply voltage should be set halfway between 1130 volts and the capacitor voltage after reversal, or at 990 volts.

Since there are nearly enough losses to critically damp the charging circuit, the power supply voltage must be raised nearly to 1130 volts.

Grid-control of the rectifier is necessary to shut off the charging current completely while the reversing switch contacts are open and to eliminate a large current surge during the time when the capacitor voltage is negative. The rectifier circuit was chosen as six-phase double-way (three-phase bridge) because this required the smallest transformer rating. It has since been found that this choice may have a false economy because of the more complicated excitation equipment required for this circuit.

The reversing switch is constructed from two Allen-Bradley 150-ampere motor-starting contactors using standard cadmium-silver contacts. Auxiliary contacts (not shown) are used to prevent each contactor from being energized while the other is closed. Except for a small current due to the charging and discharging of stray capacity, current flows only while the contacts are completely closed. This allows somewhat higher rating of the contacts. The 150-ampere contacts have operated satisfactorily in air with 300 amperes of steady a.c. for several hours and short tests at 800 amperes r.m.s. showed no damage. The resistance (at 60 cycles per second) of a single contact depends on the applied force, but in practice, at about 10 pounds, it is about 1.5×10^{-4} ohm either in air or in oil. With a high peak current lasting a short time, as in the model, each pulse appears to cause local heating and perhaps welding of the contact, without much dependence on the r.m.s. current. A set of contacts operated in air for 8500 pulses in the model circuit at 1700 amperes peak became deeply pitted and welded together. Another set operated at 700 amperes peak for 290,000 pulses showed no damage except for the slight mechanical wear on the contact surfaces. These tests were made at a rate of 1.5 pulses per second through the contacts. During the last year the model has been operated many hours at about 1800 amperes peak current with the contacts under oil, and no difficulty has occurred.

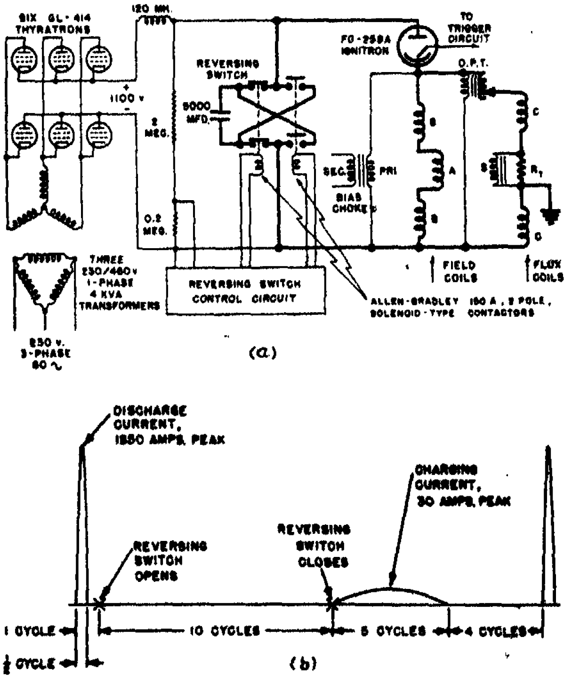

FIG. 7. (a) Pulse power supply. (b) Sequence of power supply operations at 3 pulses per second. The 4-cycle interval is increased for lower repetition rates. 60 cycles = 1 second.

The 5000-microfarad condenser capacitor bank consists of 130 microfarad units rated at 1600 volts d.c.

The fact that the betatron coils are grounded at their electrical center to reduce the insulation requirements introduces fast, high voltage surges into all parts of the power supply when the betatron is pulsed. To prevent these surges from accidentally triggering thyratrons or multivibrators, all sensitive circuits are heavily biased (say, to −100 volt) and supplied with a trigger pulse 200 or more microseconds long which is sent through a low pass RC filter with a 50-microsecond time constant. Each thyratron has a surge-limiting capacitor (0.001–0.003 microfarad) connected between grid and cathode. In addition, certain of the signal transformers are electrostatically shielded.

VI. BIAS CIRCUIT

The central section and the side packages of laminations in the pulse transformer are biased separately. Figure 8a shows the bias supply for the central iron of the core. A choke coil, Fig. 8b, is used to prevent the direct current supply from short-circuiting the voltage pulse which occurs during acceleration. The choke coil is of a special design such that its exciting current does not pass through the direct current source. This exciting current is supplied by a primary winding on the choke coil connected to the main pulsed power line to the betatron. Taps are provided on the primary to assist in adjusting it for a minimum current pulse through the direct current power supply. The resistance of the primary circuit must be chosen so that the IR drop in it is the same as the IR drop across R_T, Fig. 6. Only then will the voltage induced in the choke coil secondary be in step with the voltage induced in the bias winding around the core. A somewhat similar biasing system supplies 275 ampere turns from the same direct current source to the side packages.

Because of the extremely small field at injection time it is necessary that the leakage flux from the central core be made negligible. To do this the direct current bias winding is distributed over the core in a manner such that the ampere turns are placed where they are demanded by the core. This detailed distribution is accomplished in the following way. The tangential component of the field along the iron can be measured by energizing the core without the field pieces in place. The exciting coil is suspended in the middle of the window. The space between this coil and the iron is then free for these measurements. The magnitude of this tangential component is proportional to the ampere-turn density which must be supplied at each point along the iron. The distribution of ampere turns required is found to vary over the surface of the iron in such a way that the wires must be wound in an irregular manner. The direction in which the wires must be placed on the surface of the iron is orthogonal to the direction of the tangential magnetic field. Both the magnitude of the tangential magnetic field and its direction were determined by a conveniently small detector which is capable of measuring fields from several oersteds down to 0.01 oersted.[6] The apparatus is calibrated in a solenoid from time to time.

Special care is necessary in distributing the wires, where the gap in the field pieces is close to the central core. Final positioning of these wires was carried out in the presence of the field pieces while the field detector was placed at the position of the orbit. These bias wires were adjusted until the horizontal magnetic field at the orbit position was less than a calculated tolerance of 0.1 gauss.

VII. VACUUM TUBE

The vacuum tube is made of six glazed porcelain sections which can be maneuvered into the magnet gap through the crotches between "C's." These sections are joined by ¾-in. black Scotch Electrical Tape, Type No. 33, wrapped snugly over the joint. Four of these seals are made with the adjacent sections pulled out into a crotch so that one can examine the seal all around. A small band of No. 1201 Glyptal is painted over the edges of these four seals. The last two seals must be made with the vacuum tube in its final place between the poles. For these two seals the Glyptal painting cannot be completed, but this is not necessary if the seals are made skillfully. However, overlapping ends of the Scotch Tape are exposed so that they can be painted to avoid leaks at the overlap. Another type of seal between sections of the tube was made with rayon taffeta tapes coated with red sealing wax (Dennison's American Express No. 2) and sweated onto the tubes by heating wires; but this method, although it was successfully used for some time, was abandoned because it was more tedious to employ than the Scotch Tape method.

The injector is a very small structure shielded so that the electron beam will not be deflected by the high voltages on the electrodes. Its dimensions are shown in Fig. 12. It was waxed onto a stem in one of the porcelain sections.

The inner walls of the porcelain tubes were coated with Hanovia liquid bright palladium No. 62, and the ends of each section were terminated with Hanovia burnish silver paste No. 38. Silver paste strips were brought out to glass buttons fused to the porcelain glaze for purposes of connection. Mica spacers were inserted at three of the joints. The acceleration voltage appears principally at the insulated joints. Ten ohm external resistances were connected between the coatings of some adjacent sectors, and the total resistance at the insulated gaps was made about 1000 ohms. One of the completely insulated sections was behind the injector section so that it was possible to observe the electron beam passing through this section after it had completed one revolution. This assists in the start-up of such a machine because the injection time can be precisely set by observing the voltage signal from the beam passing through this insulated section. A DuMont 256-D oscilloscope was used to observe the passage of the beam. This helped greatly in adjusting the injection time for first trials.

It is imperative that the inside of the vacuum tube be coated so that charges cannot accumulate on the surfaces on insulating spots within the tube since charged spots on the wall will deflect the electron beam. In the conventional 22-Mev betatron small insulated areas have been known to prevent successful operation. We experienced the same difficulty in starting up the 80-Mev model, because during several attempts to install a vacuum tube a small amount of insulating material got into the tube. Operation at these times was unsuccessful. Successful operation was achieved later with no change in the magnetic field conditions but with a clean tube.

VIII. AUXILIARY CIRCUITS

The injector circuit employed gives an approximately flat-topped voltage pulse of 60 kilovolts for 5 micro-

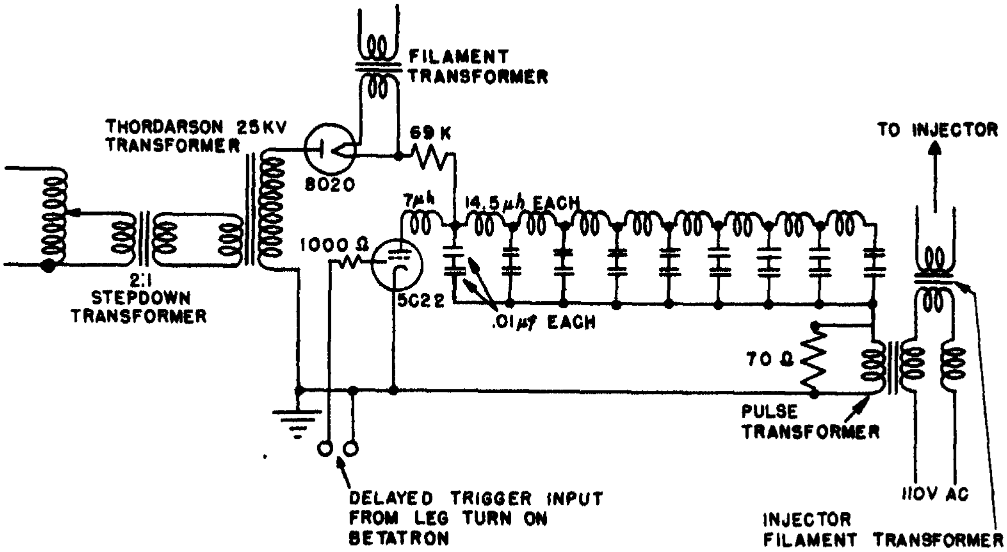

FIG. 9. Injector circuit. The pulse transformer has a 15.7 cm² core cross section. The primary has 19 turns, and the bifilar secondary has 172 turns.

seconds. This duration removes the necessity for precise timing of injection. When the beam is injected, an orbit contraction circuit is excited which suddenly draws a loss current through the backwound coil before the flux forcing circuit can react. The result is that the orbit tends to spiral inward away from the injector. The output of the machine was increased by a factor of 20 by this device.[7] Figure 9 shows the injector circuit and specifications for the associated pulse transformer. Figure 10 shows the contractor circuit.

Since residual magnetism of several gausses remains in the gap of the field magnets after a pulse, the time of injection may occur very close to the time of triggering the main ignitron. Any transients remaining in the flux forcing circuit at injection time will cause the orbit to be at an incorrect radius. To gain time in which the transients can disappear we have used a slight backward bias on the magnetic field so that the field actually comes up through zero after the betatron pulse starts. This biasing will be more important for the larger betatron. It is supplied by the circuit shown in Fig. 11.

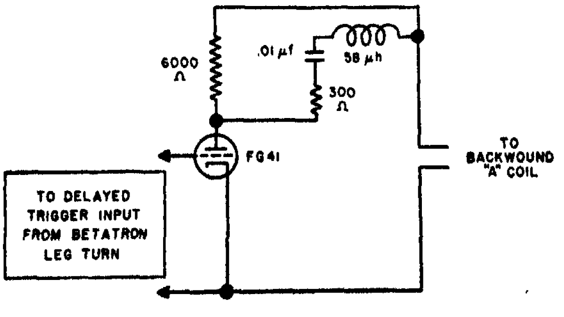

FIG. 10. Contractor circuit. The FG 41 plate circuit components were determined by trial.

The expander circuit is basically a thyratron discharging a 1000-volt 24-μf condenser through 25 turns on the side packages. An additional method of orbit expansion and radiation compensation is now in use which actually increases the flux in the central package of core laminations late in the cycle. This is accomplished by a delay line which produces a voltage on a capacitor in series with the primary of the O. P. T. when the field is approaching its peak value.

The timing circuits for triggering injection, contraction, and expansion are activated by the steep voltage rise generated in a turn around a leg of the yoke. Adjustable delay circuits provide timing controls. The most critical of these is the contraction control.

IX. STARTING TRANSIENTS

When the ignitron is fired the voltage of the capacitor bank suddenly appears across the terminals of the iron magnet and a large sudden rise of current must occur in the circuit. This is the result of the establishment, within a few microseconds, of the peak value of the circulating eddy currents in the iron laminations. Because of the close coupling between the magnet coils and these loss currents a similar working current must circulate in the magnetizing coils. The time of establishment of the eddy currents is important because it can influence the field shape between the poles of a pulsed magnet and because in the case of a betatron it will influence the time taken to establish a strict proportionality between the magnetic field and the changing flux linkage. Since the field magnets have a large air gap in them, it is merely necessary to allow the magnetic field to penetrate a slight distance into the surface of each lamination before the reluctance of the thin flux-carrying surface of the laminations of the field magnet is very small compared to the reluctance of the

---

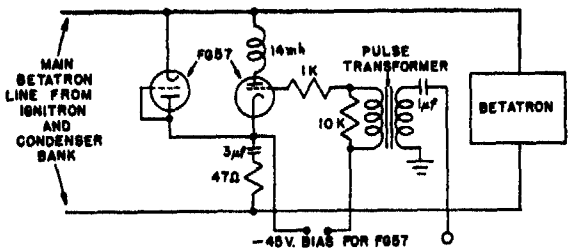

FIG. 11. The field bias circuit.

air gap. Thus in a magnet with an air gap of the proportions used in our betatron, the rate of rise of field in the gap reaches its peak value in less than a microsecond; but the closed-core flux-carrying circuit which links the orbit has no such air gap, and the rate of rise of flux density builds up to a maximum much more slowly. Accurate treatment of flux penetration is described by H. L. Rehkopf.[8] He obtains

$$t=(\pi\mu d^2)/(3\times10^9\rho) \tag{4}$$

for the time required for the eddy currents to reach 95 percent of their full value. ρ is the resistivity in ohm cm, d the thickness in cm, and μ the differential permeability. In our case, the case for heavily biased 0.014-in. silicon steel laminations, $t=7.5$ microseconds for 95 percent establishment of eddy currents. A similar time is required to establish the rate of rise of flux within the iron of the core.

The capacitor voltage is divided between the leakage inductance of the connecting wires and the magnet coils. Presence of leakage inductance will cause an additional delay in establishment of the rate of rise of flux. When one looks closely at the time for establishment of the betatron flux condition in the 80-Mev betatron, it is found that the flux condition is established within 1

[8] H. L. Rehkopf, "The equivalent circuit of a pulse transformer core," Radiation Laboratory, Massachusetts Institute of Technology Report 666.

percent of its final value in about eight microseconds. The penetration of flux into the core sets a lower limit on the time of establishment of proportionality between field and flux change.

While the closed core is acquiring its full rate of change of flux, the field in the air gap is increasing with its full rate. Consequently, the field may reach a value requiring an inconveniently high injection voltage before the equilibrium condition is established. To avoid this difficulty the slight reverse field bias is used (Fig. 11). For example, the rate of rise of field is 4 gausses per microsecond in the 300-Mev betatron, and 60-kilovolt injection occurs at 7 gausses. With 8 microseconds for the establishment of the equilibrium condition and with about 3.5 gausses of residual magnetism left in the gap from the preceding pulse the field in the gap would reach about 35 gausses before the flux condition holds. Thus a field bias of about 28 gausses is needed. In the 80-Mev model we use the same rate of rise of field and we inject at about 22 gausses so we need only about 13 gausses of bias.

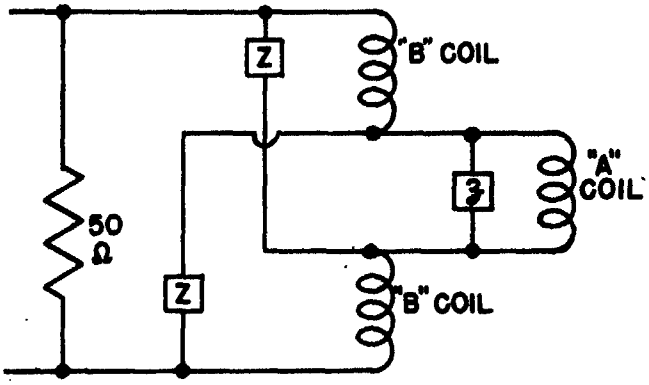

FIG. 13. Location of transient controlling networks.

Some additional transients due to shock excitation of the coils were observed. These were suppressed by increasing the rise time in the line a few microseconds with resistances across the line and by connecting the terminals of the backwound coil to the line with empirically trimmed impedances (Fig. 13).

X. FLUX SHIELDING

Core shielding is necessary for three reasons. First, to insure that the side packages of laminations do not carry an appreciable leakage of pulsed flux from the main core. Such leakage flux would partially fill the side packages which are reserved for expansion and radiation compensation. Second, leakage flux from the core would also disturb the orbit if it passed through the field magnets near the gap. This is especially true for the leakage flux produced at the time of the eddy current inrush. This leakage flux should be prevented from reaching the orbit. Third, unless a distributed pulse winding is wound on the core, shielding is needed to prevent heating of the laminations under the bunched coil which drives the core of the 300-Mev betatron.

A copper shield wrapped around the core with an insulated split to prevent a short circuit about the flux is used. A generous overlap at the split is necessary for an efficient shield. Such a shield placed over or under the bunched driving coil will distribute the magnetomotive force over the core to locations where it is demanded. Currents circulate in the shield to cancel the mmf of the bunched coil and the canceling filaments of current have a return path coincident with the locus of demanded mmf on the core. If this were not so, a leakage flux would pass out through the shield. At the lap these filaments of current run parallel to the edge and a large overlap allows a wide low resistance path for this portion of the circuit. The thickness of the shield at the bunched coil is chosen so that it can carry the canceling current without getting hot, but the thickness elsewhere presents a problem which must be solved so that the leakage flux which escapes is depressed to a tolerable level. The solutions of this problem for both continuous sine wave excitation of the core and for pulsed excitation of a core and estimates of the number of leakage maxwells were determined by S. P. Lloyd. Only $\frac{1}{32}$-inch copper shields were needed.

XI. FIELD DISTRIBUTION, FIELD ERRORS, AND FIELD TESTS

The radial variation of field is described by $1/r^n$. We placed the injector a little outside of the point where $n=1$. n was 0.5 at the normal equilibrium radius and it decreased to 0.2 at the smallest radius within the ac-

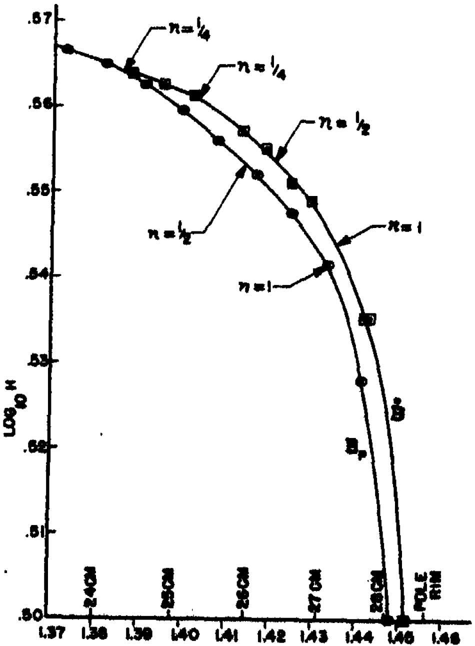

FIG. 14. Magnetic field shapes. $\dot{B}$ is the relative rate of rise of field near zero field and B_p is the residual or permanent magnetic field in the gap left as a result of unidirectional pulsing.

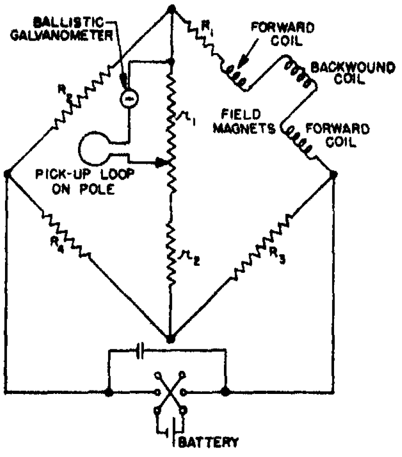

FIG. 15. Bridge for determining orbit position by reversals of direct current. Only the field magnet coils are excited by the bridge current.

celerating region. The field shape obtained is shown in Fig. 14. We have had excellent yield from other betatrons when the injector was placed near $n=1$; this is possible because restoring forces can exist outside the radius at which $n=1$. The reason for using a low value of n over most of the space is that such a field shape minimizes the shrinkage of orbit radius with energy loss due to central acceleration radiation. The contour necessary to provide this field was determined by successive trials with a d.c. model of $\frac{1}{16}$ scale of the 300-Mev machine. This d.c. model had $\frac{1}{8}$-in. laminations. The measurements were taken with a search coil and ballistic galvanometer actuated by the reversal of the field in the d.c. model.

One method of determining the equilibrium orbit position was to use the bridge circuit shown in Fig. 15. This bridge circuit allows a null comparison of the flux picked up in any one of several concentric coils distributed over the pole face with the flux linkage between the field-producing coils A and B. Since in a flux forced betatron these field-producing coils are in parallel with the flux-producing coils wound on the core, there is a fixed ratio between the core flux and the flux linked by the field-producing coils, that is, the mean flux linkage in the "C's" between the forward and backwound coils of the field magnets. One therefore need not excite the core of the pulse transformer with d.c. in this orbit position determination. The orbit is located at the point where the flux linkage divided by the radius of the pick-up loop is a minimum. In our case, the ratio between flux in the core and mean flux linkage between the field coils was chosen to be approximately three to one, that is three times as many turns are used on the field magnets as are used on the core. Thus, in determining the orbit position with the d.c. model, one reads only the flux supplied by the field magnets within the pick-up loop, but to this one adds three times the mean flux per turn linking the field coils in order to compute at what radius the ratio of total flux linkage to radius is a minimum.

An attempt was made to determine the outer radius of the pole rim which would give the proper orbit by the method of hand flux plotting using tubes of flux and the orthogonal magnetomotive force planes. The rules for plotting in the region of the gap and in the region of the current for a three-dimensional magnet with circular symmetry were used. Figure 16 shows the flux plot obtained. Although experience has shown this method of plotting is not capable of giving field details, it is capable of giving a fairly good estimate of integral properties of a magnet such as inductance and orbit

FIG. 16. Trial flux plot for three-dimensional 300-Mev field magnet. This plot shows that the 53-in. trial pole radius should be decreased to 51.75 in. for the orbit at 48 in. and that the field coil voltage is 5520 volts.

position. The flux plot and the bridge tests were used to determine the proper pole rim radius to give the three to one ratio between core flux and field magnet flux with an orbit at about 26.5-cm radius.

Electrical measurements on the pulsed 80-Mev model gave the final determination of orbit position. The measurements were made with a pick-up coil constructed with an accurately known cross section bucked against the pick-up voltage on a loop about the pole face at the position of the orbit. A pair of General Radio decade resistance boxes (Type 602J) with good high frequency characteristics was used as a potentiometer to sub-divide the voltage picked up by the turn at the orbit radius so that it gave a null comparison with the voltage picked up by the search coil. A DuMont 256-B A/R scope was used for a null detector. It is possible to use this coil arrangement to determine the orbit positions as early as a few microseconds after the pulse begins.

Distortions of the magnetic field shape due to errors and imperfections in the pole geometry can be made small simply by care in assembly. However, there are certain other causes for distortion of the magnetic field shape at the time of injection. Leakage flux from the pulsed excitation of the core and leakage flux from the core due to imperfect distribution of bias wires were discussed earlier.

There are reasons for field distortions and inhomogeneities in the magnetic field due not only to the central core but also to the field magnets themselves. First, the residual magnetism left in the gap after a pulse has a distribution depending upon the magnetic properties and the configuration of the iron circuit. This permanent magnetism corresponds to the hysteresis phase shift in a continuously excited betatron. Second, the eddy-current losses in the iron produce field inhomogeneities by time lags, or phase shifts of the magnetism. These depend upon the presence of short circuits between groups of laminations and differences in the proportions of the various iron return paths for flux. Third, time lags are also caused by the natural distribution of the mmf supplied by the eddy currents in the iron combined with the opposite mmf supplied by the eddy-current inrush in the driving coils. These effects all distort the field shape at injection time, but they cause negligible distortion during most of the later acceleration period.

Our observation of the radial distribution of the residual magnetic field in the gap after a pulse showed a fortunate similarity to the distribution of dB/dt. Figure 14 shows the distribution of residual magnetic field as a function of radius. There was also no harmful azimuthal variation of this residual field. Apparently there were no serious variations in the coercive force of the iron used in the "C's." Thus, troubles from the first cause of field irregularities did not exist. The magnitude of the residual field observed was about 3.5 gausses in the gap. This is comparable to the residual field estimated roughly from the dimensions of the field magnet and the coercive force for a symmetrical hysteresis loop of iron (Armco Trancor 52). This residual field is roughly

$$B_r = (L/G)H_c, \tag{5}$$

where L is the effective length of the flux path in the iron, G the dimension of the air gap, and H_c the coercive force. For our magnet L/G was approximately six and for the induction used in the magnet, H_c should be about 0.2 oersted. The calculated residual magnetism in the gap is thus more than one gauss. This calculation is difficult to make precise because the only coercive forces readily available are for symmetrical hysteresis loops. A strange observation which was repeated several times was that the residual field left in the gap was slightly smaller when the magnet was pulsed to its maximum amplitude than when it was pulsed to two-thirds of its maximum amplitude.

The second difficulty mentioned, namely the short circuits between the laminations in the field magnets, was eliminated by the use of 0.005-inch Kraft paper sheets every quarter of an inch in the lamination stack.

We had no evidence of difficulties caused by short circuits between laminations.

The time lag of a flux path caused by eddy current build-up is

$$T=\mathcal{L}d^2l/(4\rho A), \qquad (6)$$

where $\mathcal{L}$ is the power line inductance plus leakage inductance, d is the lamination width, l is the iron flux path length, A is the air gap area, and ρ is the resistivity.

In case the iron return paths for the flux crossing the air gap do not all have the same reluctance, there will be a field bump due to a greater time lag in starting the flux through the high reluctance iron path. The field bump, ΔB, is the difference between the fields in the two paths and is given by

$$\Delta B\sim\dot{B}\tau(1-l_1A_2/l_2A_1)(1-\exp[-t/\tau]), \qquad (7)$$

where l_1, l_2 are the iron path lengths and A_1, A_2 are iron areas for the two path lengths. The time constant, τ, for this field difference to build up is

$$\tau=\pi d^2l/(\rho G10^9), \qquad (8)$$

where G is the air gap. The field error reached is

$$\Delta B=\dot{B}\tau f=5\times10^{-8}\dot{B}fl/G, \qquad (9)$$

where f is the fractional difference in iron reluctance.

In our model

$$\dot{B}=4\times10^6 \text{ gausses per second and } l/G\approx6.$$

Thus $\Delta B\approx f$ gausses. This and the residual magnetism formula show the necessity for designing with nearly identical flux paths at all azimuths. It is important to notice that small l/G results in small residual field and small transient field errors.

The third type of field distortion caused at the time of injection is fundamental, but in our magnet the distortion is present only far out near the pole rim and outside of all positions occupied by the electrons.

To explain this third effect Fig. 17 illustrates the reason for the lagging field at the pole rim.[9] The effect is to increase the value of n at the injection time, and the cause is the presence of a flux distribution due to the inrush ampere turns in the driving coils and the distribution of eddy currents on the surface of the laminations of the field magnet. Magnetomotive force surfaces stretch between the inrush coil current and the eddy current filaments distributed around the iron core. The leakage flux produced at the time of injection is in such a direction in the winding space of the field magnet that it subtracts from the flux fringing out from the pole gap. Since the field at the gap is small at injection, and since the eddy current flux plot has maximum intensity at injection, the superimposed field distributions can cause a zero value of the resultant field close enough to the pole rim to cause a noticeable increase in n just inside the pole rim.

The distribution of this eddy current magnetomotive force was roughly modeled on a d.c. magnet. A dis-

tributed winding over the surface of the iron imitated a loss current and the working current or eddy current inrush was simulated by a current sent through the main driving coils of the model. The ampere turns in the distributed winding which imitates the distribution of eddy currents on the surface of the iron were made precisely equal to the ampere turns in the coils modeling the driving coils of the field magnet. This model study indicated what was later found on the operating machine, namely that n was affected by the loss currents only out near the pole rim for our injection field.

The 0.1-gauss tolerance for the horizontal component of the magnetic field at the orbit at injection time was chosen because this field would raise or lower the whole orbit about 1.5 inches in the 300-Mev betatron. The oscillations resulting from this shift are sufficient to cause electrons injected near the median plane to strike the tube wall.

The same tolerance was chosen for the variations in the vertical component of the magnetic field at injection time. In this case, 0.1 gauss excessive on one-half of the pole circumference and a deficiency of 0.1 gauss on the other half would shift the orbit enough to remove about 6 percent of the usuable radial space. A similar distribution in horizontal field at the orbit would cause about the same loss of space. These displacements were calculated by the method described in Section XII.

Over-all tests of the uniformity of the field at injection time were made in the following manner. The radial dependence of the rate of rise of magnetic field was determined by pick-up coils at representative azimuths. Then, with the field magnets biased a few gausses opposite to the normal direction, the time at which the magnetic field came through zero was determined for all regions of the pole face. With these data one can calculate the magnetic field at any time after the start of the pulse for any location in the gap. Fortunately, the radial distribution of the rate of rise of magnetic field was the same at all azimuths in the gap except for slight local decreases in the rate of rise at the crotches where the pole faces were separated approximately 0.020 inch extra over a small region at each crotch. The additional necessary observation, namely the time at which the magnetic field goes through zero at every point of the pole, showed simultaneity at all points of the pole face except around the outermost rim of the pole. The simultaneity observation determined that the field at any point in the gap went through zero when it was everywhere less than 0.1 gauss, the limit of the sensitivity of our observing instrument at $\frac{1}{4}$ peak excitation.

Previous experience with peaking strips[10] for the determination of the time when the field in the gap goes through zero led us to distrust peaking strips for observation of the time of zero field as a function of radius. Such an observation is necessary to determine the effective value of n at the injection time. The reason for our difficulty was that the width of the voltage pulse generated in the peaking strip was slightly greater and the wave shape was slightly different when the peaking strip was moved to larger radii where the magnetic field strength was lower. This made it very difficult to choose a correct criterion for the time on the peaker pulse which represented zero field. Our peaker pulses were nine microseconds long and had a flat top. However, we have always had good success using peaking strips to determine the azimuthal variation of magnetic field at injection time since the peaking strip was always placed at the same radius for all azimuths about the betatron.

Since the rate of rise of magnetic field is four gausses per microsecond at the injection time, or about two gausses per microsecond when the machine is run at half-amplitude where we made many of our tests, it is necessary to be able to estimate the time of zero field within one-twentieth of a microsecond if one wishes to observe field errors of 0.1 gauss. Since we were attempting to keep all spurious fields below the 0.1-gauss mark, a tolerance unnecessarily small for the 80-Mev model but one which we have adopted for the 300-Mev machine, it seemed that variations in the width of a peaking strip pulse of the order of one percent would spoil the accuracy. We chose not to use the peaking strip technique but rather to use an entirely different method for determining the time of zero field. We used a short electron gun made from the filament and grid of an injector. It shot a 100-volt beam of electrons through a three-slit collimator into a Faraday cup. The beam could enter the Faraday cup only when the magnetic field was within plus or minus $\frac{1}{2}$ of a gauss of zero. Observation of the pulse on the Faraday cup was made with an A/R scope with its own amplifier. The time of the pulse peak could be estimated to an accuracy equivalent to 0.1 gauss.

Figure 18 shows the zero field detector. It was necessary to bias the cup negatively with respect to the collimator so that stray electrons could not jump over the collimator and enter the cup, giving a wide background pulse. The filament was operated at an emission of about 20 milliamperes, and the synchroscope sweep was started by a trigger circuit driven from the leg of the magnet. Since the zero field detector was sealed off in a small glass tube one inch high which could be placed within the poles of the magnet, it could be moved around by hand while the machine was running. A series of tests showed no variation in the time of zero field at different positions in the gap except for the slight lag near the pole rim beyond the point where electron orbits were to exist.

This zero field detector was the over-all test which showed us that our magnetic field shape was that given by the radial distribution of the rate of change of field shown in Fig. 14. This method of field test includes all effects of eddy currents and residual magnetic fields.

---

[10] A. F. Clark, Phys. Rev. 70, 444 (1946) and Adams, Kerst, and Scag, Rev. Sci. Inst. 18, 799 (1947).

The successful production of a magnetic field with a vertical component uniform within 0.1 gauss was one of the main purposes for the construction of the 80-Mev model.

The determination of the strength of the horizontal component of the spurious magnetic field at injection time was much more difficult than the determination of the vertical component. The contribution of the distributed bias windings on the core to the spurious field has already been explained. An additional horizontal field due to coil transients was found. There was a tendency for the top and bottom main coils around the pole rims to ring differently when the betatron was pulsed. This horizontal flux was observed on a pick-up loop placed vertically at the edge of the gap. Adjustment of the transient trimming network successfully eliminated this oscillation. In addition, studies were made with a 14,000-turn coil placed on edge in the gap against the backwound coil so that any varying horizontal flux leaking from the central core into the air gap could be observed. With this coil in place the betatron was not pulsed since severe shock excitation would result within this multiturn coil. Instead, the machine was run at 1/20 of full amplitude at 60 cycles per second. Adjustment of the position of the coil so that no vertical flux was picked up was exceedingly difficult and had to be done with a hand in the gap. However, since we were searching for flux phase shifted by 90 degrees, it was possible to detect the presence of horizontal a.c. flux. These low amplitude tests extrapolated up to full amplitude showed regions of horizontal field protruding inward or outward at injection time, but only in a very small region was 0.1 gauss exceeded.

One reason for being careful about horizontal fields is that, in the past, horizontal fields have been known to prevent the operation of betatrons. In the conventional betatron the horizontal field can be caused by a phase shift between the top and bottom pole. The original 2.3-Mev betatron was very sensitive to this type of disturbance.

In the 300-Mev betatron the air gap will be sufficiently large so that our zero field detector can be placed first on the bottom pole for a time reading and then moved directly above to the top pole to observe differences in the time of zero field at these poles. Such a difference would be a result of a horizontal magnetic field in the central plane of the air gap, and the time difference for the two poles can be used to evaluate the magnitude of the horizontal magnetic field at the middle of the gap. The observed difference between fields at the two pole faces will be twice the value of the horizontal magnetic field in the central plane of the gap.

XII. METHOD OF STARTING AND GENERAL OPERATING CHARACTERISTICS

After complete tests of the vertical and horizontal components of the field at injection time were finished, the sectional vacuum tube was installed and operation tests were begun. In order to simplify the search for the correct injection timing, filament emission, and orbit position, the magnet was run at 1/20 of normal amplitude on continuous 60-cycle excitation. This allowed continuous operation and the possibility of rapid adjustment of the parameters just mentioned.

Bursts of 60-cycle sine wave excitation at $\frac{1}{3}$ of normal amplitude and lasting about five to ten seconds were also used to allow rapid adjustment during the burst. To eliminate the injection timing parameter the signal produced by the electron beam passing through various insulated sections of the vacuum tube was displayed on a synchroscope. A section about 270 degrees around the machine from the injector shows a brief voltage pulse if the injection timing is correct. We had a flat-topped five-microsecond injection pulse so that the timing was not very critical; but by observing the pulse of current, which was much less than five microseconds in width, passing through an insulated section of the vacuum tube we could positively adjust our injection timing and eliminate this variable.

A great deal of difficulty with the vacuum system was experienced for about four months. The trials for yield in this period were spoiled by the presence of insulating material inside the vacuum tube at locations where this material could be charged by the electron beam.

Successful operation was finally obtained by installing a clean vacuum tube. The yield was found first by a Geiger counter. No corrections of magnetic field or change of operating conditions from those used in the early tests were necessary. During a few days of burst operation at 25 Mev with no bias on the core it was learned that the temperature variation, presumably of the backwound coil, caused a change which moved the equilibrium orbit radius. This made burst operation very difficult because the orbit position would move out of the usable region during a 10-second burst. A Variac in place of the orbit positioning transformer made possible the rapid and continuous positioning of the orbit. It was gratifying to find that the usual disturbing noise of a betatron was negligible with our type of "C" structure. Sine wave operation at 8 Mev is practically inaudible. At 25 Mev the sound is a faint hum.

Operation was quickly changed to pulsing with a biased core, and there was no trouble in obtaining yield at essentially full amplitude within a couple of days. These burst and pulsed tests required about a week at the end of August, 1948. After this successful operation, the assembly of the 300-Mev machine was immediately started.

Numerous tests were subsequently carried out to determine various characteristics of the apparatus. A circular coil had been installed above and below the orbit so that the shape of the magnetic field at injection time could be altered by the passage of a current through this wire. No significant alteration of the yield of the machine resulted as the radial dependence of field strength was changed.

Studies were made on the conventional 22-Mev betatron for the purpose of understanding the action of a so-called contractor which had been in use for several years.[7] It was thought that such a device might be helpful on the 80-Mev model. Some of the facts learned during these tests and their bearing on the use of the contractor on a large accelerator are worth explaining. The contractor is a device which disturbs the flux condition at injection time in a manner such that the radius of the equilibrium orbit rapidly decreases. This is achieved by abruptly starting a loss current around the central flux of a betatron at about the time of injection. It had been observed that in the 22-Mev machine the contractor improved the yield by 33 percent when the machine was operated at maximum yield with an injector emission of 0.51 ampere; but when the emission from the injector was decreased to 0.02 ampere, the contractor was capable of increasing the rather low yield by a factor of eight. This gave encouragement to the idea that injection into conventional betatrons had been successful because of the self-contraction effect of the circulating electron beam within the vacuum tube.[11] An estimate of the self-contraction of the beam was also made by observing signals on a loop of wire around the pole of a 22-Mev betatron under the orbit. It was possible to observe the pulse of flux due to the circulation of the injected electron beam. The circuit to detect this pulse of flux was such that it was shock excited when the injected electron beam changed the flux linkage. There are generally two times during the injection voltage pulse, once on the rising side and later on the falling side, when electrons are injected with acceptable momenta. These two acceptance times could be observed and correlated with the corresponding times on the injection voltage pulse.

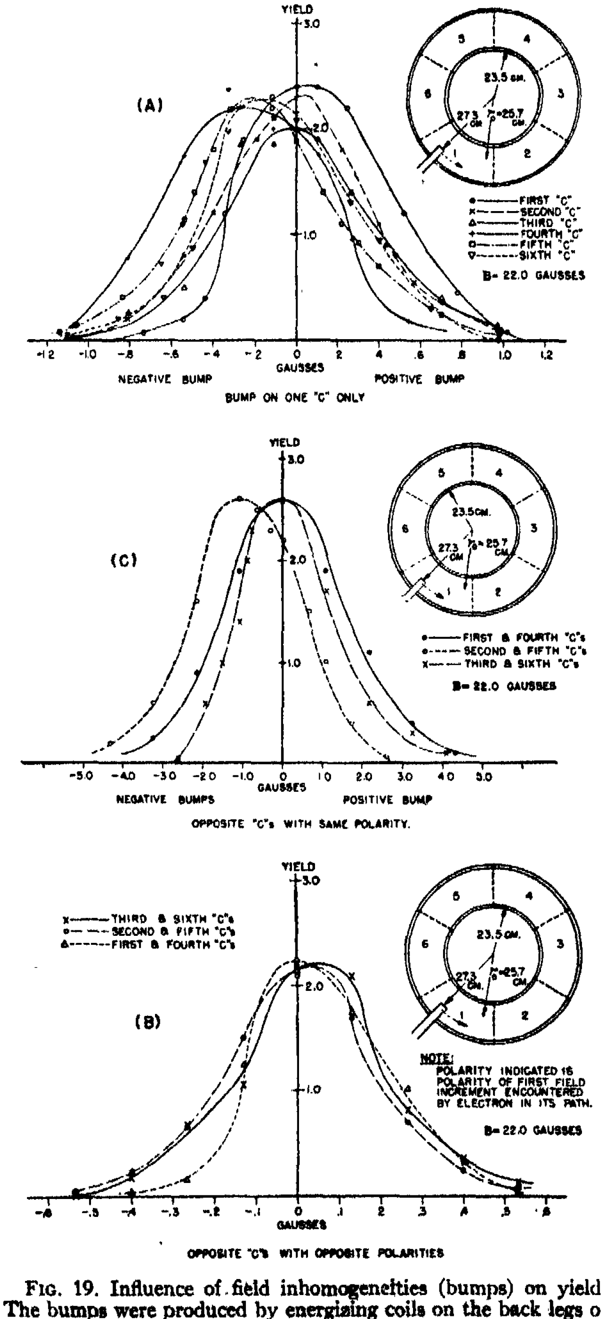

FIG. 19. Influence of field inhomogeneities (bumps) on yield. The bumps were produced by energizing coils on the back legs of each "*C*."

The measurements showed that at least 130 maxwells were withdrawn from the flux within the orbit by the start-up of the circulating beam in the orbit. This circulating current can build up for only about 10^{-7} second (the acceptance time) and the contracting effect of the pulse of negative flux is calculated to be at least 1.1 mm. The amount of circulating current immediately after injection which would be necessary to produce this flux is several times the 0.2-ampere current which we know reaches the target.[12] This is evidence that much of the current injected into the tube circulates for a while and then is lost. We know that some electrons circulate about the machine at least 100 revolutions before being intercepted by the injector structure; this was shown by the effect of firing a contractor circuit as late as one microsecond (about 100 revolutions) after injection. Some electrons destined to be lost after 100 revolutions are saved by this delayed contraction which increases the yield of x-rays.

The sacrifice of some circulating current can produce an expansion of the orbit of electrons injected late in the acceptance time thus making possible injection from a radius smaller than the equilibrium orbit. This same sacrifice of space charge can produce a pinching together of the beam about the equilibrium orbit by the decrease of space charge repulsion. The magnitude of this can be estimated in the following way: If the loss of space charge occurs during the time for many revolutions the process is adiabatic and the action is constant. For an oscillator

---

[11] D. W. Kerst, Phys. Rev. **74**, 503 (1948).

[12] L. Bess and A. O. Hanson, Rev. Sci. Inst. **19**, 108 (1948).

$$J\nu=\tfrac{1}{2}ma^2\omega^2, \tag{10}$$

where J is the action variable, ν the angle variable, m the particle mass, a the amplitude of oscillation, and ω the circular frequency of oscillation which is proportional to ν. Thus ωa^2 is a constant for the period of time considered. So $a\sim\omega^{-\frac{1}{2}}\sim(1-n)^{-\frac{1}{4}}$, where n is the field shape exponent and thus

$$\delta a/a=\delta n/4(1-n) \tag{11}$$

for radial oscillations.

An estimate of δn comes from the magnitude of the circulating current which is sacrificed. Since $\Delta B/B=-n\Delta r/r$, then $(\Delta B+\delta B)/B=-(n+\delta n)\Delta r/r$ and

$$\delta n=-r\delta B/(B\Delta r), \tag{12}$$

where ΔB is the field change caused by the pole shape in the radial span, Δr, and where δB is the part of the magnetic field caused by the beam itself. At a distance Δr from the center of the beam, which is assumed to be cylindrical and of uniform charge density, $\delta B=2I/(10\Delta r)$ where I is the circulating current contained within Δr. In the 22-Mev betatron $r=20$ cm, and at injection $B=45$ gausses and the beam width, $2\Delta r$, is about 2 cm. If we let $I=\frac{2}{3}$ ampere, then $\delta n=-0.06$ (magnetic effect). We know that the Coulomb repulsion of the beam for $v/c=\frac{1}{2}$ is four times as great as this magnetic attraction or $\delta n=+0.24$ (electrostatic effect). The net effect of the beam is $\delta n=0.18$. So $\delta a=2$ mm when $\frac{2}{3}$ ampere is sacrificed. Thus a loss of circulating current of this magnitude has a large damping effect on oscillations. The $\frac{2}{3}$-ampere figure is the calculated space charge limit of the 22-Mev betatron and it is approached at injection time.

The fact that strong self-contraction effects occurred in previous betatrons may have been an important factor in their successful operation. With the newer designs of synchrotrons and betatrons having small tube proportions for radial and axial oscillations it may be very difficult to build up a sufficiently great circulating current to produce the contraction effect. Hence artificial contraction might be expected to be more important with these compressed designs. The improvement of yield by a factor of twenty showed this to be the case with the 80-Mev model. However, in the case of the 300-Mev betatron it may be that a contractor will not have such a beneficial effect, because the voltage per turn in the machine is a much larger proportion of the injection voltage, and therefore the method of capture described in the earlier theory[13] by the damping of radial oscillations and shifting of instantaneous circles should be sufficient. For example, in the 300-Mev betatron with 60-kilovolt injection ordinary beam spiraling would be about 2 mm per turn which would easily allow the particles to pass the injector. Thus contraction is not likely to be so necessary in large instruments.

The x-ray output from the model was roughly measured with several ionization meters. The tests were made while the beam was penetrating the iron of one "C" magnet, and the accuracy of the observation is not good; but it is estimated that the output is at least 0.001r per pulse at one meter. A slight rotation of the vacuum tube is sufficient to bring the x-ray beam out between the "C's" without the necessity of penetrating iron.

It was interesting to make tests on the effect of the azimuthal variation of magnetic field with this six "C" betatron. Since it is possible to wind a coil about the back leg of each "C" and to energize them in different combinations, it is possible to arrange some well-defined variations in the magnetic field. Observations similar to those made earlier with the 22-Mev betatron[6] showed that if the field bumps are created at the time it is desired to produce x-rays, either polarity for the bumps will cause the beam to strike the target. A simple theory of the vibration generated by these bumps indicates that the field should be strengthened at the azimuth of the target and weakened at the opposite side of the orbit. However, it is found that the reverse polarity of the field bumps brings the beam to the target equally well.

In the case of the 80-Mev model the agitation produced in the orbit is not as simple as that produced in the earlier experiments in which the target was well

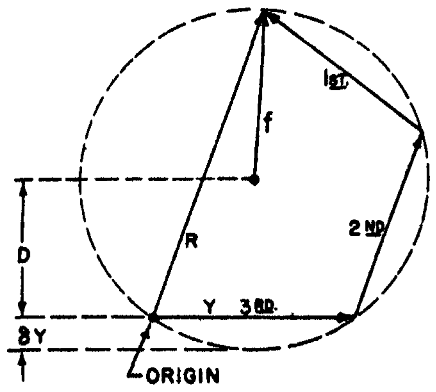

FIG. 20. Vector spiral for summing oscillations produced by the passage of an electron through a bump. Y is the maximum displacement produced by the field inhomogeneity. It is proportional to the deflecting impulse. If the particle passed through the bump only once, the projection of Y on the vertical axis would be the displacement ($Y\sin\omega t$). ω is the free oscillation circular frequency. Subsequent passages through the same bump produce the second and third vectors of magnitude Y. The resultant vector (R) can be decomposed into a free oscillation (f) which rotates with angular velocity ω, a steady displacement (D), and a forced vibration (δY). f and D are not important because they are eliminated by different initial conditions for the injected electrons, but the forced vibration (δY) is the remaining agitation due to the bump. Combinations of bumps and uniform orbit displacement can be treated by adding vector spirals.

---

[13] D. W. Kerst and R. Serber, Phys. Rev. 60, 53–58 (1941).

within the region where $n=1$. The 80-Mev model had the target placed where n was about 1.

Tests were also made of the yield from the betatron as a function of the magnitude of field bumps at the time of injection. Figure 19 shows the results for different combinations of bumps. The curves show that practically no improvement can be produced in the output of this betatron by employing azimuthal variations such as we used in the tests.

The method described below was used to estimate the magnitude of the orbital vibration generated by these bumps. The magnitude of the oscillation thus estimated which brings the yield essentially down to zero is 2 centimeters in these experiments. In estimating the amplitude of such an oscillation the problem involved is that of summing numerous sine functions having frequencies all equal to the frequency of radial oscillation. Each sine function represents a free oscillation generated by one passage over a bump, but the individual sine oscillation produced by each passage has a phase depending upon the ratio of the period of radial oscillation to the period of orbital revolution. The method used in optics to sum sine waves by a Cornu spiral is useful in determining the sum of the oscillations produced by the successive impulses given to the particle on its passages through the field bumps. The vector diagram or spiral for such oscillations is shown in Fig. 20, and the motion described by this spiral can be decomposed into a steady displacement, a forced oscillation, and a free oscillation represented by the vectors D, δY, and F. In the case of two equal and opposite field variations on opposite sides of the machine the formula for the maximum displacement of the beam from the equilibrium orbit is determined by such vector diagrams as

$$\delta Y=\{W\Delta B_Z/[2(1-n)^{\frac{1}{2}}B_Z]\}\tan 2\pi(1-n)^{\frac{1}{2}}/4, \quad (13)$$

where W is the width of the bump, ΔB_Z. Using the data shown in Fig. 19 the formula shows that the orbit moves 1 cm for the yield to cut-off. Approximately the same result is found for all combinations of bumps. This formula is one dimensional and it should hold for a few oscillations. Later coupling mixes the r and Z motions.

Because of the low repetition rate, this 80-Mev betatron is not a versatile instrument. However, it is well suited for use with cloud chambers and photographic emulsions. It has been used both with the x-ray beam penetrating a field magnet and with the tube rotated so that the x-ray beam leaves through an opening between "C's." Many accelerated electrons are scattered on striking the target and leave the machine after one revolution. This electron beam comes out between two "C's" and it has been useful for cloud-chamber studies with electrons.

Other physics department staff members carried out certain phases of the model work. Much vacuum tube work particularly on a 300-Mev size vacuum tube was done by Professor G. M. Almy, and Dr. L. S. Skaggs contributed to the development and testing of the 80-Mev tube. Professor E. M. Lyman initiated the work on excitation for the model and for the 300 Mev unit. Cuttings for both flux yokes were planned by Professor L. J. Haworth. We had the continuous assistance from graduate students R. W. Dressel, C. R. Emigh, E. L. Hahn, S. P. Lloyd, L. G. Mann, G. A. Price, and G. W. Rodeback. Other graduates who contributed considerably were G. R. Briggs, K. R. Ferguson, E. D. Klema, and F. E. Towsley.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 5 MAY, 1950

A New Mechanical Autocorrelator*

H. R. Seiwell
Woods Hole Oceanographic Institution, Woods Hole, Massachusetts

(Received January 16, 1950)

A relatively simple and inexpensive machine for mechanical computation of the autocorrelation function is described. The original design resulted from a collaboration with Dr. George P. Wadsworth of the Massachusetts Institute of Technology.

The theoretical definition of the autocorrelation function is given. This is followed by an outline of the hand computational procedure as applied in this laboratory to observational (ocean wave) data of finite scope. The machine computation is next compared with the hand process.

1. INTRODUCTION

A RELATIVELY new statistical tool for analyzing time series is the so-called autocorrelation coefficient. It is the coefficient of the product moment correlation between items of a series computed k equal intervals apart. The autocorrelation coefficient is normalized by dividing by the variance of the series, and r_0 equals 1. The diagram obtained by plotting the auto correlation coefficient of order k against k as abscissa is known as the correlogram. It was originally due to Yule.[1]

The theoretical definition of the autocorrelation coefficient assumes stationary conditions. Thus, $\phi(\tau)$ for $f(t)$ is[2]

$$\phi(\tau)=\lim_{T\to\infty}\frac{1}{2T}\int_{-T}^{T}f(t+\tau)f(t)dt. \tag{1}$$

It is normalized by dividing by $\phi(0)$.

2. HAND COMPUTATION OF AUTOCORRELATION FUNCTIONS

The following step-by-step outline of the formulas used in this laboratory for computing autocorrelation coefficients from observational data is given in view of the many inquiries. In practice, certain adjustments are made in the theoretical formulas to fit natural data of finite scope. For a series of N equally spaced discrete observations $(x_1, x_2, \cdots, x_N)$, the autocorrelation coefficients for k equally spaced time intervals are computed as follows.

For the variance we have the observations squared, divided by the number of observations (N) from which the mean squared is subtracted.

$$\sigma_v^2=\frac{\sum_{i=1}^{N}x_i^2}{N}-\frac{\sum_{i=1}^{N}x_i^2}{N}. \tag{2}$$

This gives the variance of the entire series under examination. In practice, the procedure is to compute a running harmonic mean variance. Thus,

$$\sigma^2=\left[\frac{1}{N-k}\sum_{i=1}^{N-k}x_i^2-\frac{1}{(N-k)^2}\left(\sum_{i=1}^{N-k}x_i\right)^2\right]^{\frac{1}{2}}$$

$$\times\left[\frac{1}{N-k}\sum_{i=1}^{N-k}x_{i+k}^2-\frac{1}{(N-k)^2}\left(\sum_{i=1}^{N-k}x_{i+k}\right)^2\right]^{\frac{1}{2}}. \tag{3}$$

The series is next lagged by an amount k. The cross products computed, summed, and divided by N minus k. Thus,

$$\frac{\sum_{i=1}^{N-k}x_ix_{i+k}}{N-k}. \tag{4}$$

FIG. 1. Operation of the mechanical autocorrelator.

---

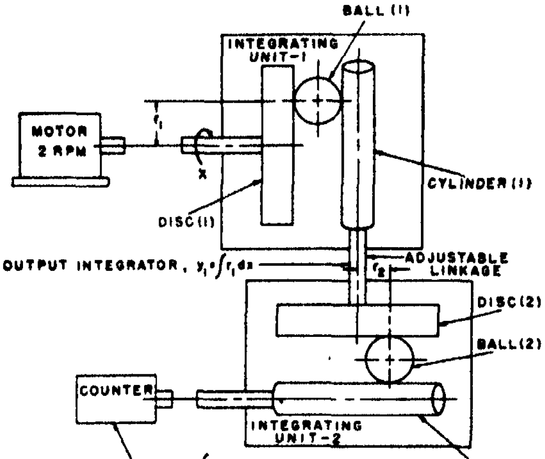

FIG. 2. Ball disk integrator hook-up for mechanical autocorrelation.

The autocorrelation of the lagged series is next obtained by subtracting the product of the mean of each column from Eq. (4). Thus,

$$\frac{\sum_{i=1}^{N-k} x_i x_{i+k}}{N-k} - \left[\frac{(\sum_{i=1}^{N-k} x_i)(\sum_{i=1}^{N-k} x_{i+k})}{(N-k)^2}\right]. \tag{5}$$

The autocorrelation coefficient is normalized by dividing (5) by the variance (3).

$$r_k = \frac{[(\sum_{i=1}^{N-k} x_i x_{i+k})/N-k] - \bar{X}_a \bar{X}_b}{\sigma^2}. \tag{6}$$

In the above, $\bar{X}_a$ and $\bar{X}_b$ are the respective means of the columns [see (5)].

3. THE MECHANICAL COMPUTATION OF AUTOCORRELATION FUNCTIONS

When using the mechanical autocorrelator described in Section 4, the mechanics of the computation differ slightly from the hand procedure, but the final result is the same. For the mechanical autocorrelator, two identical curves of observations are prepared on standard Esterline-Angus six-inch cross-section paper and then lagged in the same fashion as for discrete values in the hand procedure. The machine is so adjusted that the mean of one curve is always zero (running mean as for the hand computation). In this case, we have for the autocorrelation coefficient,

$$r_k\sigma^2 = \frac{\sum_{i=1}^{N-k} (x_i - \bar{x}_a)(x_{i+k})}{N-k}, \tag{7}$$

identical with Eq. (6).

A running harmonic mean variance [Eq. (3)] is first computed at the start of each new operation to determine the workable region of reasonably constant variance.

4. THE MECHANICAL AUTOCORRELATOR

The mechanical autocorrelator permits computation of autocorrelation functions for any length of time series, many times faster than possible by hand computation with electrically operated computing machines, and without loss of accuracy. Two operators are required to follow the duplicate observational curves with styli (Fig. 1).

The essential part of the computer consists of two linked ball disk integrators which perform continuous cross multiplications of the plotted data; their schematic operational principle being illustrated by Fig. 2. Mechanical details of the instrument are shown in Figs. 3–5. As the curves move slowly, the tracing styli transmit motions to the ball of each integrator. The disk of integrator 1 (Fig. 2) is rotated at a constant speed of two revolutions per minute (x) and, as its ball rolls, it rotates its cylinder in the opposite direction. The rate of rotation of the cylinder is proportional to the linear distance of the ball from the center of the disk, r_1, controlled by its curve-following stylus. The

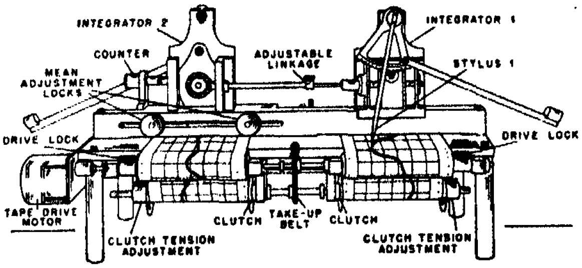

FIG. 3. Rear view of mechanical autocorrelator. This is working position of operator for left side integrator.

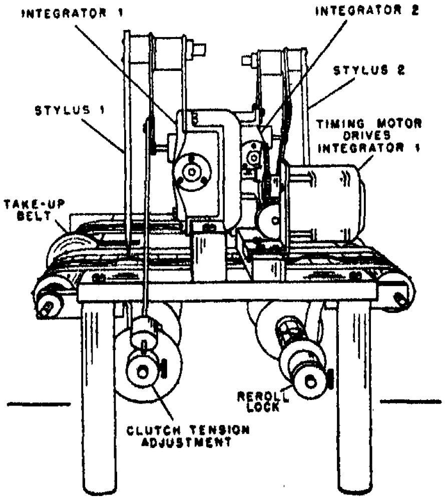

FIG. 4. Left side view of mechanical autocorrelator.

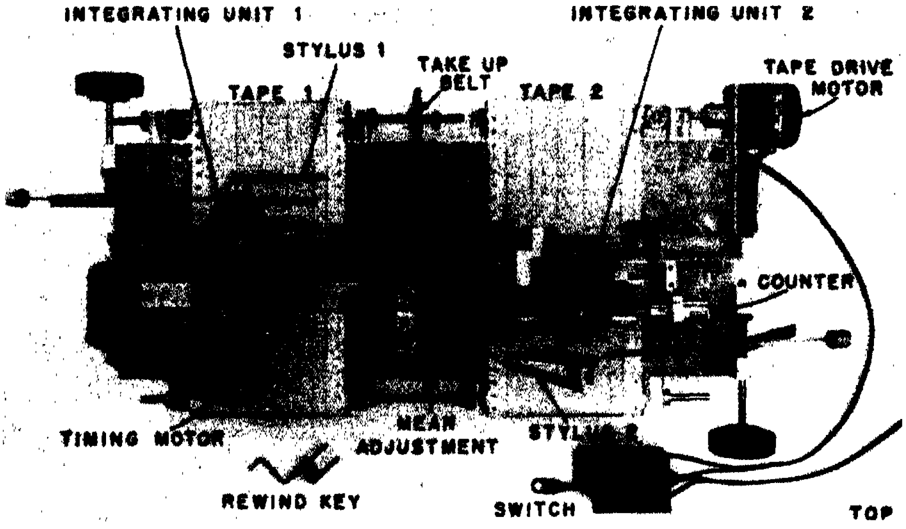

FIG. 5. Top view of mechanical autocorrelator.

output of the cylinder of integrator 1 ($\int r_1 dx$) is geared to rotate the disk of integrator 2. The final output of the second integrator ($\int r_1 r_2 dx$), proportional to the linear distance of its ball from the disk center, r_2 (resulting from its stylus operating on the duplicate curve), is read from a revolution counter (Fig. 3).

The instrument contains two separate chart-feed mechanisms, each consisting of one reroll stick and one drive roll. The two drive rolls are mounted on one axle and rotated by a Holtzer-Cabot a.c. synchronous motor of two revolutions per minute, to produce a chart-feed rate underneath the styli of approximately 9.1 in./min. (Fig. 3). Each chart, securely held by grids, revolves freely and rewinding is done manually. A zero adjustment of one curve is accomplished by changing the relative position of integrator to curve through the sliding coupling linking the two integrators (Fig. 3).

5. COMPUTATIONAL PROCEDURE

(a) A running mean (in absolute units) is computed every k units for the series of N observations, using an auxiliary computing machine.

(b) Based on the above result, one integrator is adjusted and locked at the mean position of its tape. This position may be changed as the computation proceeds to adjust for changes in the mean which exceed the machine sensitivity, e.g., one-half of a one-tenth-inch square on the cross-section paper.

(c) Next, a running harmonic mean variance (in machine units) is computed for the curves in place on the machine [Eq. (3)]. An empirical machine factor K converts to absolute units.

(d) Cross multiplications of the duplicate curves are carried out as previously described; for $\bar{X}_a$ a running mean is used, and σ^2 is an adjusted running variance. The values in machine units are not converted to absolute values for computation of the dimensionless autocorrelation coefficienct, r_k.

6. CALIBRATION

The principle of the integrators used in the autocorrelator consists in transmission of motion from a disk to a cylinder by means of a ball having sufficient friction at each point of rolling contact. The lines of rolling contact of the ball on both the cylinder and the disk are straight and parallel. In the integration of rdx, the distance from the center of the disk to the point of contact of the ball is r, and the angular distance turned by the disk from a fixed position represents x. For computation of the non-dimensional autocorrelation coefficient, the essential values are held in terms of the number of turns read from the revolution counter at the final output. However, for evaluation of the variance and other units in terms of absolute values, the machine values need be multiplied by an empirical constant, K, determined from the machine.

Constancy of the machine output was tested by running at normal procedure 12½-in. tapes for each of the constant styli settings tabulated in Table I-A and I-B; h_1 and h_2 being measured distances (inches) of the styli from zero positions of their respective integrators, and Δ is the integrated output as read from the revolution counter.

For styli settings at both constant product (I-A) and the linear graduated product (I-B), the machine output was consistent within limitation of the revolution counter. Since the latter registers discrete tenths, a reading of the counter at any time may be in error by 0.05 revolution, and the difference between any two readings by 0.10 revolution. This becomes insignificant as the readings become larger, as is usually the case. From the data we compute the evaluation constant K to be ($K\Delta = \text{area} = h_1 h_2$).

$$K = \frac{12.5 h_1 h_2}{\Delta} = 3.472 \text{ (Table I-A) and } 3.436 \text{ (Table I-B).}$$

A second computation of K from a continuous 20-min. operation with h_1 and h_2 values of 2.5 and 2.0, respectively, ($h_1 h_2 = 5.0$) gave nearly identical values of K (3.5).

To test the possibility of slippage of the ball-connecting disk and cylinder with rate of change of radial

velocity, two sine functions were plotted each in duplicate, and their autocorrelation coefficients computed by the machine and compared with theoretical values. For function 1,

$$\sin(2\pi x)/10$$
$$\text{the mean slope: } (2A)/(T/2)=0.4.$$

For function 2,

$$\sin(2\pi x)/4$$
$$\text{the mean slope: } (2A)/(T/2)=1.$$

Differences between normalized theoretical (R) and machine (r) computed values of the autocorrelation coefficient ($R-r$) are tabulated in Table II-A and II-B.

Table II bears out other experience that confidence in the machine computation diminishes as the slope of the traced curve becomes steeper. Experience has shown that curves of time series for this particular machine computation should be arranged so as not to exceed an average slope of 0.4. This is standard operational procedure, and a standard deviation of 0.017 is used to estimate the machine computational error.

7. ACKNOWLEDGMENT

The operational principle of the instrument described originated during discussions with Dr. George P. Wadsworth of the Massachusetts Institute of Technology. The machine (with the exception of the ball disk integrators) was constructed at the Woods Hole Oceanographic Institution by Mr. R. H. Bodman. Calibration of the machine and improvements in technique have been undertaken by Mr. T. C. Duke of the Woods Hole Oceanographic Institution.

The Design of a Simple Microflowmeter for Biological Perfusion Experiments

ALAN C. BURTON AND JAMES T. NICHOL*
Department of Biophysics, University of Western Ontario,† London, Canada

(Received December 27, 1949)

Various types of flowmeters are discussed with reference to their use at very small flows. The differential pressure type, using rubber membranes, appears most suitable. The steps are outlined in the design of an instrument sensitive to flows as low as 0.01 ml/min. yet with a response time less than 10 sec. In this instrument a completely differential linkage between two membranes is accomplished by the use of an incompressible fluid. The theory of the response is developed. This gives a prediction of the speed of response from the sensitivity and the diameter of the membrane used.

I. INTRODUCTION

NEW types of flowmeters are continually being devised for the measurement of the volume flow of blood or of perfusion fluid in the vascular bed of animals.[1] The devices are so varied and numerous that it is well to attempt a classification so that common disadvantages and advantages can be assessed.

II. TYPES OF FLOWMETERS AVAILABLE

A. Methods That Give a Direct Measurement of Volume Flow in Unit Time

Examples are the classical Ludwig "stromuhr" and its many modifications, in which vessels of known volume are alternately filled and emptied. These are operated manually or by devices of increasing complexity. An excellent review is given by Green.[2] Drop recorders and tilting-bucket recorders come under this classification as does the more recent simple and effective device of the bubble flowmeter.[3]

These methods have the great advantage over all others in that they unequivocally measure volume flow directly and that thus calibration is not affected by other factors such as viscosity. Their limitations are that they do not give *rate* of flow directly but quantity that has flowed in a given time, and they are not well adapted (except for the bubble flowmeter) to flows as low as 0.01 ml/min. (This would only be about one drop each 5 min.)

B. Differential-Pressure Flowmeters

In this group of methods a fixed resistance to flow, usually a short length of capillary tubing or an orifice, is inserted into the flow system and the difference of pressure at the two ends of this resistance is measured and taken as proportional to the rate of flow. This assumption is usually justified where the velocity is below that of turbulence. The variety of flowmeters of this type is due to the great number of ways by which the pressure difference may be observed or recorded, from direct observation of the standing height of liquid in manometers, to optical deflection of mirrors on rubber or metal membranes or the use of electrical strain gauges. Indeed the ingenious rotameter[4] may be regarded as of the differential-pressure type since the support of the floating ball is due to the difference of pressure below and above it.

The whole group of differential-pressure flowmeters suffers from the disadvantage that rate of volume flow is not directly measured. The difference of pressure depends on the resistance to flow of the resistance inserted, and this depends not only on rate of flow of the liquid, but also upon its viscosity. The calibration is different for each liquid used, and if the viscosity of the perfusate, as of blood in a physiological experiment, changes with time, correction must be made for this. However, in many circumstances, as where perfusion fluid of fixed composition and at fixed temperature is used, this is not a great difficulty, and the great adaptability of the differential-pressure type of flowmeter is a strong recommendation. As will be seen, this type can be made to be extremely sensitive and used for very small flows. Also instantaneous rate of flow is measured rather than quantity in unit time and thus rapid changes of flow can be accurately followed.

C. Indirect Methods of Measurement of Flow

A number of ingenious methods have been devised which do not in any sense measure flow directly, but some property which is dependent on flow. The thermostromuhr of Rein[5] and its many improvements is an example, for it measures directly effective thermal conductivity of tissues[6] which depends not only on blood flow, but also on many other factors which may not remain constant in a given experiement. There are also special devices such as the electromagnetic flowmeter[7] and those of the hot-wire anemometer type which essentially measure velocity of flow rather than rate of volume flow. In physiological cases where the diameter of the vascular bed is a variable, these methods are so indirect that they are justified only because of their applicability to specific cases, for which they may possess advantages. Methods which measure volume pulsation of tissues, or pulsation of quantity of haemoglobin (as in photoelectric plethysmography of the skin)[8] are of course still more indirect as measurements of flow.

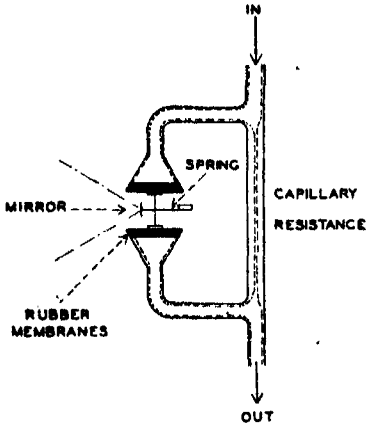

FIG. 1. Simple microflowmeter devised by Bozler.

III. DESIGN OF SENSITIVE MICROFLOWMETERS

Of all these types of flowmeters the differential-pressure group offers the best chance of extreme sensitivity combined with directness and simplicity.

An ingenious simple flowmeter of this type was used by Bozler[9] for measuring the flow in the blood vessels of the frog's hind limb. The principle of this meter is illustrated in Fig. 1. The pressure at the ends of the capillary resistance is measured by the deformation of two thin rubber membranes on the funnels, which oppose each other. The centers of the two membranes are connected by a link, the movement of which tilts a mirror and deflects a light beam. This flowmeter was the starting point in our design and development.

From the point of view of design this simple effective flowmeter has a major fault, in that it makes use of two different rubber membranes. Unless the tensions in these and their distensibilities are identical, the deflection will depend not only on the difference in pressure but on the mean pressure at the flowmeter also. For since the bulging of the first (upstream) membrane will be a function of the pressure there, say $f_1(P_1)$, and the bulging of the second (downstream) membrane will be a function of the pressure there, say $f_2(P_2)$, then the movement of the link will be proportional to $f_1(P_1) - f_2(P_2)$. Unless f_1 and f_2 are identical functions, and this requires identical distensibilities in the two membranes, this will not be a function of $(P_1 - P_2)$, the difference of pressure alone, but also explicitly of P_1 and P_2. Also in the flowmeter there is severe departure from the ideal spherical shape of the membranes under pressure, the central portion being restrained by the link and the rubber bulging between the central attachment to the link and the rim of the membrane. This will not give the optimal conditions for sensitivity.

The first step in improvement was therefore to use one membrane only and to apply the two pressures to opposite sides of this single membrane. The method of measuring the deformation can also be improved. A small mirror placed at the edge of the membrane, which takes up the inclination approximately of the tangent to the spherical shape of the membrane, is in practice much better than the linkage system, connected to the center of the membrane. Simple geometrical considerations show that to achieve the same sensitivity by a linkage, the lever arm to which the mirror in a linkage is connected must be less than the radius of the membrane. Since for speed of response membranes of very small diameter are required, this is not easily achieved.

A simple design incorporating these improvements is illustrated in Fig. 2. This type has been in regular use in our laboratory. Sensitivity of 1-mm scale deflection at a distance of 1 meter, for flows of 0.001 ml/min., is easily achieved, with a time period of response which is

less than 10 sec. Two practical difficulties had to be surmounted. One is that the very thin latex rubber first used rapidly changes in elastic properties if allowed to stand in oxygenated Ringer's solution (evidently because of oxidation). This may be avoided by using butyl rubber, which has proved to hold its calibration for more than a year. The second difficulty was that silvered mirrors, however we attempted to preserve them by coating with plastic varnishes, quickly deteriorated in saline solutions. This difficulty was met by using mirrors of stainless steel, filed from an old ferrotype plate or knife blade.

Figure 3 shows the record of the change in flow of a perfused leg of a frog when a minute dose of adrenalin was added to the perfusing Ringer solution. It well illustrates the sensitivity and speed of response of these simple microflowmeters.

However, a disadvantage of this type exists. It cannot be used where opaque perfusing fluids (blood, dye solutions, etc.) are used, since the light beam must pass through the front chamber to reach the mirror. A linkage bringing the movement of the membrane to the outside would be impractical. We have succeeded in designing a microflowmeter free from this objection, yet retaining the advantages of the single membrane type.

The final modification is shown in Fig. 4. Two membranes (part of a single butyl sheet) are used, yet the deflection is free from dependence of the mean pressure at the flowmeter, and is dependent only on the difference of pressure in the two chambers. This is accomplished by the use of a "hydrostatic link" between the two membranes. The front chamber is filled with an incompressible fluid (water). Consequently one membrane cannot bulge out without an exactly corresponding inward bulging of the other. The deflection of a mirror on either of the membranes depends on the distensibility of both membranes, not on that of either membrane alone. If there be no flow, and no difference of pressure, both membranes will remain flat whatever the pressure at the flowmeter. Figure 5 shows the components.

This type of microflowmeter has proved completely satisfactory. The volume of the water in the front chamber must be kept as low as possible to avoid the shift of zero that will occur if the temperature changes greatly, but this has been done and changes of zero during a day's experiment were negligible. The front glass window is tilted to throw the direct reflection at the surface off the scale.

IV. SPEED OF RESPONSE AND SENSITIVITY

It is well known that the two requirements often demanded in any instrument, that is, sensitivity and quick response, are mutually antagonistic. For example, sensitivity in these flowmeters can be increased indefinitely by increasing the resistance to flow in the capillary tube of the flowmeter, but the speed of response will be correspondingly decreased. A theoretical investigation has been made (see Appendix) to analyze how the two factors of sensitivity and of speed of response depend upon the tension with which the membrane is applied, upon the resistance to flow of the flowmeter, and, of particular importance, upon the diameter of the membrane used.

This analysis results in a general approximate relation, of very simple form, between sensitivity and speed of response. It is expressed by the equation:

$$t_0 = [(\pi a^3)/8]S,$$

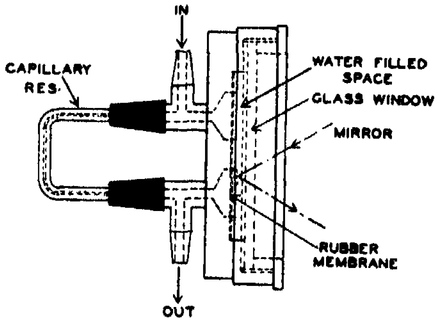

FIG. 4. Schematic drawing of final modification, using two membranes linked by water.

where t_0 is the time constant in minutes (time to reach $1/e$ of the final deflection when flow is abruptly changed), S is the sensitivity in radians for a flow of 1 ml/min., and a is the radius of the membrane in cm. It will be noted that the other variables, the tension in the membrane, and the resistance in the capillary do not appear in this relation. These variables affect the sensitivity and the speed of response in exactly opposite directions. For example, doubling the diameter of the membrane will give (other things being equal) twice the sensitivity, but will also double the time period of response.

Verification of this approximate relation has been made using three different flowmeters with the variables of diameter, tension, and resistance altered over a large range. Figure 6 shows the response curve of one of these instruments when the flow was abruptly changed from a constant value to zero. Table I gives the results for the time constant of response calculated from the theoretical relation and observed from such a response curve (the time to $1/e$ of deflection was employed for this). The correspondence with the predicted values is considered to be satisfactory in view of the obvious approximations in the theory. The bigger discrepancy in the smallest membrane is to be expected, since here the mirror cannot be very close to the tangent at the edge of the membrane.

The theoretical relation is therefore regarded as a reliable guide in design. If the sensitivity required is known, the maximum diameter of membrane that can be used to give the speed of response also required can be calculated. For example, if a sensitivity of 1 radian for 1 ml/min. is needed, and a time constant of less than 10 sec., the relation shows that this cannot be achieved, by any means available, unless the membrane used is of less than 1.5 cm in diameter.

V. SUMMARY AND CONCLUSIONS

(1) Devices for measuring rate of flow of liquids, particularly in biological research, can be classified into three main types, those that measure the volume flowing in unit time, the differential-pressure type that measures instantaneous rate of flow, and a miscellaneous group in which the flow measurement is indirect. The advantages and disadvantages of each are discussed.

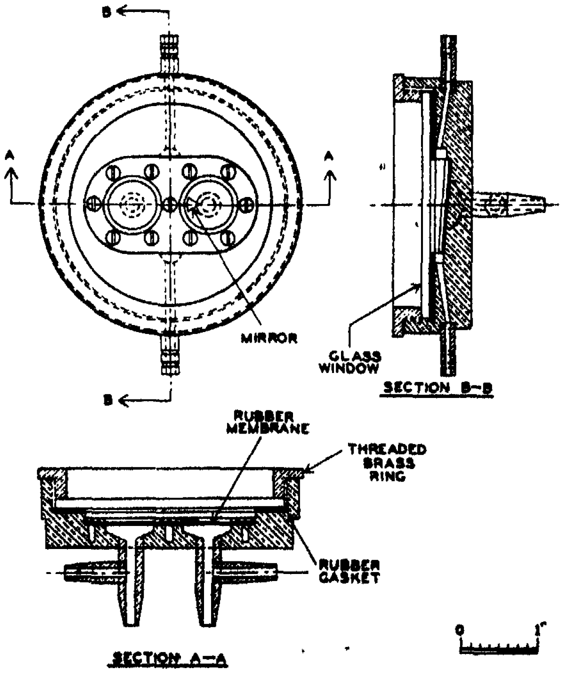

FIG. 5. Scale drawing of final model of flowmeter.

(2) For great sensitivity, simplicity, and adaptability, the differential-pressure type offers the greatest promise. The steps in improving the design of the simple microflowmeter of Bozler are discussed. A single manometric membrane can be used instead of the two in the original apparatus, or the two membranes can be connected by a "hydrostatic link." This ensures that the deflection is independent of the mean pressure in the flowmeter.

(3) Sensitivities of 1-mm deflection at 1 meter for 0.001 ml/min. are achievable with time constants of response less than 10 sec.

(4) The theory of the response curve is developed and a simple approximate formula results which enables the time constant of response to be estimated from the sensitivity and the radius of the membrane.

Allingham of the Instrument Shop of the Medical School for his patient drafting and construction of the various models in the development, also to the Life Insurance Medical Research Fund and to the National Research Council of Canada whose financial assistance made the work possible.

APPENDIX

SENSITIVITY AND SPEED OF RESPONSE OF DIFFERENTIAL-PRESSURE FLOWMETERS

The following simple analysis applies not only to those particular flowmeters described, but should apply to all of the differential flowmeter type.

A. Sensitivity

Let P = difference of pressure at any time on the two sides of the membrane (or between the two membranes).

Let T = the tension in the membrane. This will consist of a constant tension caused by the stretch with which the membrane was put on, plus a tension which will increase with the degree of deformation, that is, with P.

Let a = radius of the membrane opening.

Let r = radius of curvature of the spherical shape into which the membrane will be deformed.

Then, by the law of Laplace,

$$P=(2T)/r. \tag{1}$$

If the mirror is placed at the edge of the membrane, its tilt (α) will be that of the tangent at the edge (Fig. 8). Then:

$$\begin{aligned}\sin\alpha&=a/r\\&=(aP/2T)[\text{by (1)}].\end{aligned} \tag{2}$$

The deflection will be twice the change in α, and we may define it either as the angle turned through by the light beam, or as the sine of this angle. Where the angle is small there will be little difference. Then:

$$\theta=2\sin\alpha=(aP)/T. \tag{3}$$

The flow F is proportional to the difference of pressure P, unless there be turbulence, or with very low flows with complex liquids, i.e.,

$$P=FR_1, \tag{4}$$

where R_1 is the resistance to flow in the flowmeter. Combining (3) and (4):

$$\theta = (aR_1F)/T. \tag{5}$$

The sensitivity S is the rate of change of θ with F. If we assume that the tension is a constant, and independent of the pressure difference (and therefore of F):

$$S = (\partial\theta)/(\partial F) = (aR_1)/T. \tag{6}$$

Actually T will increase with F and the full differential is:

$$S = \frac{aR_1}{T} - \frac{aR_1F}{T^2}\,\frac{\partial T}{\partial F}. \tag{7}$$

The sensitivity will therefore decrease with increasing flows, and the calibration curve will not be linear. The fact that over the working range of these flowmeters, the calibration is approximately linear justifies taking Eq. (6) for the sensitivity. This equation shows, as was obvious, that the sensitivity is proportional to the resistance in the flowmeter. It also shows that it may be increased proportionally by increasing the diameter of the membrane.

B. Speed of Response

Let us examine the transition from a steady rate of flow to another steady rate, caused by an instantaneous change of resistance to flow in the perfused preparation. See Fig. 7. Assume that the resistance between the reservoir and the flowmeter is negligible, so that, throughout, the pressure on the "upstream" side of the membrane (or that at the upstream membrane when there are two membranes) be P' at any instant. The membrane will bulge towards the downstream side, in a spherical shape. Let V be the volume of the segment of a sphere between the bulging membrane and the flat configuration of the membrane when there is no differential pressure (no flow).

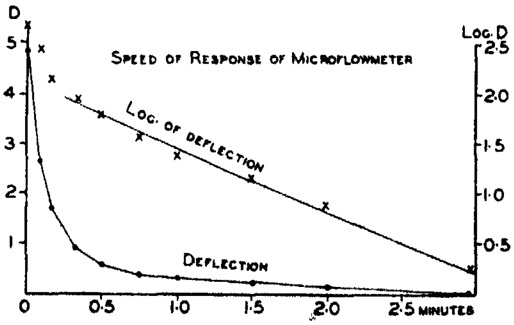

FIG. 6. Speed of change of deflection of flowmeter when flow is changed from a steady value abruptly to zero. The semilog plot shows the curve approximately exponential except for the first few seconds.

Let R_1 be the resistance in the flowmeter between the two pressure chambers and R_2 the resistance in the perfused preparation. If the "exit" pressure at the outlet of the preparation is zero, the instantaneous flow out of the "downstream" chamber will be P'/R_2. The instantaneous flow into this chamber will be $(P'-P)/R_1$. The rate of change of volume of fluid in this chamber will therefore be given by the differential equation:

$$\frac{dV}{dt} = \frac{P'}{R_2} - \frac{(P-P')}{R_1} = \frac{P}{R_2} - (P-P')\left(\frac{1}{R_1}+\frac{1}{R_2}\right). \tag{8}$$

But the volume V depends on the distortion of the membrane, which is related to the difference of pressure $(P-P')$ by Eq. (1). Let us assume that approximately, for small deflection,

$$P-P' = kV, \tag{9}$$

TABLE I. Sensitivity of speed of response of flowmeters.

Type	Radius of membrane cm	Sensitivity radians/ml/min.	Ratio res./tension	Time constant sec. calc.	Obs.
Single membrane	0.47	0.81	0.61	3.4	8
Double membrane (water-linked)	0.78	0.37	0.48	3.7	5
Double membrane (water-linked) resistance increased	0.78	1.10	1.41	11	13

This approximate relation is proved in a later paragraph. Substituting in Eq. (8):

$$\frac{dV}{dt} = \frac{P}{R_2} - k\left(\frac{1}{R_1}+\frac{1}{R_2}\right)V. \tag{10}$$

This is a linear differential equation of the first order, whose solution is:

$$V = A\exp\left[-k\left(\frac{1}{R_1}+\frac{1}{R_2}\right)t\right] + \frac{P}{k[1+(R_1/R_2)]}. \tag{11}$$

The value of A is determined by the initial and final conditions in the usual way.

Equation (11) shows that the approach to the final deflection will be exponential, with a time constant (time to $1/e$ of final deflection) given by:

$$t = \frac{1}{k[(1/R_1)+(1/R_2)]}. \tag{12}$$

The speed of response therefore depends on the distensibility "k" of the membrane, and on the resistance not only in the flowmeter but also that in the "final" state of the preparation. Thus the final deflection will be reached more rapidly when the resistance R_2 is reduced (as by dilation in a vascular bed) than when it is increased (as in vasoconstriction). The slowest speed of response and the longest time constant will be when the resistance in the preparation is increased to infinity, i.e., flow is reduced to zero. This time constant t_0 is given by:

$$t_0 = R_1/k \tag{13}$$

and may be regarded as the time constant of the flowmeter itself. In any actual change of flow the time constant of response will never be greater than this.

It remains to evaluate this distensibility "k" in terms of the tension in the membrane and the radius of the membrane opening, "a." Referring to Fig. 8, the volume of the segment of a sphere of height h is given by:

$$V = (\pi/6)h^2(h^2+3a^2). \tag{14}$$

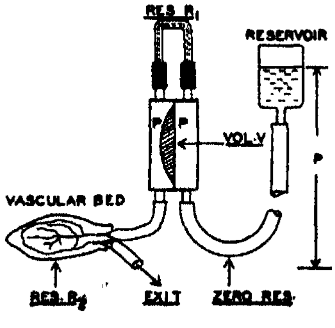

FIG. 7. Schematic diagram of operation of flowmeter.

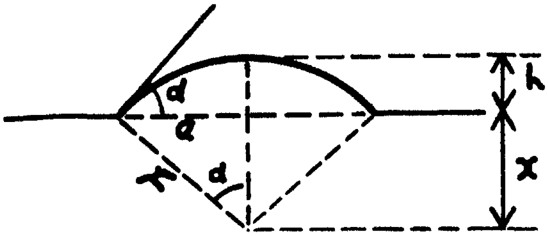

FIG. 8. Geometry of membrane under pressure.

But

$$h = r - x = \frac{a}{\sin\alpha} - \frac{a}{\tan\alpha} = \frac{a(1-\cos\alpha)}{\sin\alpha}. \tag{15}$$

Substituting in (14) we find:

$$V = \frac{\pi}{3}\frac{a^3(1-\cos\alpha)(1-\cos\alpha+\sin^2\alpha)}{\sin^3\alpha}. \tag{16}$$

Further, we may substitute for $\sin\alpha$ since by (3), $\sin\alpha = (aP)/(2T)$ This gives:

$$V = \frac{\pi}{3}\frac{T^3}{P^3}\left[1-\left(1-\frac{a^2P^2}{4T^2}\right)^{\frac{1}{2}}\right]\left[1+\frac{a^2P^2}{4T^2}-\left(1-\frac{a^2P^2}{4T^2}\right)^{\frac{1}{2}}\right]. \tag{17}$$

The final step is to make the approximation, that, for small angles α, $\sin^2\alpha = a^2P^2/4T^2 \ll 1$. Equation (17) then becomes:

$$V = (\pi a^4/8T)P \tag{18}$$

which gives the distensibility "k"

$$k = P/V = (8T)/(\pi a^4). \tag{19}$$

The final expressions for the time constants are then:

$$t = \frac{\pi a^4}{8T[(1/R_1)+(1/R_2)]} \tag{20}$$

$$t_0 = (\pi a^4 R_1)/(8T). \tag{21}$$

Substituting for T its value from Eq. (6), Eq. (21) gives finally:

$$t_0 = (\pi a^3 S)/8. \tag{22}$$

Laboratory and Shop Notes

Best Arrangement of Resistors in a Series Group

HERBERT B. BROOKS
3006 Porter Street, N.W., Washington, D. C.
February 20, 1950

IN his classical book on Electrical Resistance, Price[1] suggests a simple method for determining a preferred arrangement of *n* nominally equal resistors in a series group. In resistors taken at random, the departures from the nominal value or from the group average value will vary from one resistor to another, some being smaller and some larger than the average departure. Price's method arranges the resistors in series to make the error in percent approximately constant, regardless of the number of resistors in circuit. In many years of service at the National Bureau of Standards the writer has found Price's method useful and has recommended it to other workers, none of whom had heard of it. The purpose of this article is to call attention to the simplicity and evident advantages of the method. Price merely illustrated his method in the following manner.

"Again, in constructing a set of coils * * it is often possible to compensate for errors in the several coils by a proper arrangement of the order in which they are placed. To take an extreme case, consider the following set of ten coils, each of which is intended to be 100 ohms:

Coil No.	Resistance	Res. of Sum
1	100.01	100.01
2	99.97	199.98
3	100.05	300.03
4	99.93	399.96
5	100.09	500.05
6	99.89	599.94
7	100.13	700.07
8	99.85	799.92
9	100.17	900.09
10	99.81	999.90

The right-hand column of figures is the resistance of the dial with the corresponding hole plugged. It is seen that a set of coils, all of which are in error by amounts varying from 1 to 19 parts in 10,000, may be arranged so that there is no error in the dial of more than 1 part in 10,000."

For practical purposes Price's method may be outlined as follows. The percentage error of the sum of the resistances of the *n* coils is determining because the method aims to give the same percentage error for 1, 2, 3, ⋯ *n* coils in circuit. If therefore the percentage error of the *n* coils in series is too large for a given purpose because (for example) coils with +errors predominate, some of those having the largest +errors should be replaced with coils having −errors. The error of the entire series group having thus been reduced to a satisfactory amount, divide the resistance of the group by *n* to get the mean resistance of the coils. Select the coil having most nearly this value as the first coil of the group. Subtract the resistance of this coil from twice the mean resistance; the remainder is the most desirable value for the second coil. Choose from the remaining 9 coils the one closest to this value. From three times the mean resistance subtract the sum of the resistances of the selected coils 1 and 2; the remainder is the desirable value for the third coil of the group; and so on. It is evident that this method automatically defers, as long as possible, the selection of coils which have relatively large errors; also, that near the end of the group the effect of their large errors on the accuracy of the settings in which they occur will be relatively small.

As a practical example of the usefulness of the method the following recent case in my work may be cited. It was desired to construct a resistance decade of ten 100,000-ohm coils. Because of high humidity during Washington summers, the coils chosen were pie-wound on ceramic forms and hermetically sealed in glass containers. These units are stated by the maker to be adjusted within 1 percent. A much closer value for the proposed decade was desired. The 10 resistors purchased were "run-of-mine" and in the purchase order no selection for accuracy was requested. The Price procedure showed that with these 10 units a decade could be assembled that would be sufficiently precise at each of the 10 settings if the accuracy of the sum of the resistances of the 10 units could be regarded as satisfactory. It happened, however, that this sum was 0.4 percent higher than the nominal value because the resistances of a majority of the coils happened to be greater than the nominal value. A more accurate value being desired, five more coils of this type were purchased as commercial items without special selection for accuracy. From the total of 15 coils then available were selected 10 coils whose sum was in error at 25°C by only 0.03 percent. With these 10 coils arranged in order by Price's method the error at the other nine settings ranges from a minimum of 0.001 percent to a maximum of 0.064 percent.

To illustrate further the value of the Price selection method, three other possible groupings of these 10 coils were computed. For two of them the order of arrangement of coils in the group was determined by chance by drawing folded numbered slips from a cup. For the third grouping the Price method was used "in reverse" to give the worst possible arrangement. The results for all four arrangements are given in Table I.

TABLE I. Error at each step of a decade for Price's and other arrangements.

Step No.	Error in percent			
	Price	Random 1	Random 2	Reverse Price
1	−0.044	+0.446	+0.071	+0.581
2	+0.014	−0.199	−0.019	+0.513
3	−0.021	+0.061	−0.294	+0.395
4	+0.024	+0.018	−0.231	+0.314
5	−0.020	−0.034	−0.234	+0.243
6	−0.035	−0.036	−0.228	+0.188
7	+0.034	−0.008	−0.208	+0.145
8	−0.001	+0.002	−0.126	+0.102
9	+0.064	−0.020	−0.095	+0.062
10	−0.027	−0.027	−0.027	−0.027

It has been suggested that the Price method might be applied to other cases than resistors in series. Possible cases are: a group of *n* nominally equal capacitors of which any number up to *n* may be put in parallel to give equal increments of capacitance; and a group of *n* nominally equal Johanssen blocks used to obtain very accurate steps of length.

Test of Rupture Strength of Thin Plastic Films*

JOSES J. L. CHEN†
Department of Physics, University of Southern California, Los Angeles, California
March 20, 1950

THE purpose of this note is to describe a simple technique for making direct rupture tests on very thin plastic films and to present a criterion for evaluating the minimum practicable thickness to be used under prescribed conditions. In beta-ray spectroscopy a very thin film backed by an appropriate grille is generally used for the window of the G-M counter. The mechanical factors to be considered are, in general, the limiting differential pressure on the film, the diameter of the window (or the grille holes), the thickness and the material of the film. It has been found convenient to express the results of direct tests in terms of rupture constants so that different materials may be easily compared. The limiting pressure for any window diameter and thickness of film may be readily determined for any of the several materials tested by use of the rupture constants given in this note.

For making rupture tests a test chamber was constructed having a replaceable test plate mounted with a pressure seal at one end of the chamber. The pressure in the chamber was made to increase gradually above atmospheric pressure, the differential pressure being read on an open mercury manometer. On the test plate seven holes were drilled to give diameters from 0.1610 in. down to 0.0135 in. The test plate was carefully weighed before and after attaching the thin film to be tested, and the film thickness thus found in terms of mg/cm², the area of the plate being known.

Thin films of a few materials usually employed in beta-ray spectroscopy were made by the conventional drop technique.[1] The film floating on water was picked up by a semicircular wire loop previously immersed in water. The wire loop was made with handles, which protruded from the surface of the water near the edge of the spreading film while the wire loop rested on the bottom of the tray. This arrangement was found convenient especially when the solvent of some film material took a few minutes to evaporate from a film, such as in the case of Nylon,[2] and when a multilayer film was made by repeated picking up on the same wire loop of a few very uniform thin films.

In making rupture tests single films or multilayer films of thickness from 0.01 mg/cm² to 0.32 mg/cm² were used. After attaching the film and mounting the plate to the test chamber the pressure in the chamber was gradually increased. The limiting differential pressure at which the film ruptured at the largest hole was first observed. After closing the largest hole of the plate from outside, the differential pressure was increased again from zero up and the limiting pressure for the second largest hole was observed, and similarly down to the smallest hole, or up to maximum workable differential pressure.

For each film it was found that the limiting pressure, p, was inversely proportional to the hole diameter, d, so that the product pd was found to have a constant value. Since the total force on the film, $p\cdot\pi d^2/4$, divided by the perimeter of the film, πd, gives $pd/4$, the product pd may be taken as a convenient measure of the strength of the film. It was found that the constancy of this product gave a simple and direct test of the uniformity of thin films. For each material many films of different thicknesses were tested, and the product pd was found to be proportional to the film thickness t as expected. It is thus convenient to express the strength of films in terms of a rupture constant R defined by

$$R=\frac{p(\text{cm}\cdot\text{Hg})\cdot d(\text{cm})}{t(\text{mg/cm}^2)}.$$

Mean values of R found from rupture tests made on thin films of some materials are listed.

Material	Rupture constant R
Formvar E[3]	102
Collodion	74
Nylon	46
LC 600[4]	34
Zapon (Brevon #2)[5]	14.5

The probable error of these results was about 5 to 13 percent. The principal source of error was in the determination of film thickness. These results are compatible with the tensile strengths of 12×10^3 p.s.i. for Formvar E and 2×10^3 p.s.i. for Zapon as given by the manufacturers.

The author wishes to thank Professor C. M. Van Atta and Dr. S. D. Warshaw for their encouragement and advice.

A New Method for the Measurement of Inhomogeneous Magnetic Fields

PETER M. WEINZIERL
I. Physics Institute, University of Vienna, Austria

January 30, 1950

FOR the precise determination of magnetic field strength within strong and inhomogeneous fields, frequently of the greatest importance in electron-optical work, the usual method is to measure the flux. This method requires a very complicated experimental set-up in order to achieve the necessary precision.[1] We used successfully a very small magnetron acting as a probe for the measurement of field intensities in inhomogeneous magnetic fields. At the same time the direction of the field is determined with a high degree of accuracy.

If we calculate the movement of an electron in the electric field of two coaxial cylinders simultaneously superimposing a homogeneous magnetic field along their axis, we find that an electron starting from the inner cylinder cannot reach the outer one, if the magnetic field strength H exceeds the value

$$H=6.72((V)^{\frac{1}{2}}/r)$$

(H in gauss, V voltage between the cylinders in volts, r radius of the outer cylinder in cm; assuming the outer cylinder much larger than the inner one).[2] The drop of the anode current which is to be expected at these field intensities may be used for the measurement of H.[3]

Because of the above relation the magnetic field strength can be measured very accurately as a function of the anode voltage. According to the relation $H\propto 1/r$ it is possible to change the range of H to be measured by varying the outer diameter r. As the anode current in the magnetron will be a minimum, if the directions of the magnetic field and the cylinder axis are parallel, this direction has to be found by varying the direction of the magnetron at the beginning of each measurement.

We tried different tubes, changing diameter and length of the copper anode cylinder from 0.5 to 1.0 mm. As cathode a spiral of tungsten wire (diameter of the spiral 0.1, length 2 mm) was used. These electrodes were placed within a well-evacuated glass tube (diameter 6 mm, length about 200 mm). To avoid magnetron oscillations as far as possible[4] the cables of the electrodes should have a very small mutual inductivity and capacity. A special set-up made it possible to vary position and direction of the tube within the magnetic field.

The calibration of the magnetron, used as measuring instrument, is carried out in the following way. A certain value of the anode current is chosen, for instance the value for $H=0$ and $V=2$ volts (this voltage has to be suitable to the range of H to be measured). Now every variation in this current due to a magnetic field ($H\neq0$) is compensated by varying the anode voltage. So we obtain a calibration plot $H=H(V)$, $i=$ const. The accuracy of this measurement is about ±1 percent. Using a magnetron characteristic $i=i(H)$, $V=$ const., it is possible to measure deviations from homogeneity of magnetic fields with an accuracy of about 2 percent.

By means of one of these magnetrons (anode diameter 0.6 mm, range from 100 to 6000 gauss) we determined point for point magnitude and direction of the magnetic field, especially of the stray field, in a mass spectrometer. (The shape of the stray field depends on the size of the magnetizing current because of the effects of saturation in the iron; therefore an exact calculation of the field, as is possible for an electric condenser,[5] cannot be carried out in our case.) The values of the deflection of charged particles calculated from the measurements of the stray field were in satisfactory agreement with the experimental results obtained from mass spectra.

A High Megohm Bridge

F. M. Glass and R. K. Abele
Instrument Department, Oak Ridge National Laboratory,
Oak Ridge, Tennessee

February 6, 1950

THE instrument to be described here is a simple direct reading Wheatstone bridge capable of rapidly measuring resistances up to 10^{13} ohms with 1 percent accuracy and 1.5×10^{14} ohms with somewhat less accuracy. Several of these have been constructed and used at the Oak Ridge National Laboratory during the past two years. The need for them arises out of the fact that almost any device for measuring very small (usually ionization) currents makes use of resistors in the range of 10^{8} to 10^{14} ohms, and the accuracy of the results is only as good as the precision with which the resistance values are known.

As shown in Fig. 1, the circuit consists of a four-arm resistance bridge, balance of which is detected by a simple battery operated vacuum tube electrometer. The meter serves only to establish a null and the value of the unknown resistance R_x is read directly from the duoscale dial of the 15-turn helipot in bridge arm *D*. Two sets of multiplying factors, determined by the positions of switches *S*-2 and *S*-3, establish the decimal point.

It is at once apparent that inaccuracies may result from (1) lack of sensitivity in the null detector, (2) failure to establish a preliminary null (with no voltage on the bridge) having the electrometer plate and grid voltages identical to those of the final balance, (3) lack of linearity or error in the maximum resistance of the helipot *D*, and (4) errors in the values of the known multiplying resistances *A* and *B*. Steps taken to avoid each of these difficulties will be discussed in turn.

(1) As constructed, the vacuum tube voltmeter has a sensitivity of 0.17 volt for mid-to-full scale meter deflection. If the leakage resistance in the grid circuit is then kept above 10^{14} ohms, the sensitivity will be sufficient to determine the null setting on the helipot dial to four significant figures, even when measuring a 10^{13} ohm resistance. The introduction of a parallel leakage path of (say) 10^{13} ohms from any point at grid potential to ground, will seriously reduce the balancing sensitivity but will not otherwise lead to erroneous results.

Insulators with leakage resistance of 10^{15} ohms or higher, require special consideration.[1] Satisfactory materials are Teflon, fluorothene, and polystyrene, although the latter is much more difficult to use. Since such insulators may not be touched with the fingers a metal canopy protects the number 1 feed through insulator which supports one of the binding posts for R_x (see Fig. 2). In use, a metal shield (not shown) is placed over the unknown resistor and the exposed terminals.

Selector switches $S\text{-}1_B$ and *S*-2 must also meet the high impedance requirement. These are Cent-alab Ceramic switches which have been specially treated for minimum leakage.[1]

(2) The switching sequence of the four-deck switch *S*-1 has been arranged so that position 2 applies only filament voltage; position 3 applies plate voltage (this delay is necessary, otherwise the electrometer would drift for hours[2]), shorts the electrometer input, and allows the first zero adjustment to be made. Position 4 allows the second zero adjustment, zero′, to be made with no voltage applied to the bridge, hence the effects of grid current and contact potential may be eliminated and the conditions of balance will be identical to those of the final balance. Preliminary balance is made on position 5 with 1.5 volts applied to the bridge, while final settings are made on position 6 with 24 volts on the bridge.

(3) The helipot used in arm *D* can be obtained from the manufacturer* with the linearity of 0.01 percent specified. Its maximum resistance at 15 turns must be 150K within the same accuracy as is desired in the use of the instrument.

(4) The standards in leg *B* are precision resistors selected to within 0.1 percent. The standards for leg *A* were worked up, in factors of ten, with the greatest of care from a base of ten one-megohm precision resistors placed in series to form a 10^{7}-ohm standard. The resistor standards to be selected for leg *A* were placed in leg *C* to be measured, and then resistors were interchanged between legs *A* and *C* to check for evidence of polarization and thermal e.m.f.'s. Since it is possible to read any given resistance with several combinations of switch positions of *S*-2 and *S*-3, a ready comparison check on the stability and accuracy of each of the standards is possible at any time.

Resistors used for standards in leg *A* are Victoreen Hi-Meg resistors. In view of the necessity of selecting standards and also because of their cost (approximately $5.00) construction of this bridge is not recommended unless one has a sizable stock from which to choose. Further, these standards may not be handled without altering their values. When constructing the instrument components must be arranged to provide minimum input capacity in the grid circuit in order to keep the time required for balance to a reasonable figure when measuring resistances above 10^{12} ohms.

The voltage coefficient of high meg resistors is a matter of some concern. An indication of this effect may be had by comparing readings with 1.5, 24, and 45 volts applied successively to the bridge. Resistor polarization may be ascertained by reading an unknown, then returning *S*-1 to position 4 and rechecking the zero as a function of time.

Work covered here was performed for the Atomic Energy Project at the Oak Ridge National Laboratory.

High Speed Electronic Scaler

W. M. Sessler and A. V. Masket
Physics Department, University of North Carolina, Chapel Hill, North Carolina

March 6, 1950

In developing a counter chronograph capable of reading time intervals of the order of 0.2 microsecond, it was found that there were few circuits in the literature capable of operating above one megacycle. One of the most promising scalers in this region had been developed by the M. I. T. Radiation Laboratory[1] using British tubes. Using the ideas presented in this circuit, such as diode "grippers," a new circuit was designed (Fig. 1) using tubes and components which were available on the commercial market. Germanium diodes were used as the diode "grippers" because of their low capacity, small physical size, and low forward resistance.

Considerable work was necessary with regard to coupling several of the stages together. In order to keep the power dissipation and number of tubes to a minimum, condenser coupling was used in preference to coupling amplifiers or cathode followers between the stages. The output signal was secured by connecting the diodes, which "grip" when the tubes are conducting, to 105 volts through resistors. The resistors were so chosen that when the diode is drawing current the plate of the diode is at 100 volts and during the no-current period is at 105 volts. This five-volt variation is coupled to the next stage through a condenser. A 1.1-microhenry choke was placed in the 120-volt supply line in order to present a high impedance path to the incoming signal.

The scalers were triggered with a 6-volt negative square wave. The square wave was secured by feeding the sine wave output of a crystal oscillator into a limiter circuit. The limiter circuit was composed of two 1N34 germanium diodes so connected that one eliminated the positive swing while the other limited the negative swing to 6 volts.

The plate, grid, and output signal wave forms are shown in Fig. 2(a), (b), (c) when the input frequency was 4.046 megacycles. Figure 2(d), (e) are wave forms of the plate and output signal at 5.8 megacycles.

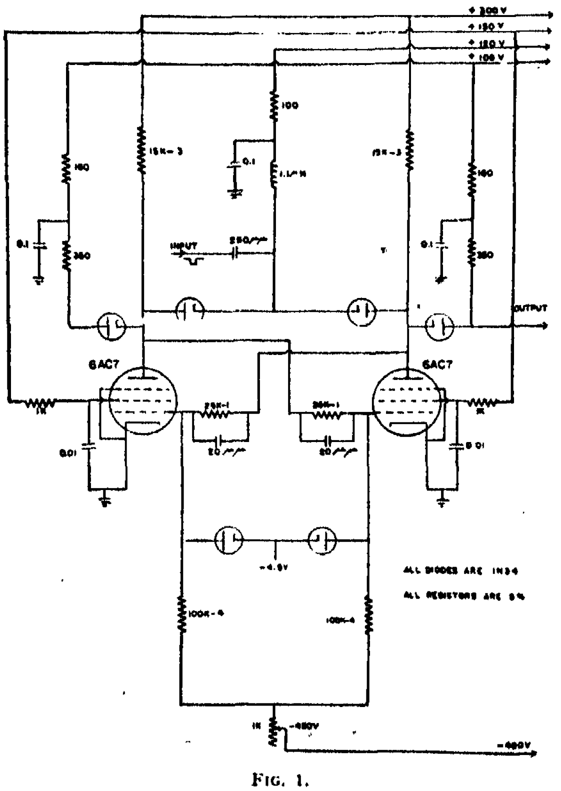

FIG. 1.

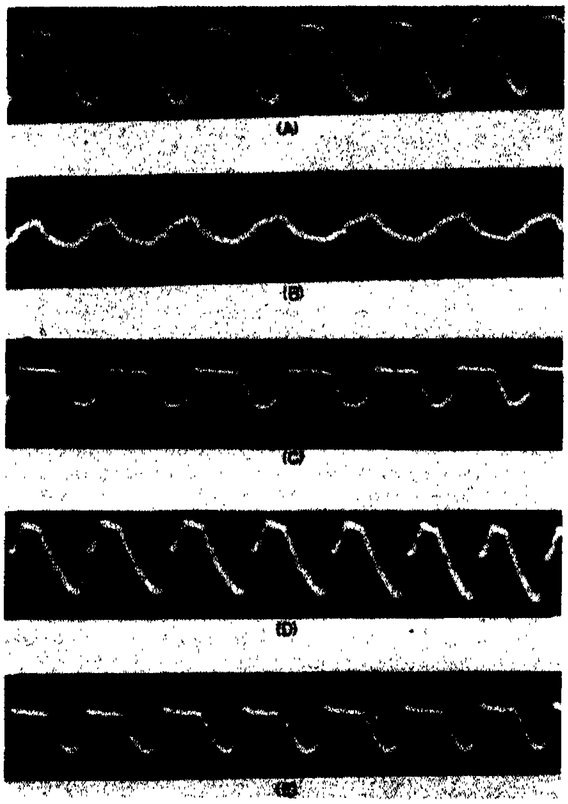

FIG. 2.

As in most high speed scalers the components were matched to within 5 percent or less. The 1000-ohm potentiometer at the bottom of the voltage divider network was provided to facilitate minor adjustments necessary due to small variations in tubes and resistors.

A New Pirani-Type Vacuum Gauge

E. Blasco and L. Miranda
High Vacuum Section of the Torres Quevedo Institute, Madrid, Spain

February 6, 1950

The following qualities are desirable for a pressure-gauge for use with a high vacuum distillation unit: simplicity of operation; pressure range from 10^{-3} to 1 mm Hg; direct-reading; ruggedness of construction; use in all types of gases; insensitivity to variations of line voltage.

A diagram of the circuit is shown in Fig. 1. The gauge is connected to the a.c. line through the half-wave selenium rectifier R, the output of which is *only partially* filtered by the condenser C^1. The purpose of C^1 will be explained later. The bridge circuit is mounted on the socket supporting the sensitive element which in turn is contained in a 16-mm diameter glass tube which may be connected with the vacuum apparatus by a standard vacuum rubber connection or clamp. The indicating galvanometer with the calibration-curve and the line switch is on a separate panel. The circuit is adjusted so that the galvanometer reads zero when the gauge is evacuated and full scale when at atmospheric pressure. Bulb dimensions are determined so that the air conductivity at 1 mm Hg will only be slightly less than atmospheric conductivity; the Pirani gauge then reaches a maximum of sensitivity in the

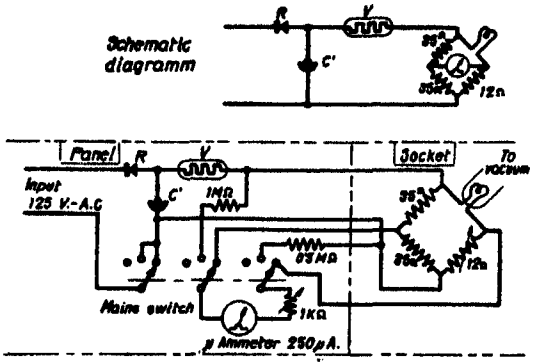

FIG. 1. Electrical connections.

10^{-3} to 10^{-1} mm Hg range. The most important problems to be solved in this type of Pirani gauge are those related to its stability in "dirty" atmospheres and its sensitivity to line voltage fluctuations.

Stability against chemical agents.—The Pirani zero-point shift when working in molecular distillation installations has been pointed out by Hickman.[1] We found the same phenomenon in the case of tungsten filaments either untreated or when covered with a tungsten hydride layer by heating in a wet hydrogen atmosphere as indicated by von Ubisch.[2] The cause of this shift as a result of which the gauge shows a tendency to read a higher pressure than that existing in the apparatus, thus indicating a decrease of temperature or resistance is probably related to the fact that the oil vapor is disintegrated when in contact with the hot wire producing a carbon deposit. As a result the specific emissive power of the filament and the accommodation coefficient (Knudsen) increases and consequently also the thermal loss, whereas the resistance simultaneously decreases due to the conducting layer by which the filament is thickened.

In order to avoid this effect we covered the filament with a fine glass capillary,[3] and worked at temperatures as low as compatible with a negligible influence of ambient temperature variations on the gauge reading. In Fig. 2 different phases of construction are shown. The filament is a tungsten spiral from a 100-watt, 110-volt lamp, with an approximate cold resistance of 8 ohms and working temperature (110°C) resistance of 12 ohms. The capillary tube is melted upon the filament while evacuating from one end in order to avoid bubbles.

All metal parts of the gauge that would be in contact with the interior atmosphere are glass covered, so that the gauge may be used with corrosive gases (excepting HF). A considerable rigidity of the assembly is obtained and the filament is insensitive to vibrations. The zero-point stability obtained by this method is very good. We did not find any appreciable shift after two years of operation in molecular distillation stills.

Of course, by introducing the glass capillary with its corresponding thermal capacity a reading delay is involved showing a small variation when different elements are used but with all of them being less than a minute and a half from the moment when the cold filament is connected till it reaches its maximum temperature corresponding to high vacuum.

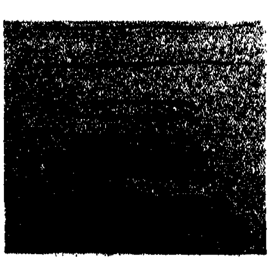

FIG. 2. Construction of the sensible filament. (a) Filament with welded terminals. (b) The same with the stuck capillary. (c) Bent filament. (d) Mounted on glass tube. (e) Complete with socket.

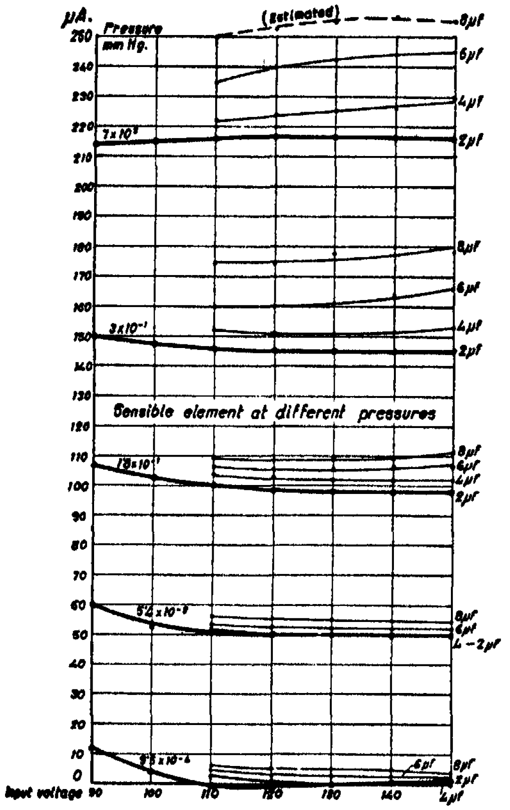

FIG. 3. Variation of μammeter indication with mains voltage.

Stability against variations of line voltage.—In order to reduce the dependence of the Pirani gauge reading on line voltage variations, a current regulating tube—Phillps C 10—(V in the diagram of Fig. 1) is connected in series with the bridge. The regulation provided by the tube is not perfect but it is improved by the effect of the incomplete filtering of supply voltage mentioned earlier.

The partially filtered current is equivalent to the sum of direct and alternating components. An increase in the direct component causes an increase in the unbalance of the galvanometer. This is partly compensated by an increase in wire temperature indicating an apparently higher vacuum, which tends to reduce the galvanometer reading. The first effect prevails over the second. On the contrary, an increase of the alternating component of the voltage is not directly registered by the measuring instrument but produces an additional heating of the wire, tending to return the galvanometer to zero. A relation can be established between the direct-current and the alternating-current components so that the increasing and decreasing effects are nearly balanced, resulting in a pressure reading which is to a certain extent independent of line voltage.

This compensating effect is not independent of gauge tube pressure. It is therefore necessary to decide at what pressure the compensation is desired, and to adjust the ratio of a.c. to d.c. current accordingly. In Fig. 3 are represented the gauge readings *versus* line voltage for different values of C^1 at five arbitrary pressures. The effect is easily seen and the value $C^1 = 2$ μf evidently gives the best compensation over the whole range. It is also seen that the higher the capacity, the lower the compensation point. With the selected value for C^1 a fairly good compensation is observed in the range 110–150 volts.

Detaching Device for Balloon Flights

Louis G. Collyer
Department of Physics, New York University, University Heights, New York, New York

August 22, 1949

WHILE conducting cosmic-ray balloon flights it was found to be necessary to terminate the flight after a given time in order to control the overland distance within reason. The most effective means to do this was found by detaching enough balloons from the flight so that the total lift of remaining string is less than the load carried.

In order to effect this detaching, many ways were tried, using heated wires which burned off a cord; squibs to break the cord; spring operated knives and so forth. All were found very uncertain.

The device described herein was found to work without fail. It consisted of a frame carrying a hook and a positive lock for same. A certain number of balloons, say three or four, carried the device with a ring on the hook connected to the rest of the flight below. The actuating device consists of an alarm clock which is set for the number of hours required for the flight to be air-borne. When the alarm trips, the turning of the winding key turns the eccentric and unlocks the hook releasing the mechanism and balloons from the rest of the flight.

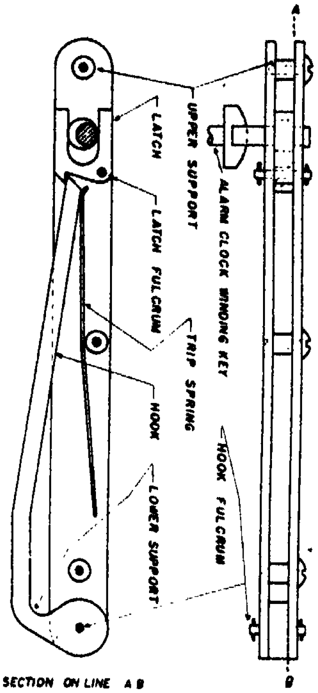

FIG. 1

The locking is very important because tripping too soon would be a serious matter especially over a city. The latch is positive and the lift of the upper balloons has no tendency to unlock it.

Very little machining is necessary and, except for the eccentric, all the work can be done with a saw and drill.

The only uncertainty found was in the clock itself. This uncertainty was found to be caused by the effect of extreme cold on the lubricant used. This may be overcome by washing out all the oil and relubricating by means of graphite or the use of the new molybdenum sulfite lubricants.

Figure 1 is self-explanatory. This device was used successfully in a number of flights in Denver, Colorado; San Juan, Puerto Rico; Bethlehem, Pennsylvania and elsewhere.

Suppressing Mercury Vapor in Vacuum Systems*

Frederick Ayer II
Physics Department, New York University, University Heights, New York, New York

February 27, 1950

IT is sometimes necessary to exclude mercury vapor from vacuum systems which are designed to operate at any pressure between atmospheric and 10^{-4} cm Hg. In such a system, the most convenient combination of pressure measuring instruments is a mercury manometer for pressures down to about two millimeters, coupled with some other device such as a vacuum thermocouple.

Mercury vapor may then be prevented from diffusing from the manometer into the system by floating a layer of some low vapor-pressure oil of the Apiezon "*B*" type on the mercury surface, to a depth of perhaps three centimeters. If the oil is placed in one arm of the manometer only, it will of course cause a lowering of the mercury column. In cases where determination of the absolute pressure in a system is necessary, equal amounts of oil may be floated on both mercury surfaces. However, where the system is being used as a means for filling evacuated vessels with certain gases, oil need be placed only in one arm of the manometer since the difference in level of the mercury column before and after admitting the gas indicates the pressure introduced.

If left to itself without continuous pumping, the system will contain, at equilibrium, both mercury and oil vapors, but as the rate of diffusion of mercury vapor through the oil layer is very slow, its concentration will be greatly lowered when the system is evacuated by large-capacity pumps. Such an arrangement is called a "kinetic system" by Strong.[1] If desired, additional "getters" of gold foil may be placed at those points in the system farthest removed from the pumps. It is assumed, of course, that the system is supplied with liquid-air traps if mercury vapor diffusion pumps are used. It may be argued that an equivalent result may be arrived at by mere substitution of closed-end oil manometers for mercury manometers, but the slowness of response of the former makes pressure readings time-consuming.

A word of caution is necessary. Many gases dissolve in Apiezon "*B*" and similar oils, and if a system is left for a time with an appreciable internal pressure, the oil will boil during evacuation, causing it to spill over into the system proper. The remedy lies in slow evacuation so that long columns of froth do not form, or breaking up the bubbles which do form by running a sparking leak tester up and down the manometer tube at the froth level.

Boron trifluoride tends to darken Apiezon "*B*" in time, but this effect may be minimized by evacuating the system after each use. Furthermore, although the oil reacts slowly with the mercury, the dirty surface does not diminish reading accuracy to any important extent for a long time.

Other investigators in this laboratory have made use of this suggestion and report that with it pressures as low as 10^{-7} cm Hg can be attained in much shorter times than when the mercury column is not sealed off.

A Metal Dewar for Liquid Helium

Warren E. Henry and Richard L. Dolecek
Naval Research Laboratory, Washington, D. C.

January 30, 1950

EFFICIENT utilization of space is of prime importance in Dewar design for cryomagnetic research where the available working space is restricted by magnet pole separation or solenoid opening. Metal Dewars can be designed for efficient utilization of space. In addition, they are durable, are convenient to manipulate because of one-piece construction, and offer the opportunity of design for electrostatic and magnetic shielding where required.

Metal Dewars have been constructed for use in solenoids of the "Bitter"[1] type having openings 1¼ inches and 4 inches in diameter. A longitudinal cross section of the Dewar constructed for use in the 1¼-inch magnet is given in Fig. 1. A maximum working space (*A*) in the liquid helium is achieved by the use of a common insulating vacuum (*C*) for the helium and nitrogen Dewars, and a radiation shield (*R*) cooled by conduction to the liquid nitrogen vessel (*B*). Axial symmetry is maintained at the top by the perforated annular ring (*S*) and at the bottom by mica spacers (*M*) designed to minimize heat conduction. Stainless steel was used in the construction of the upper portions of the Dewar and to minimize field distortion, non-magnetic materials were used for the cylinders surrounding the working space (*A*). Thus, the lower section of the helium vessel and the outer cylinder were constructed of $\frac{1}{32}$-inch non-magnetic brass, and $\frac{1}{16}$-inch copper was used for the radiation shield (*R*). These cylinders were spaced $\frac{1}{16}$ inch apart. To facilitate assembly both silver soldered and soft soldered joints were employed. For an over-all diameter of $1\frac{1}{16}$ inch, this design yields a $\frac{9}{16}$-inch working space.

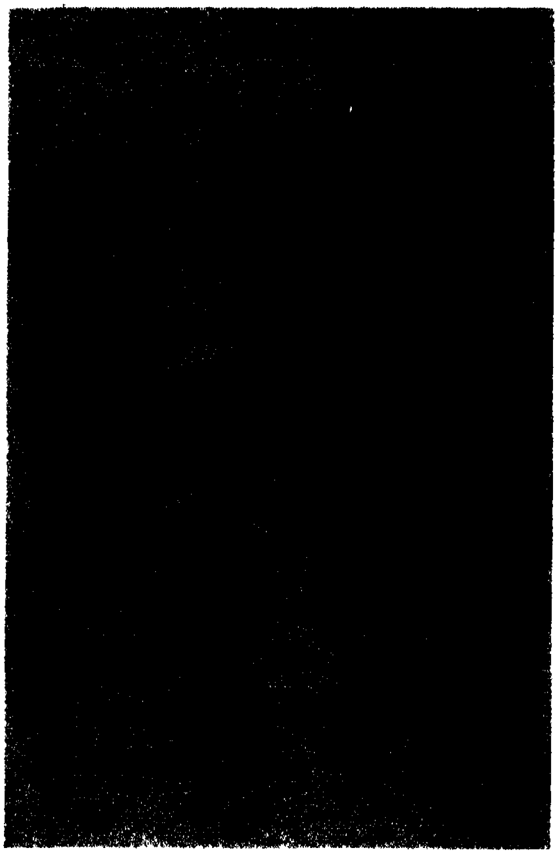

FIG. 1. Metal Dewar for use in "Bitter" type solenoid having 1¼-inch opening.

The Dewar is prepared for use by flushing with dry nitrogen, and to allow rapid precooling[2] of the helium Dewar and sample, only a partial vacuum of the order of 25 microns is established before closing a metal valve soldered to *V*.

The Dewars have proved entirely satisfactory for use in both the helium I and helium II regions. The heat leak at 4.2°K is of the order of 50 cc of liquid helium per hour. As the reservoir has a capacity of approximately one liter, considerable time is available for conducting an experimental investigation.

Power Supply for the Cenco Concentrated-Arc Lamp

JAMES M. MITCHELL
California Institute of Technology, Pasadena, California
March 13, 1950

IN using a Cenco* concentrated-arc lamp with the conventional power supply, it is necessary to hold the starting switch until the lamp fires and then to release the switch upon starting. If the switch, which supplies the high voltage required to initiate the arc, is not released quickly, the high voltage will damage the lamp. In particular applications using the lamp in enclosed spaces where it is impossible to observe when it has started, the conventional power supplies are not satisfactory. Also, in student laboratories where these lamps are used, many are damaged when the power supply is not operated correctly. To eliminate this starting trouble, the power supply shown (Fig. 1) was designed.

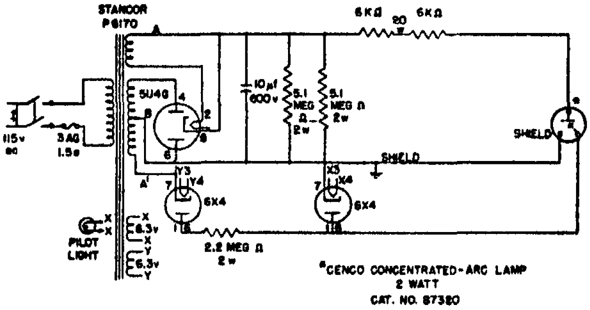

FIG. 1.

The design of this power supply is based on the high impedance of the arc lamp before it has started and the low impedance after starting. The power supply acts as half-wave rectifier across the transformer (*A*–*A*′) when no current is drawn by the circuit. However, as soon as the circuit draws current, the power supply becomes a full wave rectifier with the voltage across the center tap of the transformer (*A*–*B*). The two diodes are used to prevent a closed circuit across the lower half of the transformer (*A*′–*B*).

The values shown in the circuit diagram are for use with the Cenco 2-watt concentrated-arc lamp. However, by suitable choice of values, the circuit is satisfactory for other lamps. Also, the circuit has been used in other applications requiring a high starting d.c. voltage and a lower operating voltage.

Precision Selector for Voltage-Regulator Tubes

O. B. RUDOLPH
Carbide and Carbon Chemicals Division, Union Carbide and Carbon Corporation, Oak Ridge, Tennessee
February 6, 1950

VOLTAGE regulation, or the elimination of the ripple voltages from a.c. rectified sources, has achieved such widespread usage that one often thinks of it as a simple procedure. (The term "ripple" as used here embraces transients of not only 60 and 120 cycles, but any frequency that might be reflected in the output of the d.c. supply.) Indeed, laboratory set-ups have been made that give regulated d.c. supplies with extremely low ripple voltages; but these circuits are frequently too cumbersome to be used widely in industrial applications.

The increased usage of d.c. voltages in industrial equipment has resulted in the designing of special regulating (VR) tubes to meet most requirements; however, where an unusually constant voltage is desired, careful tube selection is necessary as tubes vary noticeably in their operating characteristics. This article presents

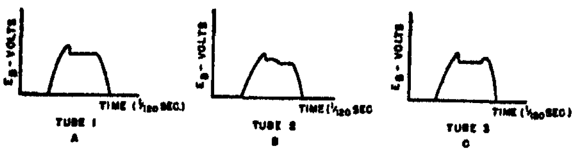

FIG. 1. Various oscilloscope traces obtained.

a simple circuit for predetermining the reliability of VR tube performance.

Since the function of a VR tube is that of an automatic variable resistor which changes its internal resistance to steadily maintain a fixed voltage drop across its two terminals within its rated current range, failure of the tube to function properly will be reflected in the action of the regulator. Particularly where the regulation network output is to be amplified, small transient variations in VR tube action cause difficulty.

Ideally, the voltage drop across the VR tube is constant throughout its rated current range; however, by employing highly sensitive laboratory-type instruments, it has been shown that in any group of tubes chosen at random, many do not give a uniform regulating characteristic. Instead, small transients caused by line variations or other reasons resulted in changes in voltage drop across the tube with consequent changes in regulated output (Fig. 1A, B, C). These results are virtually independent of tube age, and new tubes are sometimes among the worst offenders.

Thus to properly test VR tubes, it is necessary to examine each tube over its entire operating current range, while employing a sensitive detecting device to indicate voltage variations.

The tube selector circuit developed is shown in Fig. 2. By throwing the double-pole, double-throw switch S_1 to position 2, a well-filtered d.c. output will be obtained which can be used for preheating the tube undergoing test if desired and also for checking firing voltage which will be indicated on meter M_2. With switch S_1 in position 1, pulsating d.c. voltage will be applied to the tube for precision checking of the over-all voltage-current characteristic. Since meter M_1 will indicate R.M.S. value of current, care will need to be exercised to prevent the peak value of the current from exceeding 40 ma; current can be adjusted to proper value by potentiometer R_1.

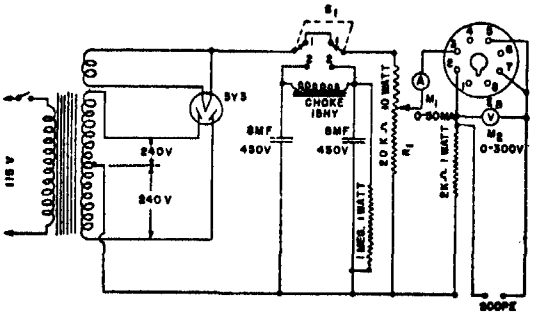

FIG. 2. VR tube selector-elementary diagram.

Shown in Fig. 1A, B, and C are three of the various types of oscilloscope traces which have been obtained from different tubes. "*A*" is ideal and the only one acceptable for many applications.

This "Precision Selector" circuit is very simple. It can be set up in the research laboratory or in industrial servicing shops in a matter of minutes after construction of the individual units; and furthermore, these units need not be "tied down" to this specific use. Pretested VR tubes may be kept on hand for replacements with certain knowledge that each will perform acceptably.

This report is based on research carried out under contract for the AEC, the Isotope Research and Production Division at the Carbide and Carbon Chemicals Division, Union Carbide and Carbon Corporation, Y-12 Plant, Oak Ridge, Tennessee.

The Use of Secondary Electrostatic Focusing in a Magnetic Beta-Ray Spectrograph

R. D. Hill, J. W. Mihelich, and M. T. Pigott
Physics Department, University of Illinois, Urbana, Illinois*
February 27, 1950

In order to detect low intensity conversion lines with a magnetic, 180° focusing, photographic beta-ray spectrograph, our experience is that exposures of many weeks duration are often required. The purpose of this note is to describe a modified spectrograph using secondary electrostatic focusing which reduces the exposure time for conversion lines of the order 100-kev energy by a considerable factor.

A plan of the modified spectrograph insert is shown in Fig. 1. This insert is placed in the field of a permanent magnet so that electrons describe circular orbits and exhibit the well-known 180° first-order magnetic focusing. In addition, a certain amount of focusing in a plane perpendicular to the orbital plane is achieved by the electrostatic lens placed directly across the electron orbits, as is shown in Fig. 1.

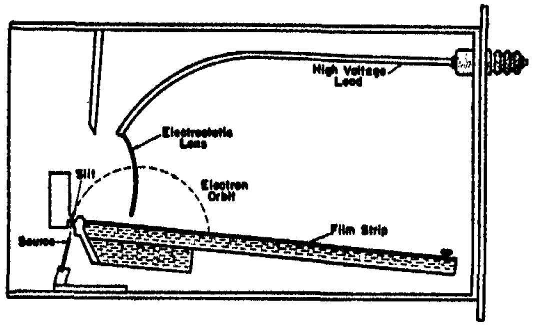

FIG. 1. Focusing insert for 180° beta-ray spectrograph.

We have experimented, using both empirical and ray-tracing methods, with a number of simple forms of electrostatic lenses. Thus far, best results have been obtained with a plane grid of five $\frac{1}{32}$-inch diameter wires, arranged one above the other, and approximately 0.2 inch apart and from the top and bottom plates of the insert. The grid wires were maintained at a constant positive potential with respect to the insert walls. The plane of the grid was placed tentatively at the correct focal distance from the photographic plate for electrons following the 100-kev trajectory, and it was then bent into an arc which was approximately perpendicular to the other electron trajectories. Experimentally, it was found that the maximum grid potential was determined by vacuum conditions in the spectrograph. We were able to attain a potential of only 8 kv, beyond which potential there was a risk of an occasional discharge fogging the photographic film.

The effectiveness of the electrostatic focusing may be appreciated by referring to Table I, where photographic densities of the same 90-kev Ta^{182} line are given for four equal-duration exposures using different focusing potentials. It is clear that at 7 kv the effective intensity of the line is about four times greater than that at zero potential. In actual practice, if a source which decays appreciably during a long exposure is used, the increase of intensity may be even higher than a factor of four. There appears

TABLE I. Photographic densities and intensities of 90-kev Ta^{182} at four focusing potentials.

Focusing potential (kv)	zero	2	5	7
Line density	0.61	0.82	1.00	1.15
Background density	0.43	0.46	0.51	0.58
Line density above background	0.18	0.36	0.49	0.57
Relative line intensity[a] above background	1.0	2.1	3.3	4.4

[a] The intensities were derived from an intensity-density calibration of the photographic emulsion.

to be a further advantage of focusing. As will be seen from Table I, the background for the line does not increase with focusing voltage at as high a rate as does the line intensity. The background is due to both continuous beta-rays and scattered electrons, and it is likely that the scattering from top and bottom plates of the insert is being reduced by focusing of the electrons.

* The work was supported in part by the joint program of AEC and ONR.

A Convenient Cell-Stage for Fluid Profile Measurements

WILLIAM FOX
*U. S. Department of the Interior, Bureau of Mines, Bartlesville, Oklahoma**

February 20, 1950

THE practical utility of profile measurements which permit the determination of contact angles at the mutual line of contact of the interfaces of solid-liquid-gas systems has been demonstrated in the field of flotation.

Although the importance of such measurements has been realized, difficulties which had previously been encountered in making determinations of contact angles through liquid-liquid-gas systems have hindered the use of these constants for an understanding of the wetting and spreading phenomena of such systems.

In the last few years, methods have been described for making direct measurements of the contact angles through mutually saturated three-phase fluid systems.[1,2]

From these measurements the wetting and spreading tendencies of each of the three fluid phases under consideration can be determined. These determinations are important in many practical problems, including those which are involved in the recovery of petroleum.[3]

For use in these investigations a cell-stage of the type shown in Fig. 1 (a) is convenient.

This apparatus is similar to one described[4] for use in flotation experiments. The cell-stage shown in Fig. 1 is a more compact unit than that previously described and can be constructed easily. Details of the construction can be noted from Figs. 1 (b) and 1 (c).

㉑ Vertical Rod Support Aluminum - 1 Req.

FIG. 1 (c).

the cell support (1). The cell is held in place by the cell-holders (2) on opposite sides of the circular hole. The cell platform is replaceable, and a larger platform can be mounted on the support to accommodate a thermostat of the type described by Hauser *et al.*,[5] into which the observation cell can be placed conveniently.

Adjustment screw (4) permits vertical adjustment of the cell support, which can also be rotated by (5) on the pivots (8) for angular adjustment.

The base (6) on which the cell support is mounted is adjustable by (9) so that the observation cell can be moved horizontally across the optical axis of the camera.

The clamp (20) is used to hold a glass tube in place in the observation cell. This clamp can be adjusted vertically on the rod support (21) by the vertical adjustment (19). This part of the cell-stage can be moved as a unit parallel to the optical axis of the camera by (16) and perpendicular to the optical axis by (12).

The cell-stage is mounted on the optical bench by (13) and held in place by clamp screw (10). This part of the unit can be modified to fit on any type of optical bed that is available. If the cell-stage is mounted on a base that can be adjusted by leveling screws, the pivots and the screw which permit angular adjustment of the cell support can be eliminated.

Details of the photographic equipment and necessary procedures for securing profiles from which measurements of equilibrium contact angles can be made have been described.[1,2]

The author wishes to thank Mrs. Joanne M. Grindstaff of the Bureau of Mines drafting department for making the drawings, and John O. Greenwalt of the Bureau of Mines machine shop for constructing the apparatus.

A Method of Preserving Specimen Grids for Electron Microscopy

JENNIE E. SHAPIRO
Biology Department, Brooklyn College, Brooklyn, New York

March 8, 1950

FREQUENTLY specimen grids prepared for electron microscopy must be used repeatedly or subjected to more than one process in preparation. This poses the problem of storing and filing, in the interim periods, in an easily accessible manner. The method, described here and illustrated in Fig. 1 has been found to be efficient in repetitive handling. In addition to maintaining the grids in excellent condition, specimen side uppermost, the material is in a form which is readily available for preliminary study with the light microscope. Moreover, it may be stored for future reference in an ordinary slide box.

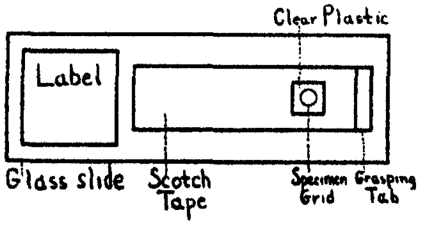

FIG. 1

The grid to be preserved is placed specimen side up on a clean glass microscope slide. A one-quarter inch square of clear plastic or celluloid (approximately the thickness of a No. 2 coverslip) is placed directly above it to protect its surface. The whole preparation is then sealed to the slide with a strip of clear cellulose Scotch Tape, one end of which is folded under to act as a grasping tab for subsequent removal. The specimen is now housed in a small chamber one surface of which is glass, the other clear plastic or celluloid. Specimens prepared in this way can be examined with the light microscope through both the Scotch Tape and plastic which function as coverslips. On peeling the Scotch Tape from the slide, the plastic cover which adheres thereto is raised and the grid with specimen side up is freed for further use.

New Instruments

W. A. Wildhack: Associate Editor
in Charge of this Section
National Bureau of Standards, Washington, D. C.

These descriptions are based on information supplied by the manufacturer in some cases from independent sources. THE REVIEW *assumes no responsibility for their correctness.*

Pulse Generator

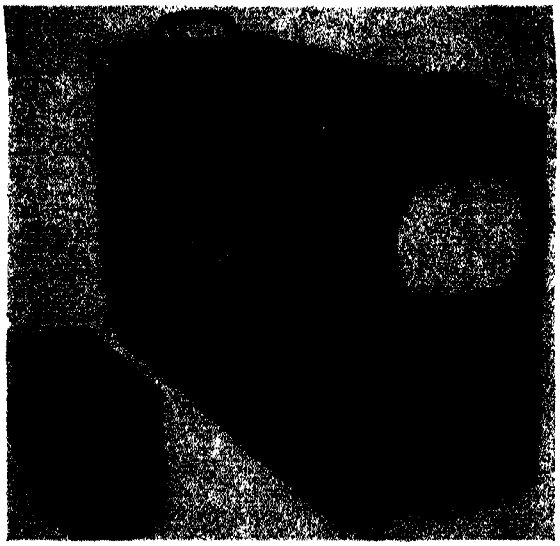
Model 212A, a new general purpose instrument, is the first commercial pulse generator to successfully combine broad laboratory usefulness with fast rise time, high power, continuously variable pulse width and other features demanded in radar, television, and nuclear work.

Among the outstanding features of the new instrument are the unusually fast pulse rise and decay time (0.02 μsec.), the high power (50 watts) pulse, and a continuously variable pulse length, 0.07 to 10 μsec. A low internal impedance of 50 ohms or less insures a pulse shape virtually independent of load. This low impedance also makes it possible to deliver accurate pulses at some distance from the instrument if transmission lines are properly terminated.

The instrument has a repetition rate (frequency) continuously variable from 50 to 5000 pulses per second, and pulse rate can be controlled internally, or from an external synchronizing source. Continuously variable synchronization pulses are available either in advance or following the main pulse. An amplifier-attenuator system is provided with low source impedance, making possible either positive or negative pulses with continuously variable amplitude.—HEWLETT-PACKARD COMPANY, *395 Page Mill Road, Palo Alto, California.*

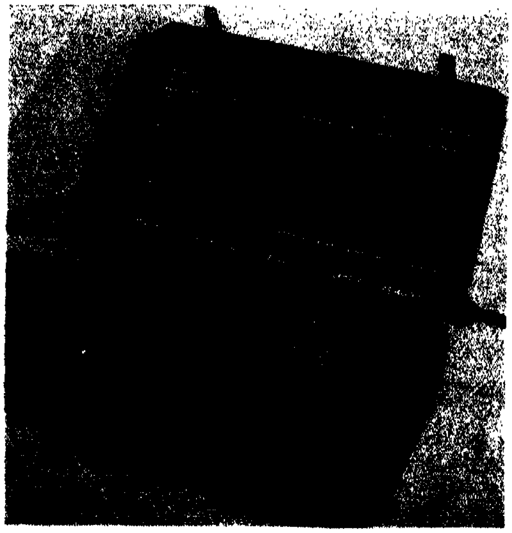
Industrial Television

The small size and weight of this new wired television equipment is chiefly due to the use of a miniature pick-up tube, only 1 in. in diameter and 6 in. long. This tube represents a departure in pick-up tube design in that it operates on the principle of photoconductivity, while the image orthicon and other current pick-up tubes in general employ photo-emissive cells. The camera is as small as the average 16-mm movie camera and is designed to employ regular 16-mm lenses with the standard Type C mount. It weighs 8 lb., is 10 in. long, 5 in. high, 3 in. wide, and requires a scene brightness of 2 foot-lamberts minimum. The Control Monitor contains a 7-in. viewing screen as well as all controls, both for itself and for the camera. Three knobs control the operation of the Monitor itself: (1) brightness, (2) contrast, and (3) blanking (black level). And three controls for the camera are also included on the Monitor panel: (1) beam intensity, (2) electronic focus, and (3) optical focus. The optical focus controls a small reversible motor in the camera which changes the focus of the lens. The Monitor weighs 58 lb. and is 26½ in. long, 17 in. high, and 8½ in. wide. It also has provision for plugging in additional television receivers, and since the scanning frequency and interlacing are the same as that employed for broadcast television, it is possible to use regular broadcast receivers as additional monitors by merely adding a one-tube amplifier. The connecting cable permits the Monitor to be located up to 250 ft. from the camera and greater distances can be covered by use of slave monitors or booster amplifiers. Power requirements are 375 watts at 110 volts, 60 cycles.—RADIO CORPORATION OF AMERICA, *Camden, New Jersey.*



Minature Seismograph

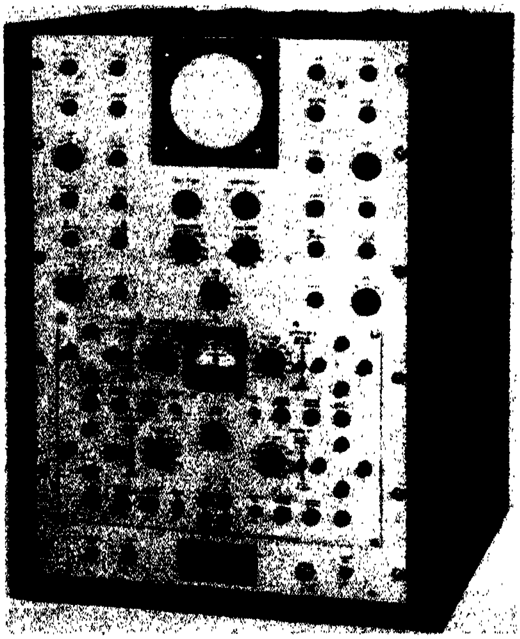
This unit, Type PSU-11, is designed around the GA-11 amplifier, which features performance equal to or better than many of the old type standard amplifiers. The waterproof amplifier case pictured measures 6×13×21 in., weighs approximately 35 lb., and contains twelve Type GA-11 amplifiers plus the control unit. The amplifiers have a gain of 120 db and no preamplifiers are necessary; the AGC operates over an unusually wide range, thus preventing distortion from high input levels. The initial suppression is individually adjustable, and filter selectors are also provided. The amplifiers are of the plug-in type, and no soldering is necessary to replace them in the field. The oscillograph makes 25 traces on 6-in. paper and has barrel-type,



electromagnetically damped galvanometers, a viewing screen, a built-in timing system, removable take-up magazine, built-in paper knife, a governor controlled cranking motor, and dimensions of 8×9×16 in. with a weight of approximately 25 lb.—SOUTHWESTERN INDUSTRIAL ELECTRONIC COMPANY, *P. O. Box 13058, Houston 19, Texas.*

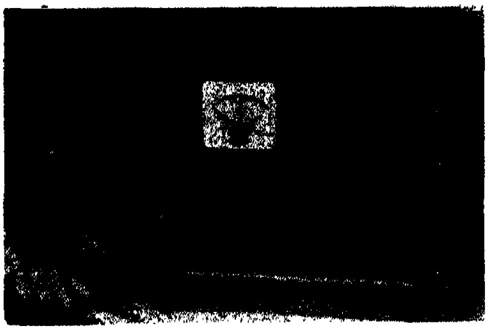
H-42 Strainalyzer

The Strainalyzer is designed for d.c. bridge excitation from self-contained batteries and has the necessary high gain d.c. amplifiers, balance controls, and voltage and calibration controls for each strain gauge bridge channel. The instrument can be used with Baldwin SR-4 strain gauges of either the "A" or "C" type from 60 to 500 ohms and will give excellent linear response. A four-gun cathode-ray tube makes possible the simultaneous observation and recording of electronic traces of four functions in correct time relationship without the necessity of optical alignment. The Strainalyzer is composed of four units: the indicator (illustrated), the indicator power supply, the camera, and the camera speed control. The strain gauge bridge control panel is a removable plug-in unit, and four binding post terminals are provided for each bridge, making all four arms available to allow use of one to four active gauges. Deflection sensitivity is better than 0.002 volt d.c. per in., maximum undistorted deflection is 3 in. peak to peak, and the input is single-ended, capacitive, and has an impedance of 10,000 ohms shunted by 40 $\mu\mu f$. The apparatus weighs approximately 200 lb. and will draw 400 watts at 105–125 volts, 50–60 cycles.—ELECTRONIC TUBE CORPORATION, *1200 East Mermaid Lane, Philadelphia 18, Pennsylvania.*



Ionization Gauge

The DPA-38 ionization gauge control circuit is a direct-reading vacuum gauge capable of measuring pressures from 10^{-3} mm Hg on into the 10^{-9} region. It has a voltage-regulated power supply and a two-stage automatic grid control, which has been provided to operate throughout the full life of the DPi VG-1A ion tube. The control circuit automatically shuts off the ion tube whenever the pressure rises above 1.2 times full-scale deflection, and it operates on all of the various ranges. An unusual feature of the DPA-38 is that it permits continuous pressure readings during the degassing of the ion tube. Readings are remarkably easy to make because the decimal negative exponent is read on the range selector and the coefficient is read on the dial gauge. The instrument can be adapted to operate in conjunction with a recording unit, and it draws 175 watts from a 110-volt, 60-cycle line.—DISTILLATION PRODUCTS INDUSTRIES, *Rochester 3, New York.*

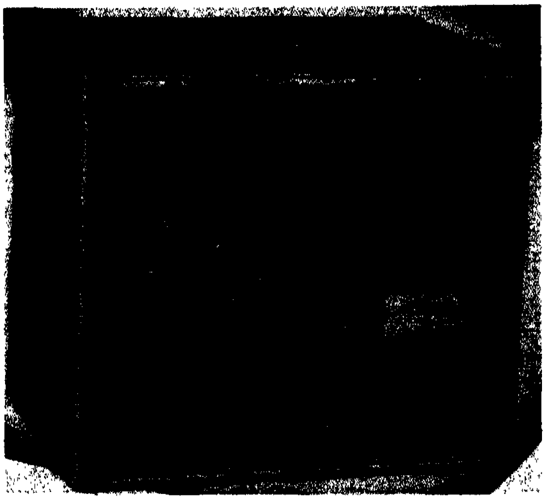


All-Purpose Scaler

Geiger, proportional, or scintillation counting can be accomplished with the Ultra-Scaler by either automatic or manual methods. Facilities for every type of counting are thus included within one instrument.

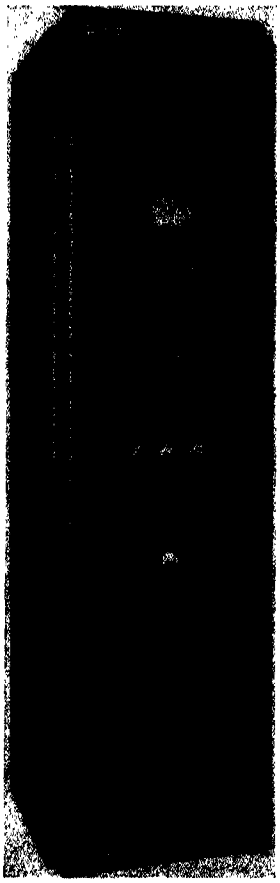
A built-in timer is provided which may be set for a predetermined length of time and will then turn off the scaling unit automatically. The instrument may also be set for a predetermined number of counts, and the scaling unit will stop at that number of counts and indicate the time on the timer. In addition, a number of features are provided so that the instrument may be operated manually or used for monitoring purposes with a suitable probe.

The Ultra-Scaler incorporates two inputs, one for Geiger pulses and the other for very small proportional pulses requiring linear amplification. The fast Higinbotham-type scale of 128 has a resolution time of only two microseconds. Scale selection is provided to permit the use of smaller scaling factors. Stabilized high voltage is available up to 2500 volts, and a built-in register indicates the total number of counts. A special time delay prevents overvoltage surge on the Geiger tube when the instrument is first turned on.—NUCLEAR INSTRUMENT AND CHEMICAL CORPORATION, *229 West Erie Street, Chicago, Illinois.*



Spectrum Analyzer

The Model LSA spectrum analyzer is a laboratory instrument used to provide a visual indication of the frequency distribution of energy in an r-f signal in the range of 10 to 16,520 mc. Three tuning units cover the bands from 10 to 1000, 940 to 4500, and 4460 to 16,520 mc, with 5-kc resolution at all frequencies. This instrument features continuous, single-dial tuning with direct reading frequency accuracy of one percent, and frequency dispersion can be varied from 250 kc to 25 mc. A frequency marker is provided to measure frequency difference from 0 to 25 mc. The microwave tuning units incorporate broad-band attenuators and use the latest design non-contacting shorts to insure long mechanical life. A 5-in. CRT display unit, a klystron power unit, and a low voltage power unit constitute the remainder of the equipment.—POLARAD ELECTRONICS CORPORATION, *100 Metropolitan Avenue, Brooklyn 11, New York.*



Infra-Red Spectrophotometer

A new double-beam infra-red spectrophotometer, known as the Model 21, with a wider range of operating variables than earlier commercial models, is the first infra-red spectrophotometer that meets the demands of the structural chemist for high resolution and sensitivity and those of the analytical chemist for speed and accuracy.

The Model 21 records directly in percent transmission against a linear wave-length scale on large, easily read charts. Use for this versatile instrument may be found in practically every application of infra-red spectrometry in both academic and industrial laboratories.

The new instrument's resolution is up to the limitations imposed by the Raleigh criterion and Johnson noise. Its speed of scanning ranges from 3 min. to 100 hr. for the rocksalt region. The wavelength drive speed can be suppressed automatically when desired. Time of response varies from a few seconds to more than a minute for full-scale deflections. The over-all range of the instrument is from less than 2 to 15μ in the rocksalt region.

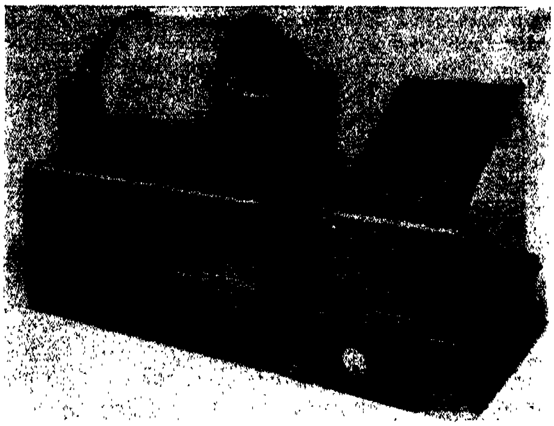


Chart scales of the Model 21 are uniform from 1 to 50 in. per micron by integral factors. The chart size is about 32 by 11 in. The instrument is 40 in. long, 22 in. high, and 20 in. wide. The amplifiers and power supplies are external.—THE PERKIN-ELMER CORPORATION, *Glenbrook, Connecticut.*

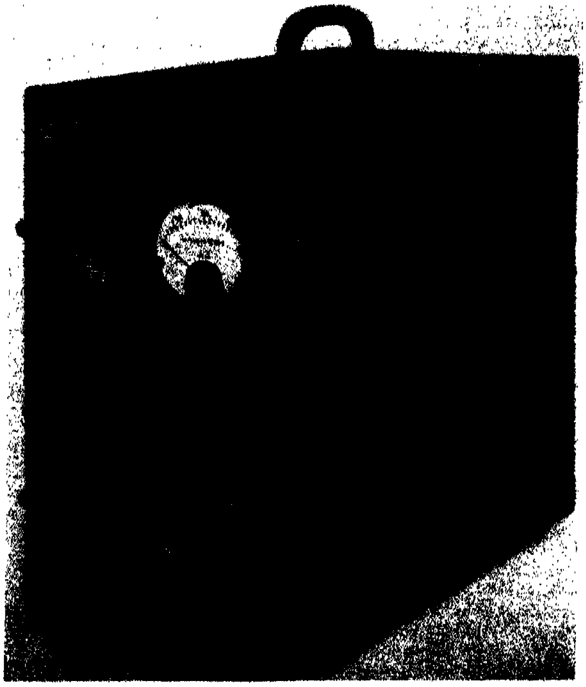
Pulse Rise Time Indicator

The Model 632-B pulse rise time indicator is an instrument for the accurate plotting of the rise time of rapidly rising positive voltage pulses. The device employs a specially designed delay line of variable length and a vacuum tube voltmeter. The VTVM reads the peak of the resultant pulse produced by the pulse under test and its reflection; its magnitude is a function of the rise time and the delay of the line. When the delay (total time of propagation) is less than the rise time, the resultant pulse amplitude will be smaller than that of the impressed



wave; when the delay of the line is equal to the build-up time of the pulse, the VTVM reading will have reached a maximum. Thus the calibrated line is a measure of the rise time and may be used to plot the leading edge. The instrument is also applicable to conditions requiring a shorted variable delay line which will fall into the steps and frequency (*Zo*=50 ohms, *Wc*=160 mc) of this model. An example—a stub tuner.

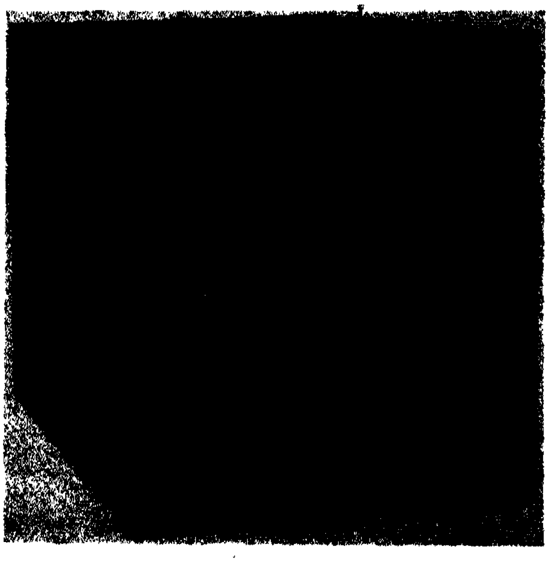
Specifications: Rise time —0.005 μsec. to 0.1 μsec. in 20 steps. Pulse repetition rate and allowable source impedance—from 30 to 100 ohms, up to 1 mc—from 100 to 200 ohms, up to 0.25 mc—from 200 to 300 ohms, up to 100 kc; voltage sensitivity—positive peak pulses from 1 to 200 volts; accuracy—a maximum error of ±0.005 μsec; weight and dimensions—under 75 lb.—16×12×7 in.; 110 volts—60 cycles 60 watts.

The controls include an on-off switch, zero set and sensitivity selector, speed and direction controls for varying the length of line, and an indicator denoting delay of line.

The 632-B thus features a radical change in the method of analyzing the build-up time of a pulse. However, the most important factor is the range available: 0.005 to 0.1 μsec. in 20 steps. Unaffected by time or voltage jitter, the instrument removes the approximate results obtained from expensive instruments and time consuming set-ups, by giving accurate results in a matter of seconds. Available in other ranges upon request.—ELECTRONIC SYSTEMS COMPANY, *555 East Tremont Avenue, New York 57, New York.*

VHF Signal Generator The Model 608A VHF signal generator (10 to 500 mc) has a master oscillator power amplifier circuit and a directly calibrated output from 0.1 μv to 1.0 v for measuring gain, selectivity, sensitivity or image rejection of receivers, i.f. amplifiers, broad-band amplifiers or other VHF equipment. The 1-v output (into a 50-ohm load) is useful over the entire frequency range for driving bridges, slotted lines, antennas, filter networks, etc. The output circuit is directly calibrated in volts and decibels for fast reading. No charts are necessary.

On this new instrument, frequencies from 10 to 500 mc are covered in five bands, calibrated directly in megacycles on a drum-type dial having effective scale length of 90 in. A single-dial, ball-bearing frequency control insures maximum convenience and accuracy in tuning and resetting. The instrument also offers microsecond pulses, wide modulation capabilities, small residual f-m, and has CW, a-m, or pulsed output.



The master oscillator and power amplifier circuits are enclosed in a heavy cast aluminum shield, insuring high stability and minimum electrical leakage. The instrument will sell for $850.00.

A new impedance-measuring VHF bridge, Model 803A (50 to 500 mc) and its companion instrument, the Model 417A VHF detector, are additional components of this line of precision VHF equipment. The bridge determines impedance by sampling the magnetic and electric fields of a transmission line. Phase is measured by determining the point of cancellation of these samples along a second transmission line. This method effectively overcomes the narrow frequency limitations of conventional bridge configurations.

This new instrument offers direct impedance readings from 2 to 2000 ohms. Its primary frequency range is 50 to 500 mc, but it is useful at frequencies up to 1000 mc and down to 5 mc. It can be used for any type of VHF impedance measurement, determining characteristics of transmission lines, antennas, r-f chokes and condensers, connector impedances, standing wave ratios, percentage of reflected power, VHF system flatness, etc. The bridge is priced at $495.00.

The detector is essentially a super-regenerative a-m receiver covering all frequencies between 10 and 500 mc. It offers high sensitivity, quick easy operation, and the customary -hp- direct-reading frequency control. It is thoroughly shielded and suitable for general laboratory work including approximate frequency checks, noise and interference measurement, etc. The detector will sell for $200.00.—HEWLETT-PACKARD COMPANY, *395 Page Mill Road, Palo Alto, California.*

Manufacturers' Literature

Millivolt Meter—Technical Report TR-21, 8 pp., describes instrument for high impedance measurements above 5 mc. Crystal rectifiers are used as "pseudo-thermocouples," combined with a high impedance vacuum tube millivoltmeter for d.c., to make measurements at lower levels than possible with ordinary heater-type thermocouples.—MILLIVAC INSTRUMENTS, *P. O. Box 3027, New Haven, Connecticut.*

Electric Instruments—A new, revised edition of General Electric's "Manual of Electric Instruments" (GET-1087A) describes the fundamentals of construction and operating principles of all major types of electric instruments. Manual is 150 pp., extensively illustrated by photographs and diagrams, and includes a full reference index. Priced at $1.00 per copy.—GENERAL ELECTRIC COMPANY, *Schenectady 5, New York.*

Phototransistor—Press release dated March 30, 1950, announces an entirely new type of "electric eye"—much smaller and sturdier than present photoelectric cells. The sensitive element is a germanium disk with a dimple ground into one side, and the entire apparatus is housed in a tiny cylinder about as large as a .22 caliber rifle cartridge.—BELL TELEPHONE LABORATORIES, *463 West Street, New York 14, New York.*

Spectro Computer—Bulletin 278 describes the Phillips 66 spectro computer, which solves simultaneous linear equations of the type encountered in infra-red and mass spectrometry. This computer, which makes use of d.c. potentials substituted for the unknowns in the equations, solves these equations by a method of iteration. Multiplication, division, addition, and subtraction steps necessary in solving as many as ten simultaneous equations can normally be performed by the computer within 5 to 30 min. Results of spectrographic analysis of hydrocarbon samples have been computed to an accuracy of 0.1 percent with this instrument.—PHILLIPS PETROLEUM COMPANY, SPECIAL PRODUCTS DIVISION, *Bartlesville, Oklahoma.*

Pulp Density Scales—Bulletins S1C-B and S1C-B1 include the Denver pulp density scales, for speed and accuracy in determination of specific gravity of pulps and liquids in routine mill-control work. S1C-B is for specific gravities 1.4 to 3.2, and S1C-B1 is for specific gravities 1.35 to 1.85. Scales can be used wherever metallurgical results are dependent upon water-to-solids relationship in mill pulps, such as: Ball mill discharge, classifier overflow, thickener discharge, condition discharge and agitator circuit. Also included are pulp density formulas and tables.—DENVER EQUIPMENT COMPANY, *1400 Seventeenth Street, Denver 17, Colorado.*

Water Demineralizer—Catalog No. 123 describes in detail the difference between distilled and demineralized water. This 20-p. catalog highlights the advantages of either distilled water or demineralized water as used in manufacturing and processing operations which call for pure water.—BARNSTEAD STILL AND STERILIZER COMPANY, INC., *2 Lanesville Terrace, Forest Hills, Boston 31, Massachusetts.*

Instrument News—Vol. 1, No. 2, 8 pp., features articles on a mobile infra-red spectrometer, mass analyses of plant tissues and soils by means of a flame photometer, the use of electrophoresis apparatus in clinical diagnoses, and includes other items of general interest.—THE PERKIN-ELMER CORPORATION, GLENBROOK, CONNECTICUT.

Experimenter—Vol. XXIV, No. 10, features the Type 1021-A standard-signal generator for frequencies between 50 and 920 mc and also includes description of the Type 100-P6 amplitude modulator for video frequencies. Specifications included.—GENERAL RADIO COMPANY, *275 Massachusetts Avenue, Cambridge 39, Massachusetts.*

Hastings Indicator—March, 1950 issue describes briefly two new Raydist two-dimensional hyperbolic systems constructed for the U. S. Naval Ordnance Laboratory and the U. S. Navy Bureau of Aeronautics, a vacuum gauge, and a miniature temperature compensated non-directional pick-up and contains other items of interest.—HASTINGS INSTRUMENT COMPANY, INC., *Box 1275, Hampton, Virginia.*

Modern Precision—Winter 1949–1950 issue of tabloid-size review of industrial use of Leeds and Northrup control and recording instruments.—LEEDS AND NORTHRUP COMPANY, *4902 Stenton Avenue, Philadelphia 44, Pennsylvania.*

Mercury Manometer Flowmeters—Catalog 37, 12 pp., illustrates and describes the new mercury manometer flowmeters. These flowmeters require no pressure-tight bearings or stuffing boxes; they use the Fischer and Porter magnetic clutch, or the impedance bridge electric transmitter.—FISCHER AND PORTER COMPANY, *Hatboro, Pennsylvania.*

Ratosleeve Flowmeters—Catalog 83, 12 pp., describes and illustrates Ratosleeve meters, suitable for liquids, gases, pulps and slurries.—FISCHER AND PORTER COMPANY, *Hatboro, Pennsylvania.*

CEC Recordings—Vol. 4, No. 1, 12 pp., features the Telereader, which speeds reading of oscillographic records, and includes articles on vibration measuring and recording without amplifiers, studies of ferromagnetic materials, new torsiograph now in production, recording galvanometers, control analysis of methyl mercaptan, and other items of interest.—CONSOLIDATED ENGINEERING CORPORATION, *620 North Lake Avenue, Pasadena 4, California.*

Laboratory Microscopes—Catalog D-185 presents the company's line of laboratory microscopes. Photographs and prices included.—BAUSCH AND LOMB OPTICAL COMPANY, *Rochester 2, New York.*

Kelefax—Vol. 1, No. 1, the first issue of a new bimonthly publication of interest to personnel engaged in radiation and industrial instrumentation, nuclear science and technology. Included in the first issue are useful reference data and tables for working with radiation or radioactivity, information about the complete line of Keleket instruments, equipment and components, announcements of new Keleket products, and other articles of interest.—THE KELLEY-KOETT INSTRUMENT DIVISION, *12 East Sixth Street, Covington, Kentucky.*

Testing Machine—Bulletin 305, 4 pp., gives full details on the Baldwin-Tate-Emery testing machine, having ranges from 0-2 lb. full scale to 5000 lb. capacity. This bulletin illustrates the loading system internally as well as externally, giving an explanation of operation, details on ranges, accuracy, new features, specifications and accessories.—THE BALDWIN LOCOMOTIVE WORKS, TESTING EQUIPMENT DEPARTMENT, *Philadelphia 42, Pennsylvania.*

Hydraulic Weighing Systems—Bulletin 303, 20 pp., dedescribes and illustrates new Baldwin portable hydraulic weighing system components for various applications. Also covered are hydraulic lifting jacks and hand pumps for use with compression-type load cells.—THE BALDWIN LOCOMOTIVE WORKS, TESTING EQUIPMENT DEPARTMENT, *Philadelphia 42, Pennsylvania.*

Coil Checker—Bulletin 19-B provides complete technical data on the new Model 301A coil checker, consisting of a vacuum tube voltmeter, a calibrated variable capacitor and an amplifier tube. When coupled with any r-f oscillator, the 301A measures inductance, distributed capacity, and the "*Q*" of any inductor, as well as the capacity of mica condensers.—CLOUGH BRENGLE COMPANY, *6014 Broadway, Chicago 40, Illinois.*

Radiation Instruments—Information Bulletin No. 9 presents the company's line of radiation instruments.—RADIATION COUNTER LABORATORIES, INC., *Chicago 8, Illinois.*

Nickel-Clad Copper

Kulgrid, heat-resistant nickel-clad copper wire which combines the electrical conductivity of copper with the corrosion-resistant properties of nickel, is being made in diameters from 5 to 10 mils. These sizes are adapted both for stranding and for lead wire applications where the high temperature working of hard glass frequently renders solid copper wire brittle. Stranded conductors of nickel-clad copper may also be suitable as electrical leads in aircraft, for electric furnaces, jet engines, and a wide range of laboratory and industrial equipment where high temperature or corrosive atmospheres tend to make solid copper conductors brittle and unreliable. A practically uniform ratio of nickel to copper (27 to 29 percent nickel) is maintained throughout the drawing operations and perfect bonding of nickel to copper is obtained. Good workability and electrical characteristics are assured through heat treating or annealing at frequent intervals and after the final draw.—Sylvania Electric Products, Inc., Parts Division, *Warren, Pennsylvania.*

Rolled Gold Plate

Rolled gold plate having a highly finished gold layer more than 10 times as thick as the average gold electroplate is now commercially available at relatively low cost. In the *Inter-Weld Process* used for this purpose a bar of gold is welded to a barrier layer of pure nickel. This dual layer is then silver-soldered to a metal base. The interposition of the nickel layer prevents diffusion of the silver solder to the surface of the gold. The surface texture is further enhanced by the use of a special lapping process applied to the rolls of the mill in which the material is reduced to its final thickness. The rolls are highly polished and their variations are less than 1 microinch. The finish imparted to the plate is protected by a thin plastic coating (less than 0.0005 in. in thickness) which remains in place during blanking and forming operations on the material, but which can easily be removed by stripping at any time. This virtually eliminates the expensive finishing and polishing operations required when gold-electroplated brass is used. Rolled gold plate, having a mirror finish protected by "Filmcote," is available in any ratio of gold to base metal on a variety of base metals such as brass, copper, nickel, nickel silver, beryllium copper, etc. It is made in thicknesses down to 0.005 in. and in widths from ¼ to 4½ in.—American Silver Company, Inc., *Rolled Plate Division, Flushing, New York.*

Interlocking Lead Bricks

Model 3039 interlocking lead bricks, for background shielding, are designed to eliminate the low density "joint space" between ordinary rectangular bricks. The interlocking sections are so designed that a completely dense wall may be obtained by fitting suitably shaped bricks together. Provision is made for corners and similar construction. Standard 4×4×2-in. wall bricks can be assembled with two types of corner bricks, and a triangular filler is available to eliminate the low density area at the bottom of the structure. Complete information and construction suggestions are available from the maker.—Nuclear Instrument and Chemical Corporation, *223 West Erie Street, Chicago 10, Illinois.*

Nuclear Track Emulsions

Two new photographic emulsions for recording nuclear tracks have been developed by Eastman, extending the range of special plates and films available for scientific use.

Kodak Type *NTB2* is intermediate in speed between nuclear plate Types *NTB* and *NTB3*, and is especially useful where stray radiation may produce undesirable background with faster emulsions. Electron tracks to 400 kv have been observed on this emulsion, which will be available in both plate and pellicle form. The second new emulsion, Type *NTC3*, is designed to record low energy alpha-particles and low energy protons to 7 Mev. It is recommended for cyclotrons and synchrotrons where background radiation is of high intensity.

Two additional emulsions, Types *NTB* and *NTA*, are now available in pellicle form along with Types *NTB2* and 3. These pellicles permit an emulsion thickness of approximately 250 microns without the problems of uneven development which may be encountered when emulsions of this thickness are coated on glass.—Eastman Kodak Company, *Rochester 4, New York.*

"Teflon" Tape

"*Teflon*" (tetrafluoroethylene) tape is characterized by heat resistance, toughness over a wide temperature range, excellent electrical properties and chemical inertness. It is capable of continuous service without deterioration at 250–270°C and is therefore suitable for use as Class *H* insulation (180°C hot-spot temperature), and maintains its flexibility to temperatures below −70°C. It is strong, smooth, and conforms well to sharp corners. Furthermore it has "plastic memory" and tends to return to its original shape when heated. Thus the tape tends to recover the stretching caused by the wrapping operation, so that it becomes tighter as the temperature rises. Its power is less than 0.05 percent from 60 cycles to 30,000 Mc; its volume resistivity is greater than 10^{15} ohm-cm after prolonged soaking in water; and its surface resistivity is greater than 10^{13} ohms even at 100 percent relative humidity. Short-time dielectric strengths range between 1000 and 2000 volts/mil at room temperature and are almost as high at 200°C. (The maker recommends working stresses between 50 and 100 volts/mil.) *It is not recommended for use in the presence of corona*, which degrades it slightly. It is attacked only by molten alkali metals, and by fluorine and chlorine-trifluoride at elevated temperatures and pressures. Outdoor weathering has no observable effect.—E. I. du Pont de Nemours and Company, *350 Fifth Avenue, New York, New York.*

Teflon Rods and Tubes

Teflon is now being processed into machinable rods and tubing. It may be used in the electrical and electronic fields as high frequency insulation, and in other applications where complete inertness, resistance to high temperatures, and non-sticking qualities are indicated. Information should be obtained from the maker concerning sizes of rods and tubing that are now in commercial production.—The Polymer Corporation, *Reading, Pennsylvania.*

Silicone Rubber

Two new silicone rubber compounds, *GE#13011* and *GE-#13012*, have been developed for special applications, and are designed for use at extreme temperatures for shock mounts, light spring-loaded gaskets, damping devices and related uses where conventional or silicone sponge-rubber parts either deteriorate or collapse from "compression set."—General Electric Company, *Pittsfield, Massachusetts.*

Vacuum Pump Fluid

Narcoil-20 diffusion pump fluid (di-2-ethylhexyl sebacate) especially treated for high vacuum use is now available in quantity. This ester is capable of attaining as low or lower pressures than any other pump fluid. It is recommended for use in any diffusion pump for service in which pressures less than 0.1 micron are required. It is available in pint, quart, and gallon containers.—National Research Corporation, *70 Memorial Drive, Cambridge, Massachusetts.*

Glass Orifice Plates

While the advantages of dimensional stability and corrosion resistance of glass orifices have long been recognized, use has been limited because of the high cost of production to required standards. By employing a new technique, Pyrex-glass orifice plates can be made economically to extremely close tolerances with sharp square edges maintained where required. Both inside and outside dimensions are ground on a diamond wheel. Glass orifice plates are available in various thicknesses from ¼ in. up, and in sizes up to 16 in. O.D. Further information is available from the maker.—Precision Thermometer and Instrument Company, *1535 Brandywine Street, Philadelphia 30, Pennsylvania.*

A Vacuum Furnace for Use in the Temperature Range 1000–2000°C

J. W. TOMLINSON* AND J. O'M. BOCKRIS
Department of Inorganic and Physical Chemistry, Imperial College of Science and Technology, London, England

(Received February 27, 1950)

A laboratory vacuum furnace with a glass envelope has been developed, using as a heater a cylindrical grid of tungsten wire enclosed by radiation shields.

The furnace is suitable for physicochemical measurements in the range 1000–2000°C.

INTRODUCTION

A SURVEY of the literature revealed the absence of a record of a vacuum furnace for use in the range 1000–2000°C, suitable for physicochemical measurements, those vacuum furnaces described being of complex design and generally unsuitable for quantitative experiments. A suitable furnace was therefore constructed, the details of which are recorded in this paper.

GENERAL CONSTRUCTION

The envelope and all glass parts are of Pyrex glass; the dimensions shown in Fig. 1 being most suitable, the joints are of standard sizes. The window *A* is of 2 mm optically flat Pyrex glass and is situated at the end of tube *B* to avoid darkening due to condensation of evaporated metal. Connection to the pumping system, which should have a speed of 10–20 liters/sec. at 10^{-4} mm Hg, is via the B29 standard joint at *C*. All joints and the flanges at *D*, are greased with Dow Corning silicone high vacuum grease which retains its viscosity and stability up to 200°C.

The main functional parts of the furnace, shown in Fig. 2, are suspended from tungsten rods which are sealed into joints which fit into joints sealed to the upper flange; from the rods *E* the heater is suspended, and from the rods *F* the crucible, which in the present case is of molybdenum, but which could be fabricated from any desired material. The heater is in the form of a cylinder of twelve 4 cm loops of 0.5 mm diameter tungsten wire, supported by hooks suspended from a silica ring attached to the two rods *G*; this method of support eliminates sagging at high temperatures. The ends of the heater wire are welded into the two molybdenum rods *H*, the length being such that the heater is in the center of the radiation shields *I*. The size and length of wire used are chosen to correspond to the power available and in operation 35 amp. at 40 v were required to maintain a temperature of 2000°C for a heater of the dimensions given; thicker wire might be used with advantage to reduce the applied voltage, thus avoiding the gaseous discharge which occasionally occurred with the present apparatus at low vacuum. The crucible *J* is suspended from molybdenum rods *K* sealed into joints fitting into the flange diametrically opposite to those supporting the heater; contact between heater and crucible and heater and radiation shields must be avoided by accurate centering of these parts relative to each other.

The cylindrical radiation shields *I* are of 0.2-mm molybdenum sheet and are 12 cm in length and have diameters differing by 0.5 cm; the assembly is secured on molybdenum rods and spacers *L*, into which are slotted tungsten rods *M*, these resting in side arms *N* off the main envelope. The function of this type of shield as radiation reflectors is well known and has recently been treated mathematically,[1] indicating an optimum number of four or five.

The furnace is run at a pressure of approximately 10^{-3}–10^{-4} mm Hg after an initial period of outgassing at 10^{-6} mm Hg. Deposition of metal from the heater on the wall of the envelope occurs and is due to evaporation and possibly attack by gases given off from the hot glass; the deposit may be periodically removed and

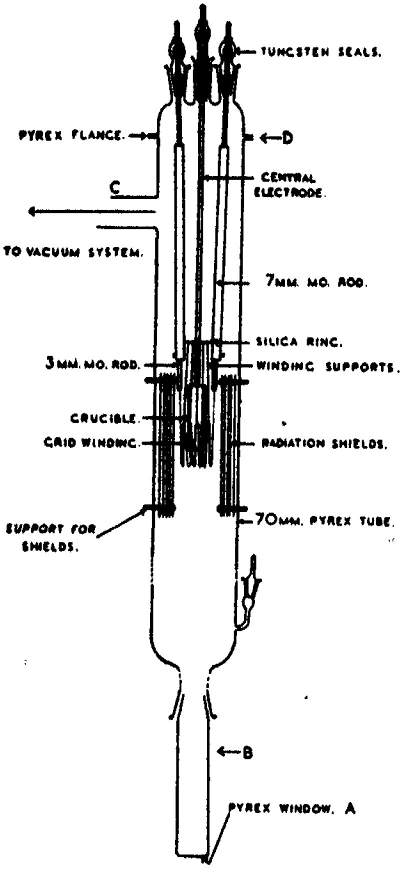

FIG. 1.

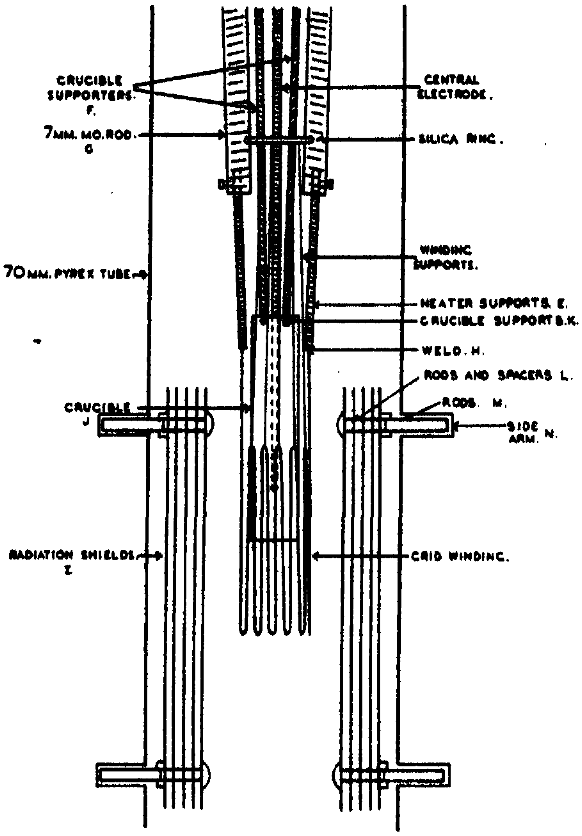

FIG. 2.

constitutes no disadvantage in operation. All metals other than molybdenum and tungsten are rigidly excluded in construction.

TEMPERATURE MEASUREMENT

The temperature is measured by optical pyrometer sighted through the window *A* onto the crucible bottom, and, as the estimation of the blackbody conditions would be extremely difficult, the pyrometer is calibrated over the range up to 1700°C to determine these conditions. Comparison readings are taken against a *Pt/Pt-Rh* thermocouple suspended inside the crucible the leads being sealed through joints in the upper flange. By means of a magnetic device, which enabled the couple to be moved inside the crucible relative to the bottom, the temperature constancy was found to be within 10° over a distance of 1.5 cm.

ADVANTAGES OF THE FURNACE

(i) Ease and rapidity of reaching temperatures of the order of 2000°C. (15 min. or less is sufficient time to reach 2000°C.) (ii) Neutral atmosphere and vacuum. (iii) Possibility of rapid cooling, i.e., quenching. (iv). Higher temperatures attainable; there is no reason why, by the addition of top and bottom shields, etc., the range should not be increased to temperatures of the order of 2500°C. (v) Ease of construction, low cost and ease of replacement of winding. (vi) Possibility of micro-work because of small size.

USES

The furnace was used by the authors for the measurement of electrical conductivities of liquid silicates using a central electrode. The potential uses of the apparatus are many and include investigation of phase equilibria, chemical reactions at high temperatures, solid phase reactions, melting point measurements, high temperature sintering and general measurement of properties at high temperatures.

A High Intensity Ultraviolet Continuum Source for Use in Spectrophotometry

NISSON ASCHER FINKELSTEIN
Massachusetts Institute of Technology, Cambridge, Massachusetts

(Received November 8, 1949)

A high intensity ultraviolet continuous spectrum d.c. source emitting between 50 and 100 times as much light as comparable commercial sources has been designed and constructed. Transitions between two molecular energy states of hydrogen are induced to produce a continuum from 1850A to 6000A. The arc is run at approximately 14 amperes and 90 volts from a 220-volt d.c. line. A hydrogen pressure of 3 mm of mercury is used. Lifetimes greater than 40 hours have been obtained.

INTRODUCTION

FOR the performance of experiments in ultraviolet reflection spectrophotometry it was found necessary to design a continuous spectrum source emitting radiation through a large solid angle and having a greater intensity than any lamp commercially available. Three possibilities for a continuous spectrum in the ultraviolet are the molecular spectrum of hydrogen, the helium continuum, and the hydrogen atomic Lyman continuum. The helium continuum is above 3000 angstroms and the Lyman continuum below 2000 angstroms. Only the molecular spectrum of hydrogen is in the 2000 to 4000 angstrom ultraviolet region desired. The fact that this spectrum extends up to almost 6000 angstroms facilitates a check with reflection spectrophotometry previously accomplished in the visible.[1]

The source designed is an extension of the work of Munche[2] and Allen,[3, 4] and was constructed with the assistance of Mr. H. Wyckoff of the Massachusetts Institute of Technology Biology Department.

THEORY OF OPERATION

The ultraviolet continuous spectrum of molecular hydrogen[5, 6] results from transitions from a stable upper state to an unstable lower state[*] which immediately dissociates into two unexcited hydrogen atoms with accompanying emission of radiation, any excess energy available being converted into kinetic energy of the dissociated atoms. The initial upper state must be excited by a potential which is a function of the frequency of radiation emitted. The minimum potential for excitation is given by various investigators[5, 6] as lying between 11.6 volts and 12.7 volts. The observed continuum extends from about 6000 angstroms down to the Schumann region (1850 angstroms) with a maximum at about 2500 angstroms. Superposed upon the continuum are the lines of the Balmer series due to atomic excitation in this region. When the source is used with a spectrophotometer having a slit width of about 20 angstroms, the line intensities integrated over this 20-angstrom band produce a signal less than three times as great as that produced by the continuum. No lines are present in the 2000-angstrom to 3700-angstrom region.

DESIGN AND CONSTRUCTION

Figure 1 shows a simplified cross-sectional view of the electrode arrangement inside the source. The discharge passes from the cathode *F* through the localizing orifice *C* to the anode *A*. It is viewed along the axis through a rectangular slit, 3 mm×6 mm, in the anode. The voltage required to start the arc is 220 volts d.c. The operating cathode-anode potential difference is between 80 and 120 volts, depending on what arc current is being drawn. A Tesla high voltage coil is applied to the starting ring, *E*, to facilitate striking the arc.

The cathode, *F*, is constructed of a 1½-in.×14-in. piece of nickel screening folded twice on the long dimension to form a strip ½ in.×14 in. This strip is then folded accordian-wise to assume the shape shown in Fig. 2.

Finally, the cathode is sprayed with a barium strontium carbonate solution to give high electron emission when the cathode is heated by passing an a.c. current through it. The resistance of the cathode at a temperature of 900°K is about 0.1 ohms. The two ends of the cathode are mounted on nickel rods which are brought

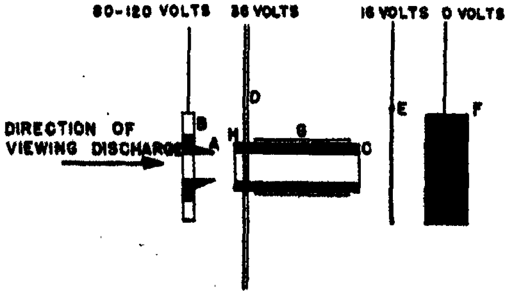

FIG. 1. Simplified cross-sectional view of electrode arrangement inside the hydrogen arc source. Typical operating potentials are shown.

[*] It has thus far not been possible to determine experimentally exactly which pair of molecular levels it is between which transitions are induced to produce the continuum; but a typical pair between which suitable transitions might take place is the upper stable $1s\sigma 2s\sigma\,^3\Sigma_g$ and the lower unstable $1s\sigma 2p\sigma\,^3\Sigma_u$.

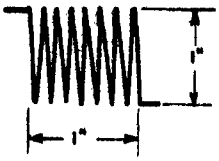

FIG. 2. Nickel screen cathode as seen from direction of anode.

out through the top of the brass can enclosing the electrode system by means of Kovar-glass seals which maintain electrical insulation of the rods from the can. The a.c. source of cathode heating power is applied to these two rods.

The starting ring, *E*, is a 30-mil molybdenum wire bent in a 1½-in. diameter circle and brought out through the can top by a Kovar-glass seal.

The localizing orifice, *C*, is a ½-in. diameter molybdenum rod ¾ in. long through which an axial rectangular slit 4 mm×7 mm has been machined. The arc is forced to pass through this long slit passage, since a 60-mil sheet of molybdenum, *D*, prevents it from passing around the orifice to the anode. The shield is held on to the orifice by a molybdenum nut, *H*, which threads on to the orifice.

The anode, *A*, is made of molybdenum and has a slit 3 mm×6 mm through it, also lined up with the localizing orifice. The orifice slit is machined 1 mm larger in each dimension to make allowance for the arc's "pulling away" from the sides of the orifice as it passes through.

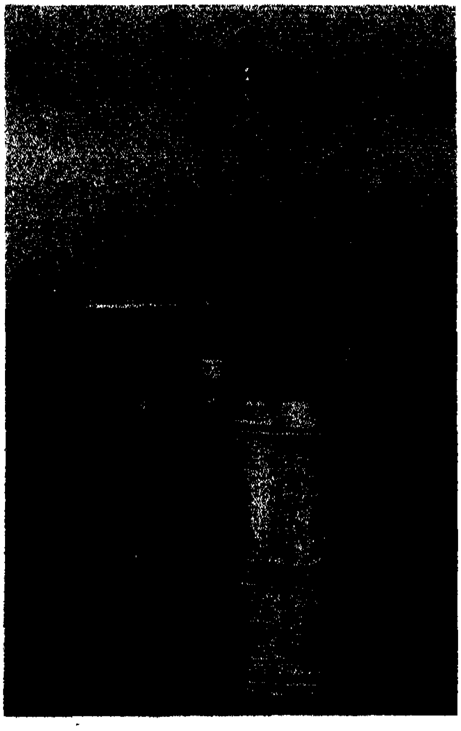

FIG. 3. Ultraviolet source ready for use. 1. Cathode terminals, 2. starting ring terminals, 3. anode terminal, 4. outlet to pump, 5. water cooling tubing, 6. beam port, 7. observation port.

Because of the high current density of the arc, molybdenum was chosen as an electrode material because of its high melting point, 2620°C. It was found necessary, however, to water-cool the anode and orifice to prevent evaporation of molybdenum into the arc and subsequent appearance of molybdenum lines in the spectrum. Since it is not possible to solder to molybdenum or to make any simple welded connection, the anode was set into a copper plate, *B*, to which it was tightly screwed for good thermal contact. In the case of the molybdenum orifice tube, a copper jacket, *G*, was thermally shrink-fitted about the tube by machining the jacket undersized 1½ mil in diameter and heating it while cooling the molybdenum. In this manner a quite satisfactory thermal contact was gained. Copper tubing, $\frac{3}{16}$ in. in diameter, was silver soldered to the anode copper plate and about the orifice copper jacket; this tubing was brought out through the top of the can and water passed through to provide cooling. The copper tubing soldered to the anode plate was brought out through Kovar-glass seals for electrical insulation and the positive d.c. anode potential was applied to this tubing. The tubing also serves to support the anode in position in the can. Since the localizing orifice is hung from the can, the two are at the same potential and the orifice water cooling tubing is not brought out through Kovar-glass seals but through holes in the can cover sealed with silver-solder.

The electrode system is contained in an all brass can with two quartz window ports 1 in. in diameter, one for viewing the discharge and the other for checking operation of the tube. This latter observation port is mounted in such a manner that the cathode, starting ring, and cathode side of the localizing orifice are visible. The brass can and cover are water cooled by means of copper tubing silver soldered on for good thermal contact. The quartz windows are sealed to the ports and the cover to the can with deKhotinsky wax cement. Figure 3 is a picture of the source ready for use.

AUXILIARY EQUIPMENT

The d.c. power for operation of the arc is drawn from a 220-volt d.c. line and the arc current is adjusted by switching 9 Calrod 6-ohm resistors into different series-parallel combinations to vary the resistance in series with the source.

The cathode is heated by an alternating current of approximately 50 amperes to a color temperature of about 850°C as estimated with an optical pyrometer, this being the temperature necessary for satisfactory electron emission. The power is shut off immediately after the arc is struck in order to save excessive wear and tear on the cathode and to prevent 60-cycle oscillations in the light source.

In order to strike the arc an electrostatic field must be passed through the orifice from the cathode to the anode. This is difficult because of the narrowness of the orifice passage, and it is found necessary to touch a high voltage Tesla coil to the starting ring to cause the arc to jump first to the ring and then through the orifice to the anode. If difficulty is experienced in starting the arc the cathode current is increased to provide more electron emission and hence higher ionization.

It is found that the source is quite pressure sensitive with respect to ease of starting. While it can be started immediately at hydrogen pressures of from 2.5 to 3.5 mm of mercury, higher and higher anode-cathode voltages are necessary when pressures above this are existent. As a result of the absorption and emission of hydrogen gas by the brass container and the various electrodes during the processes of cooling and heating it is found most convenient to provide a means of adjusting the hydrogen pressure within the source. A palladium leak hydrogen input is used in conjunction with a fore pump to adjust the pressure, and the pressure is measured with an oil manometer.

PERFORMANCE CHARACTERISTICS

The lamp operates with arc currents between 10 and 20 amperes at arc voltage drops of between 125 and 75 volts.

The radiation emitted originates at the positive column of the discharge situated along the length of the localizing orifice. The angle through which radiation is emitted is such as to fill an $f/4.3$ system in the horizontal plane and an $f/2.2$ system in the vertical plane. In comparison with commercially available sources of this type which fill an $f/35$ system, this source emits radiation through 64 times as great a solid angle.

For operation at arc currents of 14 amperes cathode lifetimes of more than 40 hours have been obtained thus far.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 6 JUNE, 1950

A Rotary McLeod Gauge*

M. Axelbank**
Distillation Products, Inc., Rochester, New York

(Received November 15, 1949)

The use of the sensitive McLeod gauge is limited by its fragility, bulk, and lack of portability. A new type of McLeod gauge is described which greatly reduces these difficulties. A helix of several turns of glass tubing provides the volume through which the gas is compressed by a small quantity of mercury as the gauge is rotated upon its rotary seal. A model has been constructed which is 16×16×21 cm in over-all dimensions and weighs less than 1 kg. Its gauge constant with a 0.8 mm capillary is 1.4×10^{-6} mm^{-1}.

McLEOD gauges of high sensitivity, intended for accurate measurement of pressures below 10^{-3} mm of Hg, are characteristically non-portable, fragile, cumbersome to operate, and subject to accident. The rotary or swivel form of McLeod gauge[1,2] has provided a satisfactory solution of these problems for measurement in the higher pressure ranges. However, the ordinary rotary type of gauge is not practical for the lower ranges because of the large weight of mercury required.

Among the gauges capable of higher sensitivity, the leveling bulb McLeod[3] is widely used in laboratories because of its simple construction, but it is not portable and is subject to contamination of the mercury by the rubber connecting tube. The original McLeod gauge[4] was of this form. Plunger type gauges[5] are more convenient to operate but are not portable and are subject to accidents in which mercury is thrown into the system

Fig. 1. Front view of the rotary McLeod gauge.

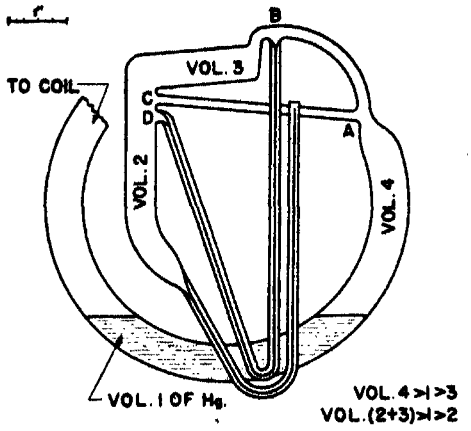

FIG. 2. The "head" of the gauge.

or back out of the reservoir into the room. The short form of McLeod gauge, in which the mercury is raised by atmospheric pressure and lowered with a mechanical pump, has been utilized to provide the greatest sensitivities yet achieved with McLeod gauges. However, if a model is desired which will indicate pressures much below 10^{-5} mm of Hg[5,6] the weight of mercury required exceeds 50 lb. and large cast supports must be built for the bulbs. Such a gauge with its associated mechanical pump is expensive, non-portable, and easily broken by mercury surges.

It is the purpose of this article to describe a gauge developed by the author which obviates many of the difficulties which have previously limited the use of the sensitive McLeod gauge to the laboratory. The gauge is constructed entirely of glass except for the rotary "O" ring vacuum seal (see Fig. 1). For purposes of analysis it may be divided into three sections—the "head" (Fig. 2) which contains the open and closed capillaries, the coil or helix, and the end section (Fig. 3) comprising the reservoir, cut-off, and rotary seal.

In the rest position of the gauge the pool of mercury lies in the lower part of the first turn of the helix which forms the reservoir. Only 300 g of mercury are required for the gauge illustrated. The gauge is free to turn about the rotary seal which is rigidly clamped to a support or to the vacuum system. The fixed part of the rotary seal may be attached to a glass system with a glass-to-metal seal, or soldered directly to a metal system. In the case of a rigid metal system no further support is necessary.

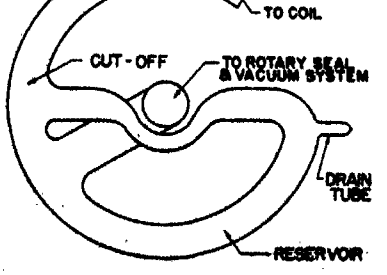

FIG. 3. The end section.

The operation of the gauge proceeds as follows. As the mercury leaves the reservoir and enters the coil, it cuts off the gas in the coil and head from the system. Proceeding through the turns, it compresses the gas into the head. When it reaches point A (see Fig. 2) it flows into the spillway (AC) as well as toward point B. At B it cuts off the upper end of the reference capillary. It then fills volume 3 and cuts off the upper end of the spillway at point C before opening the lower end, since volume 1 is greater than volume 3. When point D is reached, the lower end of the reference capillary is cut off and a certain volume of gas is trapped in the capillary at the pressure existing in the head at this moment. With further rotation the upper end of the reference capillary is opened and the trapped air released to the system. A simple development from Boyle's law shows that this loss of gas does not appreciably affect the final reading. The error is approximately equal to the ratio between the volume of the open capillary and volume 2, which is negligibly small. As the volume (2+3) is greater than volume 1, and most of volume (2+3) is substantially below the reference capillary at this moment, then all of the mercury which entered the capillary flows out at point B into volume 3. When the capillaries are brought to a vertical position, the gas is compressed into the closed capillary and the excess mercury drains through the spillway, leaving the reference column approximately at "zero" level. The gauge is rotated slightly beyond the vertical position, so that when it is returned the mercury in the open capillary is at the proper level. With a little practice this may be done quickly and easily. The pressure is then read directly from a square law scale mounted behind the capillary tubes.

The gauge is reset by counterclockwise rotation. All the mercury drains from the head, as volume 4 is greater than volume 1. If this were not the case, an extra revolution would be required in resetting. The design of the reservoir section makes it impossible for any mercury to escape into the system.

The gauge described is approximately 16×21×21 cm in over-all dimensions. It gives a gauge constant, $C=1.4\times10^{-6}$ mm^{-1}, where $C=\pi r^2/V$ with r, the radius of the capillary, equal to 0.4 mm and V, the volume of the gauge beyond the cut-off point, equal to 3.6×10^5 mm^3. The volume V may be easily measured as follows. In constructing the gauge a drain tube is provided on the reservoir in the position shown in Fig. 3. Initially this tube is open and the end is fire polished. The required amount of mercury is inserted in the reservoir, and with the axis horizontal the gauge is rotated until the mercury level reaches the cut-off point. A line is then drawn around the outside of the glass at the level

---

[5] See reference 1, p. 269.
[6] Rev. Sci. Inst. 10, 131 (1939).

of the mercury with a "glass marking" pencil or crayon. The mercury is poured out through the drain tube and the gauge weighed to the nearest tenth of a gram. The axis of the gauge is placed in a vertical position with the rotary seal end upward, and distilled water is poured in through this open end while the gauge is rocked slowly from side to side until all trapped air bubbles rise to the top and the excess water escapes through the drain tube. The gauge is carefully tilted while keeping the drain tube uppermost until the axis is horizontal, and then the reservoir is rotated upwards and the drain tube downwards until all the water in the reservoir has escaped through the drain tube. The rotation is continued until enough water overflows at the cut-off and escapes through the drain tube to bring the water surface exactly at the position outlined by the "glass marking" pencil. The gauge and its contents are then weighed to the nearest tenth of a gram. The trapped water may also be emptied through the drain tube into a beaker for weighing, but it is difficult to remove all of the water from the narrow tubes in the head of the gauge. After drying the gauge, the drain tube is sealed off as shown in Fig. 3. The calibration constant C can also be determined by calibrating the rotary gauge against a standard laboratory McLeod at two or three points. The pressure in mm of Hg is given by $P=Ch^2$ where h is the depression of the mercury in the closed capillary when the level of the mercury in the open capillary is set to the top of the closed capillary. The length of the closed capillary from the top to the bend is about 15 cm, and the useful range of pressure covered by the scale is from 2×10^{-6} mm to 2×10^{-2} mm Hg.

The weight of the rotating part of the gauge, including the mercury, is less than one kilogram. Thus no undue strain is put on the glass-to-metal seal or the rotary joint. A cylindrical guard of perforated sheet metal or wire mesh may be placed around the glassware to protect the gauge from accidental blows. However, it has been found convenient to use the unprotected gauge without any accessories in the laboratory.

For the design of the rotary "O" ring seal, the author is indebted to Mr. Judd Black of the D.P.I. instrument shop. As shown in Fig. 4 it consists of a single "O" ring of Neoprene and a needle bearing (Torrington B-912X) supported in a brass housing. The rotary member is a brass tube soldered to a glass-to-metal seal which is connected to the gauge. This seal has functioned satisfactorily without any measurable leakage and with negligible outgassing since the first model of this gauge was constructed.

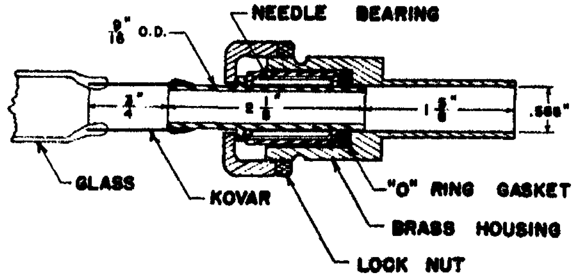

FIG. 4. Details of rotary seal.

It is readily seen that the gauge is nearly accident proof. Should atmospheric pressure be suddenly admitted to the system or the gauge by breakage or inadvertent opening of the wrong valve, the mercury resting in the reservoir would not be displaced. Even should an accident occur while the gauge is in use, with the mercury in the coil, it is unlikely that mercury would escape into the system or break the head of the gauge, as most of the impact of the air on the mercury would be taken up in the turns of the coil and air will by-pass the mercury at the top of each turn.

The rotary seal will admit small quantities of condensable vapors to the system, but probably not more than the stopcock usually placed between a McLeod gauge and the vacuum system. This is generally unimportant, as McLeod gauges are almost invariably trapped.

A somewhat different helical gauge has been described by Reden.[7] It involves a glass spiral ending in a capillary "U" tube. A tapered ground glass joint is used for the rotary seal. Our experience has shown that such joints "freeze up" after a short period of time even with the best of lubricants. Every reading must be computed by multiplying the compression ratio corresponding to the mercury level in the closed arm by the height of the level in the open arm above that in the closed arm. Reden's gauge is not suited for measuring extremely low pressures because the cross section of the coil tube cannot be too large compared with the cross section of the capillary.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 6 JUNE, 1950

A Multiple Kerr-Cell Camera

A. M. Zarem* and F. R. Marshall
U. S. Naval Ordnance Test Station, Pasadena Annex, Pasadena, California

(Received January 25, 1950)

The need for new ultra-high speed photographic techniques in studies of brief transient phenomena has led to the development of a multiple Kerr-cell camera designed to take a sequence of three photographs at submicrosecond exposure times. This camera uses shutters of the electro-optical type utilizing the Kerr effect in nitrobenzene. Pulsing networks for the Kerr cells and synchronizing networks for the entire system are described. The system has shown itself to be capable of high shutter speed, high sequence rate, and very good stability of timing. With this camera, studies of electrical discharages at effective exposure times of 0.04 microsecond and framing rates corresponding to 40,000,000 frames per second have routinely been made. It is felt that cameras of this type are valuable research tools that will help open the way for further important studies.

INTRODUCTION

TECHNOLOGICAL advances in the last few years have resulted in renewed interest in the study and investigation of physical phenomena of a transient nature. In the field of photography, particularly, a growing need has been felt for (1) techniques to obtain ultra-short (submicrosecond) exposure times, (2) a means for synchronizing operation of the camera with the phenomenon to be studied.

To date, the shortest exposure times obtainable with mechanical shutters are of the order of a millisecond. Commercial motion picture cameras employing rotating prisms are available when exposure times down to the order of 75 microseconds are needed. For exposure times of a few microseconds, special cameras using rotating mirrors are available. In these mechanical shuttering methods, the problem of precise synchronization between the phenomenon studied and the operation of the camera shutter may be one of moderate difficulty. Flashlamp techniques which overcome this problem have been developed for use when exposures down to a microsecond are required. Such lamps, however, have obvious shortcomings for the photography of self-luminous objects or of objects having very high level background light.

When submicrosecond photographic exposure times are required, one is obliged to seek new methods, since both mechanical means and flashlamp techniques have not yet been commercially developed to be effective in this range. A shutter which can be used in the submicrosecond range is the Kerr-cell shutter, named for the discoverer of electrically induced birefringence. This shutter consists of the cell proper and two suitably positioned, "crossed" polarizers placed before and after the cell along the optical path. The cell is a transparent container of a liquid, usually nitrobenzene, and is provided with electrodes for establishing an electric field in the liquid in a direction perpendicular to the optical path. With no electric field, the crossed polarizers prevent transmission of light; with a field applied, the state of polarization of the light passing through the cell is altered, permitting light to pass through the second polarizer.

The optical transmission of a Kerr-cell shutter for

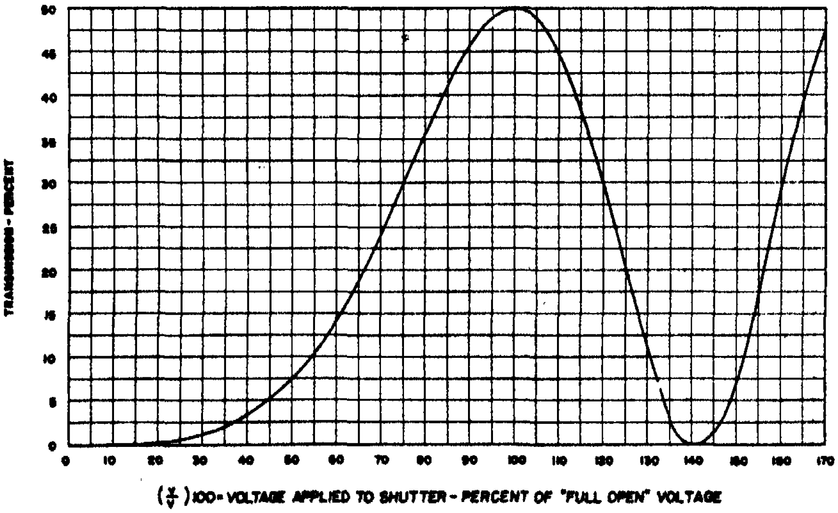

Fig. 1. Optical transmission of ideal Kerr cell shutter.

---

* Consultant to U. S. Naval Ordnance Test Station, is now Director of the Los Angeles Division, Stanford Research Institute and Chairman of the Department of Applied Physics.

axial rays is given by

$$T=A\sin^2[\pi/2(v/V)^2], \qquad (1)^1$$

where v = voltage applied to the electrodes, V = "full open" voltage of the cell, A = a constant which takes into account rejection of one-half of the light by the first polarizer and absorption and reflection losses in all components of the shutter. A plot of Eq. (1) is given in Fig. 1. Attention is directed to the very low transmission at low voltages.

The full open voltage for a Kerr cell may be calculated from the expression

$$V=300d(2lK)^{-\frac{1}{2}},$$

where d = distance between plates, cm, l = length of the electrodes, cm, K = Kerr constant of the cell fluid, c.g.s. e.s.u., V = voltage applied to the electrodes.

Because of its high Kerr constant, nitrobenzene is usually used as the active fluid in these cells. The Kerr cells in the camera to be described in this paper have rectangular electrodes which are 1 cm wide, 2 cm long and are separated by 0.5 cm. Figure 2 shows two models of Kerr cells which were used. For both models the full open voltage is approximately 12,500 volts. J film polaroid was used as polarizer.

The theory of operation of Kerr cells and their application in a wide variety of scientific investigations has been described in the literature. The development of a compact and simply operated shutter of this type for ordinary photographic purposes has taken place only recently. Since the speed of operation of a Kerr-cell shutter is limited intrinsically only by the rapidity with which certain molecular phenomena can occur and practically only by the rate of application of electrical potential to the cell, such cells have been used successfully in obtaining effective exposure times as brief as 0.01 microsecond.[2] The all-electrical operation of such shutters greatly enhances their utility by making possible the application of electronic techniques to high speed photographic shuttering. For such shutters the problem of synchronization of the camera with the phenomenon under study becomes an electrical timing problem of little difficulty.

Much could be said about the general design requirements for a Kerr-cell shutter but it is felt that this subject should be covered in a separate paper. However, brief comments on some of the common problems are pertinent here. The limitations of the Kerr-cell shutter arise from the fact that the design is usually a compromise between two factors—high operating voltage and electrode configuration that tends to restrict the areal and angular aperture of the camera. Details regarding spectral transmission of nitrobenzene and dispersion in the Kerr constant may be found elsewhere.[1] In addition, consideration must be given to the purity of the nitrobenzene used, on which further comment is made in the Appendix.

FIG. 2. Two models of Kerr cells used in multiple-Kerr-cell camera.

THE KERR-CELL CAMERA

A Single-Cell Camera

The essentials of a Kerr-cell camera are (1) a suitable camera, (2) a Kerr-cell shutter, and (3) an electrical circuit capable of delivering voltage pulses to the Kerr cell under suitable synchronization with the phenomenon to be photographed.

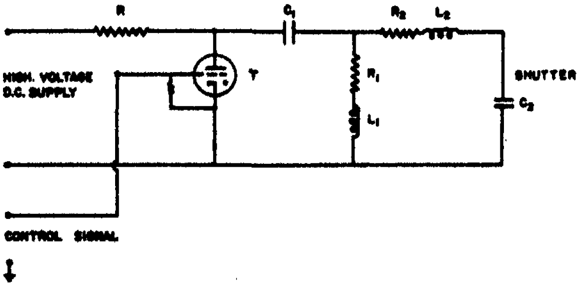

FIG. 3. Circuit diagram of Kerr-cell pulser.

---

[1] Zarem, Poole, and Marshall, "An electro-optical shutter for photographic purposes," Inyokern, U. S. NOTS (May 1948), NavOrd Report No. 1016; "An electro-optical shutter for photography," Elec. Eng. 68, No. 4, 282–288 (April 1949).

[2] W. M. Cady, and A. M. Zarem, "Brief pulses using Kerr cells," Nature 162, No. 4118, 528–529 (October 2, 1948).

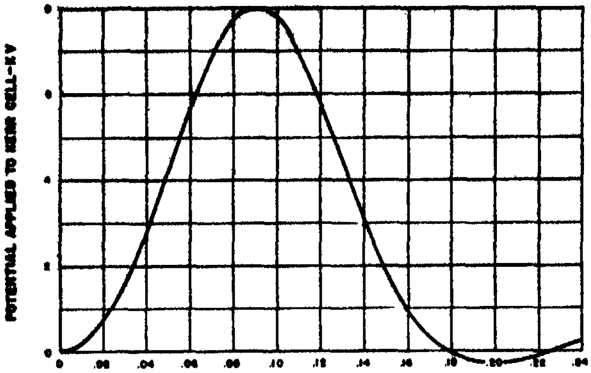

FIG. 4a. Voltage-time curve of Kerr-cell pulser.

There are many methods for obtaining brief electrical pulses of many kilovolts in magnitude, but most of these were thought to be objectionable from the point of view of economy, simplicity, or other technical grounds. The system finally decided upon was quite simple and operated with complete satisfaction. Figure 3 is a circuit diagram of the Kerr-cell pulser[3] used to supply a high potential, short-duration electrical pulse for operation of the Kerr-cell shutter.

When the thyratron T is in a non-conducting condition, capacitor C_1 is charged to supply voltage. Applying a voltage pulse to the grid of thyratron T causes it to conduct, discharging capacitor C_1 and creating a transient disturbance in the network which results in impressing on the Kerr cell (capacitor C_2) a voltage-time wave of the shape indicated in Fig. 4a. Observe that the capacity of the Kerr cell forms part of the network. The thyratron T in Fig. 3 may be any of several types, depending upon the peak voltage it is desired to switch to the Kerr-cell electrodes. The hydrogen thyratron series 3C45, 4C35, and 5C22 were used. Further details are given later.

It should be noted that the peak voltage impressed upon the Kerr cell with this network is approximately equal to the voltage to which the network is initially charged. For this reason, the circuit described has some advantages over the "line" type of pulse-forming networks, which ideally supply to a load only one-half of the voltage to which they are charged.

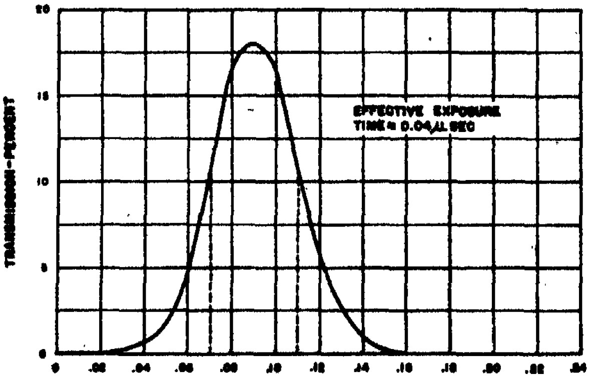

FIG. 4b. Transmission-time curve of Kerr-cell pulser based on Fig. 4a.

The curve of Fig. 4b shows the optical transmission as a function of time for a Kerr-cell shutter pulsed with the voltage-time wave form of Fig. 4a. The transmission characteristics of Fig. 1 indicate that in general the transmission-time characteristic of a Kerr-cell shutter will be briefer than the electrical pulse applied. Attention is called to this fact in Fig. 4, in which the transmission-time characteristic is seen to be much shorter than the voltage wave form. In Fig. 4b, 70 percent of the total exposure occurs in an interval of 0.04 microsecond; this is called the effective exposure time.

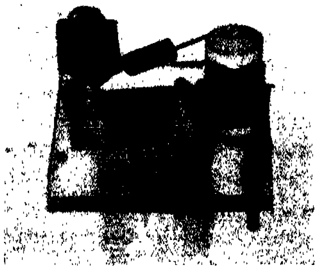

FIG. 5. Plug-in type network.

The electrical parameters of the circuit, Fig. 3, can readily be changed in order to accommodate Kerr cells of different electrostatic capacitance or to vary the duration of the output voltage. Since output voltage is unchanged by change in the impedance of the network as a whole, for Kerr cells of different electrostatic capacitance the circuit parameters are altered as follows:

$$C_1' = [C_2'/C_2]C_1$$
$$R_1' = R_2' = [C_2'/C_2]^{-1}R_1$$
$$L_1' = [C_2'/C_2]^{-1}L_1$$
$$L_2' = [C_2'/C_2]^{-1}L_2.$$

Notation of components is as in Fig. 3. Primes indicate values in the altered circuit.

To alter the pulse duration, thereby varying the effective exposure time, the time constants of the circuit are changed by the ratio of new to original exposure time. When Kerr-cell capacitance is assumed to be constant

$$C_1' = C_1$$
$$C_2' = C_2$$
$$R_1' = R_2' = [t'/t]R_1$$
$$L_1' = [t'/t]^2 L_1$$
$$L_2' = [t'/t]^2 L_2,$$

where t is effective exposure time. Primes indicate values of the altered circuit. When necessary, both of the above transformations can be utilized successively.

Using the above formulas, plug-in-type networks as shown in Fig. 5 were designed and constructed. To change the effective exposure time available with a Kerr cell, one merely substitutes the proper network designed by the equations given above. With such networks, pulse durations corresponding to effective exposure times of 0.007 to 7 microseconds were readily achieved.†

---

[3] A. M. Zarem *et al.*, "Circuit for pulsing capacitive loads," U. S. Patent No. 2,464,279 (March 15, 1949).

The Multiple-Kerr-Cell Camera

Framing—the recording of successive photographic exposures on separate film areas—presents a number of special problems at framing rates in excess of 100,000 per second. However, for a small number of frames, a simple arrangement is obtained by providing a separate Kerr-cell shutter and associated lenses, etc., for each frame in the sequence. Such a system will record slightly different aspects of the phenomenon on the several frames (unless semireflecting mirrors are used), but this limitation may not be serious, particularly if the subject is either distant or has convenient symmetry.

An arrangement of components in a three-frame camera is shown in the line diagram of Fig. 6 and the photograph of Fig. 7. The three frames are recorded on a single 4×5 photographic film of a standard Speed Graphic camera. This arrangement has an equivalent numerical aperture of about f:16 and a total angular field of approximately 5 degrees. It should be noted that a more compact arrangement might be achieved with a Kerr cell of smaller over-all dimensions. Such a cell, recently developed, has a maximum over-all dimension of 1 inch. It will be described in a note to be published soon.

The pulsing network for each of the Kerr cells is mounted above the Speed Graphic camera. More complete discussion of the circuitry is given below.

With the camera design indicated in Fig. 6, the optical paths from object to image are necessarily not equidistant. Difficulties due to this circumstance are avoided by placing the object at the focal point of the first lens and the photographic film at the focal point of the camera lens. The images I_1, I_2, and I_3 then appear in equal focus. The use of two mirrors or prisms on the longer light paths insures that neither of these images will appear reversed. However, the optics of the system is such that images I_1 and I_3 are of lower intensity than image I_2. To remedy this defect a neutral filter can be placed behind the second shutter to equalize the intensities of all three images.

Camera-Synchronizing System

A diagram of the camera-synchronizing system is shown in Fig. 8. This particular arrangement permits timing of the camera operation to be accomplished in two separate adjustments. One adjustment controls the

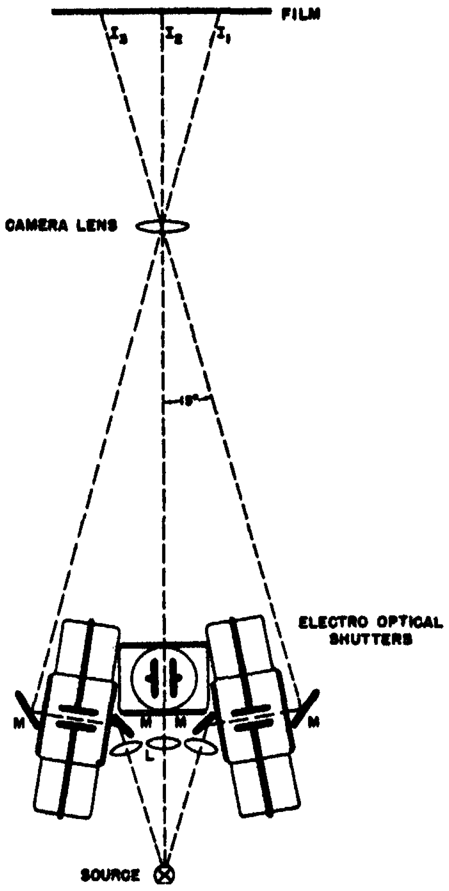

FIG. 6. Line diagram of multiple-Kerr-cell camera.

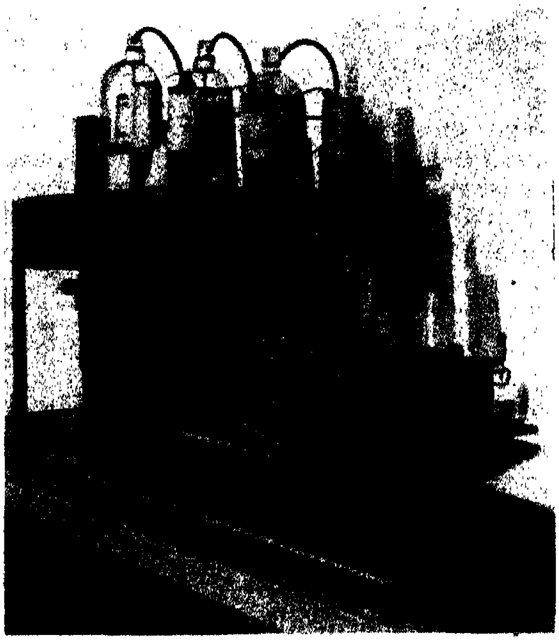

FIG. 7. Photograph of multiple-Kerr-cell camera.

---

† All statements on time intervals were verified with the aid of a high speed oscillograph with resolution time of 0.002 microsecond.

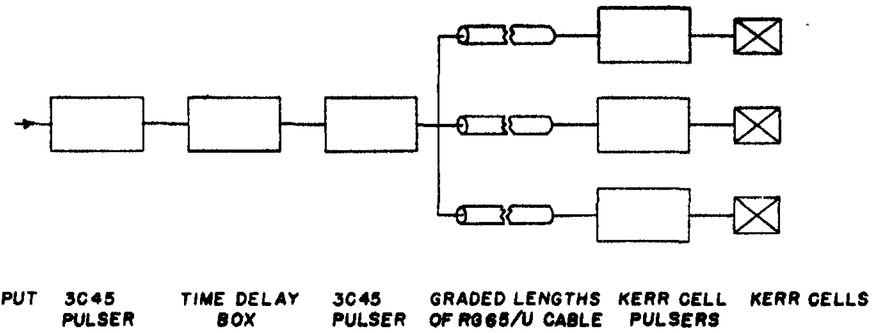

FIG. 8. Block diagram—circuit of triple-Kerr-cell camera.

time at which the shuttering sequence starts; it is effected by the delay box with a range of 2 microseconds in steps of 0.025 microsecond. The other adjustment varies the time interval between the operation of the three shutters; it is made by varying the cable lengths between the second 3C45 pulser and the various Kerr-cell pulsers. The time interval between successive shuttering operations can easily be made as small as 0.01 microsecond, corresponding to a framing rate of 100,000,000 per second.

The circuit diagrams of the 3C45 pulsers and the delay box are shown in Figs. 9 and 10. The cable used in the delay box and elsewhere in the camera-synchronizing system is a spirally wound, high impedance, high delay cable type RG 65/U.

The second 3C45 pulser is not functionally necessary. Its purpose is primarily to insure a more precisely timed sequence of the Kerr-cell pulsers by regenerating (sharpening) the synchronizing impulse at this point. A secondary purpose is prevention of voltage loss that would occur if cables were simply branched at this point.

The synchronizing signal is of much larger magnitude (2,000 volts with rise time approximately 0.01 microsecond) than is necessary to ionize the several thyratrons. The excess voltage serves to decrease the ionization time, thereby eliminating the need of carefully matched thyratrons in the three Kerr-cell pulsers. A fine adjustment of the timing of these thyratrons is provided by means of a 10,000-ohm rheostat in series with each grid.

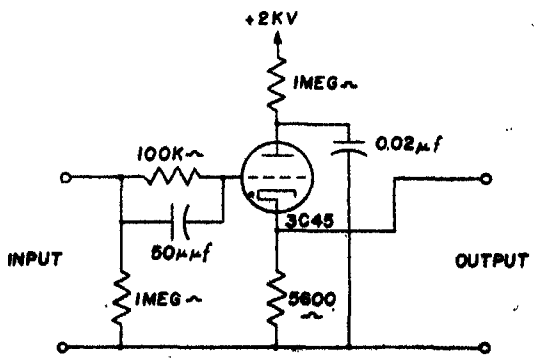

FIG. 9. Circuit diagram of 3C45 pulser.

The synchronizing system is capable of very precise timing. In a recent experiment,[2] in which the time resolution was 0.001 microsecond, no "jitter" could be observed in the time interval between the operation of two Kerr cells.

Oscillographic check on the timing of the multiple-shutter camera was maintained. Figure 11 is an oscillogram showing the three voltage pulses applied to Kerr cells 1, 2, and 3. The timing-wave frequency is 10 megacycles.

APPLICATIONS AND RESULTS

The Kerr-cell shutter is a useful device for obtaining exposure times in the microsecond and submicrosecond ranges. When a few frames are adequate, and in particular when framing rates are greater than 100,000 exposures per second, the multiple-Kerr-cell camera described will be useful. A particular application of this type of camera has been made in the study of microsecond electrical discharges of different types.

Figure 12 is a photographic record taken with the multiple-Kerr-cell camera, showing various stages during the vaporization of a single fine platinum wire. The effective exposure time, as determined by the Kerr-cell pulser, was 0.04 microsecond for each of the Kerr cells. The pulsing rate or interval between pulses was 0.01 microsecond; for this reason, the framing rate is said to be 10,000,000 exposures per second.

Figure 13 is a photographic record showing the vaporization of a single fine gold wire. The exposure time of each frame was 0.04 microsecond and the framing rate 40,000,000 exposures per second.

Using the multiple-Kerr-cell photographic technique, it has been possible to obtain a qualitative depiction of the vaporization process when fine filaments are electrically surged. Photographic record of the fuse action of such filaments continues to reveal interesting results. It is hoped that a more detailed report on this topic can be given at a later date.

CONCLUSIONS

It has been demonstrated that the multiple-Kerr-cell camera is a valuable and versatile device for obtaining photographic sequences of short exposure time and high framing rate. As a research tool it may find addi-

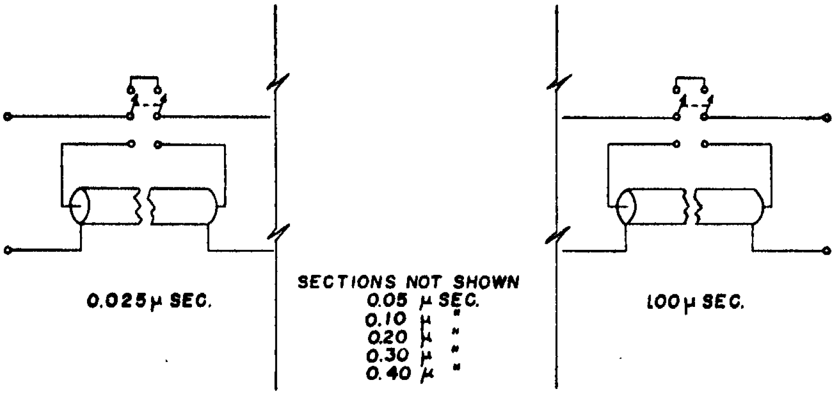

Fig. 10. Schematic diagram of time-delay box.

tional application to studies of ballistic and explosive phenomena.

APPENDIX

Comments on Purity of Nitrobenzene

A question frequently raised in Kerr-cell work concerns the effect of the purity of nitrobenzene on the operation of the Kerr cell. The consensus is that such impurities are important only because of their effect in increasing the electrical conductivity. For this reason the criterion of high purity is usually taken to be low electrical conductivity.

There appear to be three deleterious effects of increased conductivity of nitrobenzene.

(1) The loading effect of the lowered Kerr-cell impedance on the electrical circuits used to operate the Kerr cell needs no detailed comment. Difficulties may be avoided by proper design of circuits to be used.

(2) The heating of the Kerr cell by conduction currents—this is objectionable chiefly because non-uniform heating will cause optical distortion. Additionally, increased temperature lowers the Kerr constant of the nitrobenzene. Heating can be diminished by lowering the conductivity of the nitrobenzene by purification or, as is frequently possible, by short-time or intermittent application of voltage to the cell electrodes. Water jackets can be used to prevent temperature rise.

(3) The distortion of the electric field in the Kerr cell caused by concentration of ions near the Kerr-cell electrodes—this difficulty can be avoided if the potential is applied to the Kerr cell for so short a time that insignificant ion concentrations occur. H. J. White[4] states that this time is of the order of 0.01 second, but does not specify the conditions under which this is true.

Since the Kerr-cell shutters described in this report were operated at exposure times much shorter (i.e., in the order of 0.01 microsecond) than the time necessary for concentration of ions, one would expect the shutter operation to be highly independent of nitrobenzene purity. This expectation has been corroborated in two ways.

(1) It was observed that, over a period of months, the purity of the nitrobenzene in a Kerr cell deteriorates appreciably, but that no detectable difference in photographic results obtained.

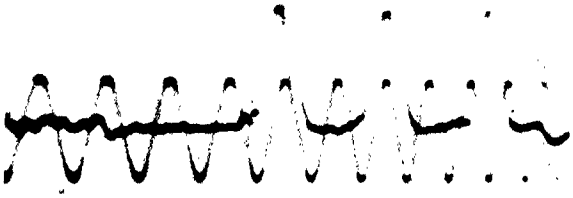

Fig. 11. Oscillogram of timing pulses applied to Kerr cells. The timing-wave frequency is 10 megacycles and the three pips indicate the instant of operation of cells 1, 2, and 3, respectively.

Fig. 12. Three stages during vaporization of a fine platinum wire. Effective exposure time per frame: 0.04 microsec. Framing rate: 10,000,000 exposures per sec.

Fig. 13. Three stages during vaporization of a fine gold wire. Effective exposure time per frame: 0.04 microsec. Framing rate: 40,000,000 exposures per sec.

(2) A measurement of the magnitude and duration of the optical transmission of a Kerr cell when operated at a 60-cycle repetition rate with a pulse duration of approximately 0.01 microsecond was made using two samples of nitrobenzene of widely different conductivity. Again, no difference in operation could be detected, indicating that under such pulsed conditions the purity of nitrobenzene is not a critical factor.

Although these experiments are definitely not critical, the results are in accord with those of White.[4] They are mentioned to provide added emphasis to this subject for those workers who may be considering the use of Kerr cells under pulsed operation.

A Method of Measuring Spurious Counts in Geiger-Müller Counters*

D. WILLARD AND C. G. MONTGOMERY
Sloane Physics Laboratory, Yale University,† New Haven, Connecticut

(Received February 13, 1950)

A counter was excited by a series of x-ray pulses of short duration occurring at regular intervals. Spurious counts were then easily recognized since they occur between the x-ray pulses. The counter pulses were displayed on an oscilloscope screen with a synchronized sweep and the counter deadtime, recovery time, and number of spurious counts determined by inspection. More quantitative information of the time distribution was obtained with an electronic circuit that recorded counts in a small arbitrarily chosen interval. It was found that the interval distribution shows at least two maxima. A mechanism is suggested for the appearance of the second maximum in terms of negative ions formed at the cathode by positive-ion bombardment.

THE principal difference between good and bad Geiger-Müller counters is the relative number of spurious counts, that is, counts caused by the action of no external agent. Nearly all recipes for counter construction were found with this criterion as the deciding factor; a good plateau means few spurious counts. Investigations of counter behavior necessitate a determination of the number of these spurious counts. If spurious counts are numerous, they are of course easily recognized; if they are few in number, it is extremely difficult to distinguish spurious discharges from those which are the desired result of an external agent. The only method by which spurious counts can be recognized is by a measurement of the frequency distribution of intervals between counts. An interval distribution with spurious counts contains more short intervals than a random distribution. Interval distributions have been measured by several observers[1] in the past. This method suffers from the disadvantage, common to all statistical measurements, that a large number of observations must be taken to obtain reasonable accuracy. We have therefore investigated a possible improvement in this method of distinguishing real from spurious discharges.

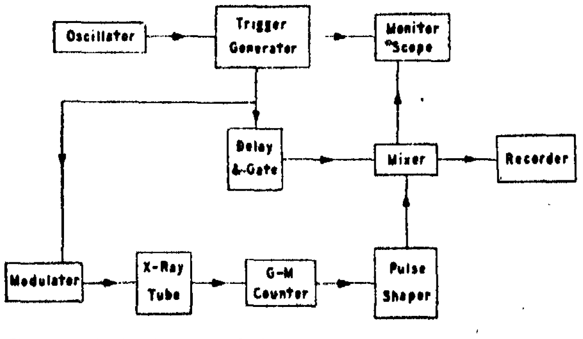

FIG. 1. Block diagram of circuit for counting spurious counter discharges within an interval delayed an arbitrary amount from a genuine discharge.

The number of genuine discharges can be increased at will with suitable sources of radiation, and the spurious counts are also increased. If, however, it is possible to arrange the true counts to occur at regularly spaced intervals and in sufficient numbers, then nearly all counts that take place between true counts are spurious ones and can be recognized readily. Ultraviolet light can be easily produced in pulses but most counters are either not photoelectrically sensitive or have absorbing envelopes. X-radiation, on the other hand, can penetrate most counter envelopes and can excite discharges even though the efficiency is not high. To obtain x-rays a standard tube with a tungsten anode (Type *RW*, General Electric Company) was used. Negative voltage pulses of 15 kv with a duration of 0.5 μsec. were applied to the cathode by means of a radar modulator, nicknamed "vest pocket" from an *AN/APS-2* radar. The pulse repetition frequency could be varied from 500 to 2000 per sec. The filament current was furnished by a low capacitance transformer. X-rays impinged on the counter and produced discharges which were amplified and inspected on the screen of a *P4-E* synchroscope which also furnished the trigger pulse for the modulator. The spurious discharges occurring between the x-ray pulses were easily visible and the screen could be photographed to obtain a permanent record. The size of the pulses was also evident on the screen and the deadtime and time of complete recovery of the counter could easily be observed. It was found in all cases that most spurious counts occurred at the time of complete recovery.[2] That is, spurious counts occurred following a genuine count when the positive ions formed in the genuine count reached the counter cathode and produced electrons which traveled to the anode and there gave rise to a spurious count. Not all spurious counts occurred at this time, however. Some happened before the counter was completely recovered, and others a considerable time after complete recovery.

It was difficult to obtain quantitative measures of the time distribution of the spurious counts from the synchroscope pictures and a counting circuit was devised for this purpose. Since the component parts of this circuit were all commonplace, only a block diagram is reproduced here as Fig. 1. A gate of adjustable length was formed which started at an arbitrary time after the trigger pulse. The number of counts admitted by the gate were recorded. A sample of the results obtained is shown in the curve in Fig. 2. For these data the pulse repetition frequency was 500 per sec., and the gate was 8 μsec. wide. It should be noted that the ordinate is plotted on a logarithmic scale. At the bottom of Fig. 2 is sketched the envelope of pulse heights on a linear scale as a function of time after the x-ray pulse. The counter used had a copper cathode 8 by 1⅝ in. in a glass envelope with a 0.003-in. wire. The filling gas was 1 cm of alcohol plus 9 cm of argon. The counter voltage was high, and the counter was operating above the plateau. It is evident from the figure that the spurious counts are distributed in time with two peaks, the first and larger at the time when the counter is fully recovered after the x-ray pulse and the second at approximately twice this interval. A graphical integration of the area under this curve plotted on a linear scale, resulted in a spurious counting rate of about 100 sec.$^{-1}$, or about one-fifth of the genuine counting rate.

[2] C. G. Montgomery and D. D. Montgomery, Phys. Rev. 57, 1030 (1940); J. Frank. Inst. 231, 526 (1941).

Putman[1] has analyzed his observations on spurious counts into a whole series of maxima such as this. He has suggested that each peak is composed of spurious counts which are the result of the counts occurring in the preceding peak. We have endeavored to extend our observations to find other peaks, since according to this hypothesis there must be an infinite geometrical series of them. We were unable to prove to ourselves that a third peak existed. Spurious counts do occur after the second peak, but the low counting rates prevented a certain detection of additional peaks.

Although the whole series of peaks of spurious counts undoubtedly occurs, it is possible that the second peak is higher because of another mechanism of production of spurious discharges. It may happen that when the positive ion sheath strikes the cathode after the genuine discharge not only electrons are formed but also some negative ions. These negative ions would travel in toward the counter wire, lose an electron by a collision near the wire and produce a spurious discharge. This discharge would occur at an interval after the genuine discharge equal to two traversal times for ions across the counter. The mechanism of formation of these counts is thus somewhat similar to the production of long time lags by electron capture.[3] It is well known that positive ions striking a metal surface sometimes do produce negative ions. In carbon dioxide gas, this process is apparently rather probable.[4] Counters containing alcohol vapor must eventually contain some CO_2 from the breakdown of the vapor during the discharge.

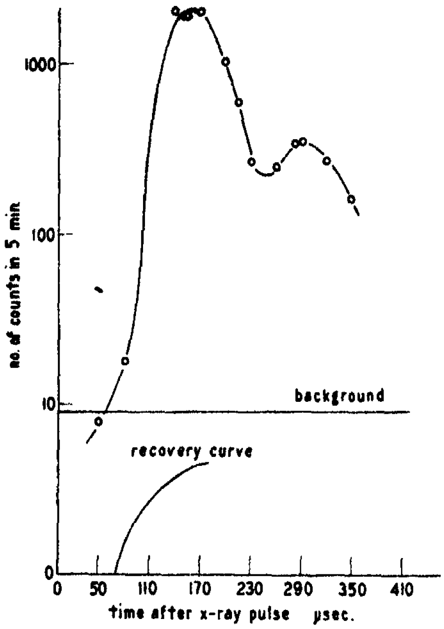

FIG. 2. Time distribution of spurious counts. The gate length was 8 μsec.

The Measurement of the Magnetic Field in a Nuclear Spectrometer*

L. M. LANGER AND F. R. SCOTT
Physics Department, Indiana University, Bloomington, Indiana

(Received February 27, 1950)

An arrangement is described which gives a continuous measurement of the relative magnetic field strength in a nuclear spectrometer with an accuracy of about 0.1 percent. The method consists of balancing the a.c. voltage picked up by a coil rotating in the field of the spectrometer against that picked up in a standard Helmholtz field.

INTRODUCTION

THE main limitation to taking full advantage of the high resolution available in a large nuclear spectrometer[1] employing iron has been that of obtaining sufficiently accurate determinations of the magnetic field strength. This difficulty can only be fully appreciated when one attempts to determine the shape of a line of internal conversion electrons whose spread in momentum ($H\rho$) at half-maximum is only 0.5 percent or less. Clearly, in order to be able to place ten to twenty points on such a line, one must be able to measure relative values of the magnetic field strength with an accuracy of 0.1 percent or better. It is further desirable to have available a continuous indication of the field strength so that predetermined settings may be made for optimum spacing of the data. The usual method of employing a flip coil and ballistic galvanometer does not readily satisfy either of these requirements. The elegant method of nuclear magnetic resonance is not applicable to the extremely low values of magnetic field which are necessary at low energies with a spectrometer employing a 40 cm radius of curvature.

The scheme to be described has been found to be extremely satisfactory. It is quick and simple to operate and yields results which are reproducible to better than 0.1 percent. Basically, it is a null method whereby the a.c. voltage picked up by a coil rotating continuously in the field of the spectrometer is bucked against a similar voltage picked up in the standard field of a set of Helmholtz coils. Measurements are made in terms of the accurately determined d.c. current through the Helmholtz coils. Although the general idea is straightforward, some of the details of the complete system may be of interest.

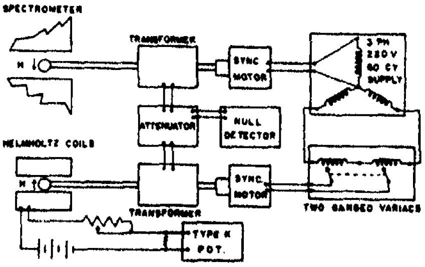

FIG. 1.

METHOD

Figure 1 shows a schematic arrangement of the system. The two pick-up coils are rotated by separate synchronous motors whose relative phase of rotation can be adjusted by means of the Variac arrangement. The voltages induced in the pick-up coils are brought out by means of the special transformers. These transformers have rotating primaries, which are rigidly connected to the shafts of the respective pick-up coils. The secondaries are stationary. By this means, the variable contacts usually associated with slip rings or brushes are avoided. The continuity of the magnetic flux through the core of the transformer is maintained by the means of the precision ball bearings. The transformer outputs are passed through an attenuator and balanced in a null detector. The attenuator is designed to permit operation over the extreme range of spectrometer fields (0–750 gauss) with only a relatively small change in the Helmholtz field. The attenuators offer constant loads to the generators on all settings so that no large phase shifts are encountered in switching scales.

In operation, the Helmholtz current and the phase of rotation are varied until a null is indicated. The magnitude of the Helmholtz current, as read on a type *K* potentiometer, gives a direct measure of the field. It is also possible to pre-set the Helmholtz current to correspond to a given field and then vary the spectrometer field until a null is obtained. This latter procedure is extremely useful in locating narrow electron lines.

DESIGN AND CONSTRUCTION

The Helmholtz coils are of conventional design. Five thousand turns of No. 22 Heavy Formvar magnet wire with a current of 200 milliamperes in each coil yields

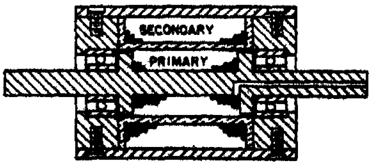

FIG. 2.

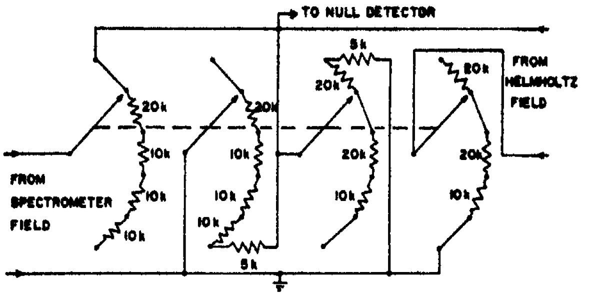

Fig. 3.

a field of 100 gauss at the center. The current for these coils is supplied by a 48-volt bank of storage batteries and is continuously variable by means of several rheostats rated for much higher currents than those employed. As indicated in the figure, the current is measured by means of a standard resistance and a type *K* potentiometer.

The pick-up coils each contain 30,000 turns of No. 40 Formvar covered wire and are wound on Lucite spools 1.4 in. O.D. and 1.1 in. long. The coils are held on brass shafts seven inches from the bearing support. No vibrational difficulties were encountered.

Although the design of the rotating primary transformers is far from ideal, they do serve satisfactorily to bring out the induced voltages with good wave form and without the use of rotating electrical contacts. As shown in Fig. 2, each primary, consisting of 6000 turns of No. 36 Formvar covered wire, is wound on an iron core which is directly coupled to the brass shaft supporting the pick-up coil. The secondary of each transformer contains 11,200 turns and is wound on a stationary brass spool which is supported concentrically around the primary by means of the iron shell. Precision ball bearings are used to complete the iron circuit.

The attenuator circuit shown in Fig. 3 permits balancing the whole range of spectrometer fields with the Helmholtz field varying only between the limits of 50 to 100 gauss. The upper limit is set to preclude any heating of the convection-cooled coils. The lower limit is imposed so as to minimize the effect of the earth's magnetic field on the calibration. The apparatus was calibrated for each step of the attenuator. Since the time constant seen by each generator remains essentially constant as the attenuator is switched, only slight phase shifts result. The exact phase balance is obtained with the Variac arrangement which provides a very sensitive means of shifting the one synchronous motor with respect to the other.

The null detector is a negative feed-back amplifier tuned for 30 cycles and discriminating strongly against 60 cycles. By avoiding the use of chokes and transformers the usable sensitivity of the instrument at 30 cycles is two microvolts. The balance is indicated on a "magic eye" tube.

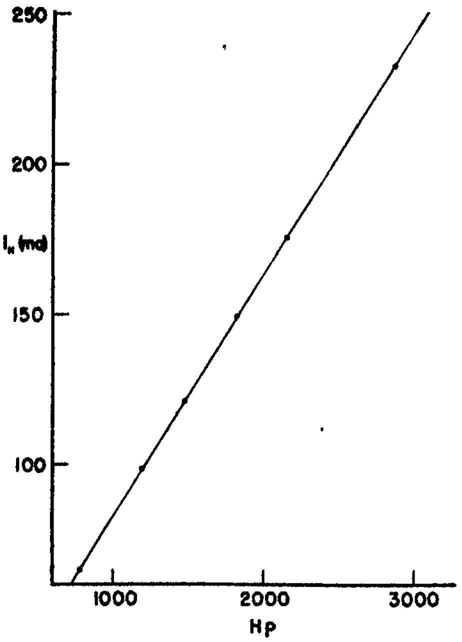

Fig. 4.

For the proper operation of the apparatus, the Helmholtz coils must be isolated from all stray magnetic fields. To minimize the effect of the earth's field, the Helmholtz coils are arranged with their axis horizontal. The vertical component of the earth's field which would give a quadrature component to the pick-up voltage is canceled out by means of an auxiliary set of degaussing coils.

CALIBRATION

For each setting of the attenuator, the spectrometer field was varied and the Helmholtz current required for a balance was determined. At the same time, the relative magnetic field was determined by repeated readings with a flip coil and ballistic galvanometer. The galvanometer was calibrated against a standard mutual inductance at each point. A section of the straight line calibration for one setting of the attenuator is shown in Fig. 4. The absolute calibration is in terms of the Au^{198} internal conversion line. Relative field settings may easily be made to better than 0.1 percent. The absolute calibration seems to remain constant to about the same accuracy.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 6 JUNE, 1950

Tests of Flowing Junction Diffusion Cells with Interference Methods

L. G. Longsworth
Laboratories of The Rockefeller Institute for Medical Research, New York, New York

(Received February 6, 1950)

The construction and manipulation of two diffusion cells, one of glass and the other of stainless steel, are described. In both cells the initially sharp boundary is formed by allowing solution and solvent to flow together into a narrow horizontal exit slit in the side wall of the diffusion channel. These cells have been tested by diffusion measurements with the aid of the Gouy interference method. Moreover, in the case of the metal cell which is provided with a reference channel in close proximity to that in which diffusion occurs, an interference method that gives the refractive index directly as a function of the height has also been studied.

INTRODUCTION

Although the use of the Gouy interference fringes[1-3] to follow the spreading of a boundary between solution and solvent permits precise measurements of ideal diffusion the available theory does not provide for those cases in which the coefficient is sufficiently concentration-dependent to give skew gradients. It is desirable, therefore, to adopt supplementary interference procedures for skew boundaries. Since the one suggested by Philpot and Cook[4] and by Svensson[5] gives the refractive index directly as a function of the level in the boundary it appears to be well adapted for the study of non-ideal diffusion and some preliminary tests with this method are reported below. Also included in this report is a description of two new diffusion cells, both of which utilize a modification of the siphoning procedure of Kahn and Polson[6] for the formation of an initially sharp boundary between solution and solvent. As in the British work[3] the modification consists in allowing solution and solvent to flow from below and above, respectively, into a narrow horizontal slit in the side wall of the diffusion channel. A boundary formed in this manner will be called a flowing junction boundary in order to distinguish it from one formed by a shearing mechanism as in the Tiselius,[7] Neurath,[8] and Claesson cells.[9] The results of tests of the new cells with the aid of the Gouy method are also described.

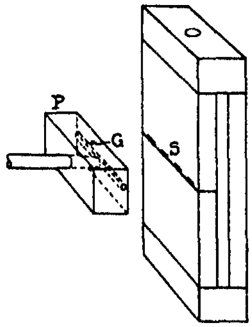

Fig. 1. The essential components of the glass diffusion cell.

THE DIFFUSION CELLS

One of the cells to be described has a stainless steel body with a closable exit slit in the diffusion channel whereas the body of the other cell consists of glass plates cemented together with a corrosion-resistant flux. Thus far it has not been possible to build a glass cell with cemented windows, as in the Tiselius cell, in which the optical quality is comparable with that of clamped windows. Consequently both cells have clamped windows, of 15 mm thickness, the flatness of which before clamping is better than one wave-length and the angle between opposite faces less than 20 sec. of arc. In both cells the cross section of the diffusion channel is 5×50 mm and the height 86 mm.

THE GLASS CELL

In the case of the glass cell the two most essential parts are shown in perspecitve in Fig. 1. The unique feature of this cell is the four colinear slits, *S*, at the center of the left-hand wall of the channel. Each slit is 5 mm in length and the spacing is such that the maximum horizontal distance that liquid must flow in entering one is 6.4 mm, a value only slightly greater than the narrow dimension, 5 mm, of the channel. The vertical dimension of the slits is 0.05 mm. Since the wall thickness is 8 mm, only 8 cu. mm of solution is trapped in these exit slits when the sharpening flow is stopped at zero time. The disturbances that may arise from the contact of this stagnant solution with the diffusing boundary are considered later in this paper.

The flow is stopped with the aid of the take-off plate, *P* of Fig. 1. When the face of this plate con-

taining the groove, G, of 2 mm square cross section is greased and pressed against the side of the cell so that the solution from the slits flows into this groove, and hence into the waste flask, F of Fig. 2, a vertical movement of this plate of 2 mm is sufficient to close the slits.

The arrangement for moving the take-off plate and for clamping the windows, W, to the cell is shown in Fig. 2, together with the brass masking plate, A, the solution reservoir, S_1, and the solvent reservoir, S_0. Although not shown in this figure the stopcocks of the reservoirs are provided with handles for operation from outside of the thermostat.

The filling procedure that appears to require the least material is to allow solution to run into the dry channel until the meniscus is just below the exit slit. With the waste flask disconnected, solvent is then slowly pipetted through the exit slit into the channel until it is filled and the meniscus has passed the stopcock of the solvent reservoir. Since some solution is thereby carried into the solvent portion of the apparatus this reservoir is rinsed, filled with solvent and its stopcock opened to allow the contaminating solution to be flushed out through the exit slit. Then with the reservoirs filled to the same level both stopcocks are opened and the boundary sharpened until the exit slit and stopcocks are closed at zero time.

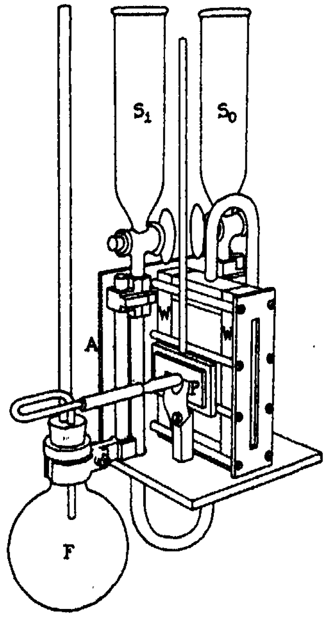

FIG. 2. The assembled glass cell.

THE METAL CELL

A horizontally exploded view of the stainless steel cell is shown in perspective in Fig. 3. When assembled as indicated in the figure the walls of the diffusion channel are formed by the plates A, B, and C whereas those of the reference channel are formed by C and D. Access to the reference channel is afforded by the tubes d and e whereas solution and solvent enter the diffusion channel through b and c, respectively. The tube a connects with the exit slit.

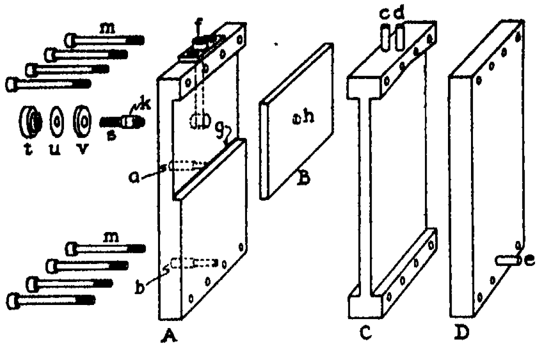

FIG. 3. Horizontally exploded view of the metal diffusion cell.

In this cell the exit slit may be closed, as described below, so that no stagnant solution remains in contact with the boundary. The plate B fits in the recess in A with a vertical clearance of 1 mm. Otherwise its dimensions are those of the recess. It is held with the post, s, that is threaded into a blind hole, h, in B, the thumbscrew, t, and the metal and Neoprene washers, u and v. A small vertical movement may be imparted to this plate by means of the hollow headed screw, f, that is threaded into the hole, k, of the post, s. Rotation, with the aid of an Allen wrench, of the screw f opens, or closes, the exit slit that is formed by the lower edge of B and the lower edge of the recess in A.

In order to insure uniform sharpening of the boundary along its entire length a groove, g, of relatively large cross section, 1.5×1.5 mm, funnels the solution into the tube a. Although not shown in Fig. 3 dowels are used between the screws, m, that hold the cell together and the window faces are ground, after final assembly, to a flatness of about one wave-length. Moreover since the windows serve as guides for the vertical movement of the plate B this plate is always left in the closed position when these windows are removed for cleaning. The filling procedure for the metal cell is similar to that for the glass cell.

OPTICAL METHODS

In testing the diffusion cells described above the Gouy interference method has been used in conjunction with the procedures outlined by Gosting *et al.*[10] and by the British workers,[3] for the determination of the normal slit image position and the fractional part, F, of the

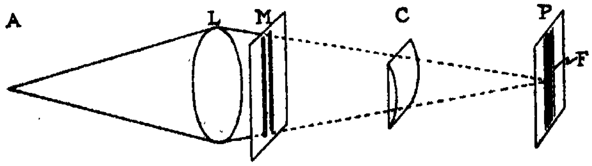

FIG. 4. Optical system of the concentration fringe method.

---

[10] Gosting, Hanson, Kegeles, and Morris, Rev. Sci. Inst. **20**, 209 (1949).

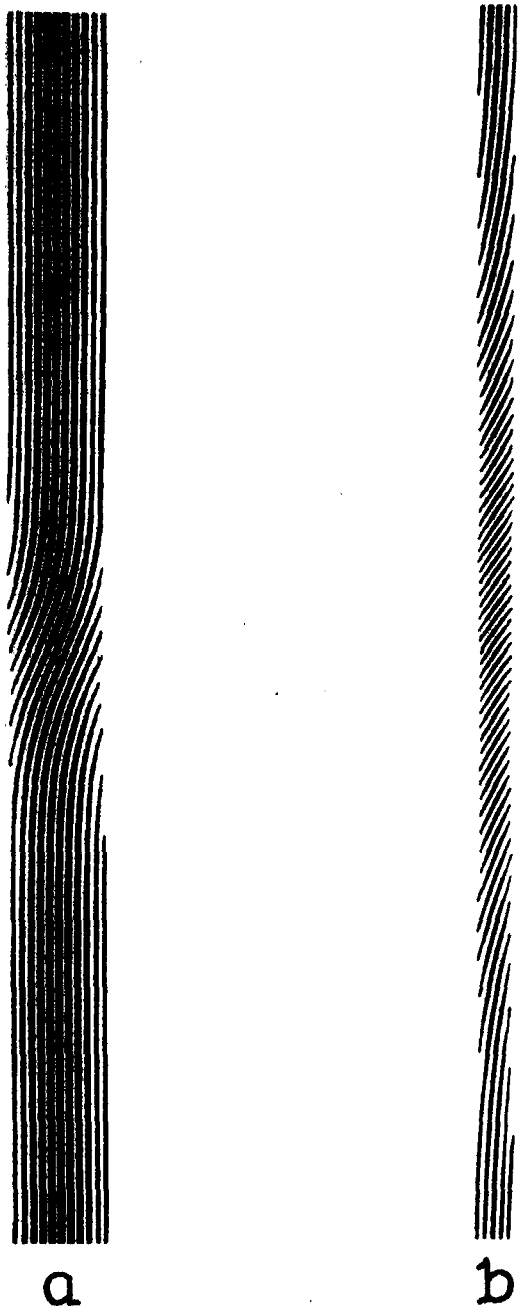

FIG. 5. (a) Photomicrograph of the concentration fringes obtained during the diffusion of 0.008N KCl into water. Slit width = 0.8 mm. Slit separation = 6.5 mm. (b) Photomicrograph of the concentration fringes obtained during the diffusion of 0.05N KCl into water. Slit width = 1.6 mm. Slit separation = 6.5 mm.

total fringe number, j_m. These procedures are clearly superior to those suggested by the author.[1] As in the British work the reference fringes are photographed simultaneously with those from the diffusion channel, superposition of the images being avoided by the use of a displacing plate in the reference path.

In the case of the metal cell it has been possible to supplement the Gouy method with one[4,5] that gives the refractive index directly as a function of the height in the boundary. The principle of this method is shown in Fig. 4 in which A is a point source of monochromatic light, L is a lens that forms an image of this source in the plane at P, M is a plate containing two vertical slits that mask the diffusion and reference channels, respectively, and C is a cylinder lens with its axis horizontal that focuses the cell vertically but does not affect the horizontal spacing of the Rayleigh fringes, F, that are formed at P by the vertical slits. If the liquid in the diffusion channel is homogeneous these fringes are vertical. With a boundary in this channel, however, they are warped, as shown in the photomicrograph of Fig. 5a, into a trace of the refractive index-height curve. With sufficiently narrow masking slits the number of fringes within the central diffraction maximum can be made to exceed the path difference, in wave-lengths, between solution and solvent. As is shown in Fig. 5a at least one of the fringes will then remain within the envelope throughout the transition from solution to solvent. This is the self-plotting procedure suggested by Philpot and Cook.[4] The author prefers, however, to use wider slits and larger concentration differences. As shown in Fig. 5b successive fringes then intersect the envelope diagonally as overlapping segments of the complete refractive index-height curve.

Fringes of the type shown in Fig. 5 will be called concentration fringes in order to distinguish them from the Gouy fringes that afford a measure of the concentration gradients in the boundary. Since the concentration fringes spread as the boundary spreads, whereas the converse is true of the Gouy fringes, the two methods supplement each other. Thus the Gouy fringes may be photographed during the early stages of diffusion, while the concentration fringes are frequently too close together to be resolved, after which the necessary changes in the optical system are made without disturbing the boundary and the concentration fringes then recorded. The changes consist in (a) the superposition of a vertical slit upon the horizontal one[11] that serves as light source in the Gouy method, (b) the insertion of vertical masking slits at the cell, (c) the removal of the displacing plate from the reference path and (d) the introduction of the cylinder lens.

EVALUATION OF THE PHOTOGRAPHS

The procedure for evaluating the Gouy fringe photographs has been adequately described elsewhere.[1,12] In the case of the concentration fringes the plate is aligned in the comparator with the vertical fringes that are conjugate to the homogeneous column of solvent above the boundary[13] parallel to the comparator axis and with the cross-hairs focused on a minimum, say. As the plate is moved the diagonal fringes conjugate to the boundary come under the cross-hairs and their positions are recorded as a function of the fringe number. Since each fringe corresponds to a path difference of one wavelength a plot of the comparator reading against fringe number gives, if the refractive index, n, varies linearly with the concentration, c, the concentration-distance curve in a coordinate system involving only apparatus constants. Moreover, since both maxima and minima can be used a 50-fringe system, for example, affords 100 datum. Using only the minima this is illustrated for a typical experiment in Fig. 6 where the small circles represent the comparator readings and the large circles the reciprocals of the tabular differences of these readings.

---

[11] As Philpot and Cook have noted, a vertically extended source may also be used but the fringe resolution is inferior to that with the essentially point source that is obtained with the crossed slits.

[12] L. G. Gosting and Margaret S. Morris, J. Am. Chem. Soc. 71, 1998 (1949).

[13] If solvent is also present in the reference channel, as is the usual procedure, these fringes are spaced symmetrically about a

When, in the foregoing comparation, the vertical fringes conjugate to the homogeneous column of solution below the boundary are reached, it is generally observed that the cross-hairs are now displaced from a minimum. If the comparator is provided with a graduated cross-axis movement, a value for the fractional part, F, of the total fringe number may be obtained from this displacement. It is better, however, to obtain F from a concentration fringe photograph that is taken during the sharpening process since at this stage the boundary is thin and the alignment of the plate in the comparator is less critical.

Since the comparator readings from a concentration fringe photograph are proportional to heights in the cell corresponding to a constant increment in n, and hence in c, they appear to be well adapted for tabular integration of Boltzmann's equation[14] and hence the evaluation of differential diffusion coefficients as a function of the concentration. However, as will be shown below, the author's present cylinder lens distorts the fringe pattern and no attempt to use the Boltzmann relation will be made until this distortion has been eliminated.

The following procedure for utilizing the data is due in part to L. J. Gosting and assumes that the diffusion is ideal. If, for example, $j_m=50.52$ the comparator reading, Δ, corresponding to the center of the boundary at which $j=j_m/2=25.26$ is determined by interpolation between the positions of the 25th and 26th fringe. This value of Δ is then subtracted from all readings to give the distance, H_j, on the plate of the jth fringe from the level conjugate to the center of the boundary in the cell at $h=0$. Since

$$\frac{\pm 2j}{j_m}\mp 1=\frac{2}{(\pi)^{\frac{1}{2}}}\int_0^{h_j/[2(Dt)^{\frac{1}{2}}]} e^{-y^2}dy,$$

a value of $h_j/2(Dt)^{\frac{1}{2}}$ for each fringe can be interpolated from the WPA "Tables of Probability Functions."[15] If A_j is the ratio of $(h_j/2(Dt)^{\frac{1}{2}})$ to H_j the diffusion coefficient, D, is then given for each fringe by the relation

$$D_j=(1/4t)(h_j/H_jA_j)^2$$

in which H_j/h_j is the magnification due to the cylinder lens, 1/1.533 in the present example.

In Fig. 7 values of D_j for a typical case are plotted against the fringe number and show a drift with that parameter that is probably due, not to boundary skewneww, but to imperfections in the cylinder lens that become evident when this lens is subjected to a Foucault knife-edge test. Moreover, these imperfections introduce a systematic error since the mean value, 2.409×10^{-6}, is 0.4 percent less than the Gouy value of 2.421×10^{-6} obtained earlier in the same experiment. It is clear that the simple plano-cylindrical element now available must be replaced by a corrected lens if the present apparatus is to yield precise results.

DISCUSSION

In testing with the aid of the Gouy method the cells described above the diffusion of 0.05N potassium chloride and of 0.379 percent sucrose into water has been studied. No significant difference between the results in the two cells has been observed. Thus at 1.01° in the metal cell sucrose gave a value of 2.421 $\times 10^{-6}$ while in the glass cell the value was 2.422×10^{-6}. The value reported by Gosting and Morris[12] for 0.5 percent sucrose at 1.00° was 2.418×10^{-6}. After correction to 0° the values for potassium chloride were 9.382×10^{-6} in the glass cell and 9.391×10^{-6} in the metal one. The value given by the Onsager-Fuoss theory is 9.399×10^{-6}.

The zero-time corrections in all of these experiments were 4–6 sec. and may be compared with values of 20–30 sec. observed by Gosting and Morris with a single tipped siphon, or about 10 sec. with a two-prong

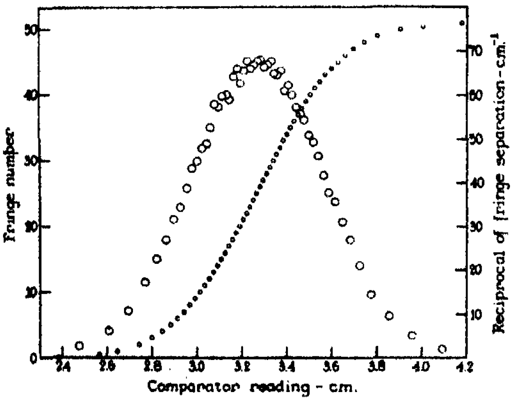

FIG. 6.

central maximum. It has been repeatedly observed, however, that this symmetry is lost if solvent is left too long in the reference channel. This is probably due to slow extraction, by the water, of a soluble component of the grease that is used in sealing the windows.

capillary. The exit slit thus represents an improvement over the Kahn-Polson procedure and yields boundaries whose sharpness is comparable with that of a shearing mechanism.

Except possibly in the case of the lowest Gouy fringes in the early photographs the stagnant solution in the exit slits of the glass cell does not appear to be a source of error. Computations for a 50-fringe system indicate that the path difference over the width of this slit is less than two wave-lengths after 515 sec. in the case of sucrose at 1° and 133 sec. for potassium chloride. At such early times the proportionality between the deflection and the gradient at the center of the boundary probably fails also[16] and the slit error is thus simply superimposed thereon.

Although the metal cell, with its reference channel, is the more adaptable of the two cells it is my impression that it is also more prone to warp. For example, as the metal cell has aged it has become difficult to close the exit slit completely. Although incomplete closure of this slit is not a source of error, if the stopcocks of the two reservoirs are also closed at zero time, it does indicate the difficulties in annealing the steel so that it will retain its shape. Similar experiences with a Claesson-type cell have made me skeptical of stainless steel as a satisfactory material for diffusion cells.

In the case of the optical system shown in Fig. 4 the horizontal spacing of the fringes increases as the separation of the masking slits decreases. In order to obtain precision in the measurement of the fractional part, *F*, of the total fringe number it is essential, therefore, to keep the partition between the reference and diffusion channels thin and in the metal cell it was possible to do this. It is also possible to do this in a glass cell if the windows are cemented but difficulties remain to be overcome if the windows are clamped. In this connection it may be noted that, caused, apparently, by the inhomogeneity of the green line in the *H*4 lamp, interference is not observed if the path difference is excessive. Thus one cannot use a limb of the Tiselius cell as a diffusion channel with the reference path through the adjacent thermostat water unless duplicates of the channel windows are included in this path. When this is done, however, the concentration fringe method may be used with this cell and preliminary experiments indicate that greater precision can be achieved thereby in the electrophoretic analysis of a protein mixture, say, than with the schlieren scanning procedure.

Although the present diffusion measurements were obtained with a twin lens system, i.e., parallel light through the thermostat and cell, the results with a single lens or convergent light system were the same. This affords experimental confirmation of the conclusion[2] that the spacing of the Gouy fringes is the same in both systems if the "optical lever arm," *b*, is determined correctly. In the convergent light system *b* is the optical distance from the center of the diffusion channel to the focal plane of the schlieren lens and was measured directly to the nearest 0.001 in. by means of a 9 in. micrometer, a set of seven 8 in. to 9 in. rods calibrated therewith and shorter telescoping rods. In determining the distance from the photographic emulsion to the thermostat window, for example, the calibrated rods were placed, end to end, in a brass tube whose length was somewhat less than the distance being measured and a telescoping rod set to fill the remaining gap. Its length was then determined with the micrometer and added to that of the rods. In the parallel light system *b* is the distance from the second principal plane of the second spherical lens to the focal plane. In order to avoid locating the principal planes of this lens the displacement of Rayleigh fringes by a prism that had been calibrated in the convergent light system was used in determining *b* for the parallel arrangement.

ACKNOWLEDGMENT

It is a pleasure to acknowledge my indebtedness to Mr. Emil Maier of the Pyrocell Manufacturing Company for his care and ingenuity in the construction of the glass cell and to Dr. D. A. MacInnes of this Institute for his critical review of this report.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 6 JUNE, 1950

Balloon-Borne Instrumentation for Neutron Detection*

MELVIN PAVALOW, WILLIAM O. DAVIS,† AND WILLIAM P. STAKER
Research Division, New York University, University Heights, New York, New York

(Received March 6, 1950)

A description is given of balloon-borne proportional counters and circuitry for telemetering and recording cosmic-ray neutron intensities. The preamplifier, amplifier, scaler, and trigger circuit described all use low drain directly heated battery-type tubes. Methods and reasons for pressurization of high voltage circuits are discussed. Included is a description of a multiple-level flight technique using single large plastic balloons for long time intervals at pre-set altitudes.

INTRODUCTION

To measure the neutron intensity as a function of altitude, BF_3 counters with suitable instrumentation were flown by means of free balloons to very high altitudes. In common with all balloon-borne cosmic-ray instruments it was essential that the circuitry and counters be as lightweight as possible. In addition, atmospheric neutron intensities are in general low, so that special attention must be paid to obtaining adequate statistics when measurements are made. This may be accomplished by using large counters, by increasing the pressure of the counter to increase its efficiency, or by operating the counters for a long period of time. Increasing the pressure of the counter would mean a higher operating voltage, thus using a large power supply and increasing the danger of corona, or alternatively, a high gain amplifier with very good stability which in turn would require more tubes and batteries, thus increasing the weight of the instrument. A compromise was reached by using a reasonable size counter, a medium gain amplifier, and operating for a long time at desired altitudes by means of a two-level balloon technique.

Most previous experimenters[1] have used a cadmium shield to discriminate against background in the measurement of slow atmospheric neutron intensities. In view of recent calculations by Davis[2] which show that a sizeable proportion of neutrons in the atmosphere are captured at energies above the cadmium cut-off, it is seen that such instrumentation will not give a true picture of the neutron intensity. In the present experiment, two counters were used, identical in construction and filled to the same pressure, but with one containing isotopically enriched BF_3 (96 percent B^{10}) and the other one containing isotopically depleted BF_3 (10 percent B^{10}).[3] If counters A and B are exposed to the same neutron flux, containing the same background of recoils and other cosmic-ray events, then the neutron intensity, N, is given by: $N=(A-B)/0.86$, and the background, b, is: $b=B-0.1N$; where A is the counting rate of the enriched counter, B that of the depleted counter, and N is the neutron intensity which would be measured by a counter filled with BF_3 containing only the B^{10} isotope.

This form of instrumentation effectively eliminates the high energy recoils and other background since B^{11} would presumably be as effective as B^{10} in this type of event. It has a major advantage over the cadmium shield method in that all neutrons are counted rather than merely those in the lowest energy region. In addition, there is no cadmium shield around one counter so no correction factor nor auxiliary tin shield is needed around the second counter.

A general block diagram of the circuit used is given in Fig. 1. It will be noted that the counters are operated with the outer cylinder at a high negative voltage and the central wire near ground potential. The purpose of this arrangement was to avoid the necessity of a large blocking condenser between the counters and the amplifier and also to avoid the necessity of bringing a high voltage line out of the pressure shield, or placing a bulky condenser inside. The purpose of the pressure shield will be discussed later.

The leads from the center wires of the counters emerge from the pressure shield through a hermetic seal and feed into the two sides of a single-pole-double-throw microswitch. The microswitch is actuated by a wooden rod, cam-driven by the program motor. The cam is cut for a two-to-one ratio of times. The cam wheel is geared to turn at approximately ⅓ r.p.m., giving approximately 3 min. on one counter and 1½ on the other. At the time of switching from one counter to the other, an auxiliary contact in the switching motor causes the telemetering transmitter to be modulated so that the time of switching may be recorded. This switching signal is different for the two positions so that it is possible to tell at once which counter is being recorded.

The counter pulse, taken from the microswitch, is fed into a simple cathode follower preamplifier and then into a two-stage resistance-coupled amplifier. A scale of four follows which is also a pulse-shaping circuit, and from here the pulse goes to the trigger circuit. Since a relatively low frequency a-m telemetering sys-

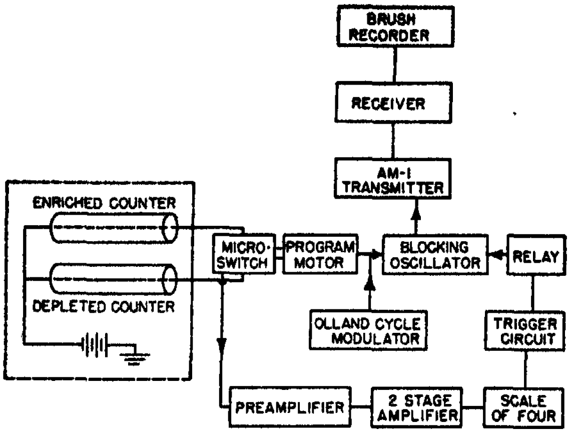

FIG. 1. General block diagram.

tem was used for maximum range (up to 500 miles), it was necessary for each count signal to be lengthened to about 0.2 sec. so that its characteristic modulation might be distinguished from random noise at great distances. Therefore, a scaler was found to be necessary because of the required long time constant of the trigger circuit.

The trigger circuit (a univibrator) contains the primary of a relay in its plate circuit. The relay secondary is in series with a resistor connected between the grid of a blocking oscillator and ground. When the relay closes, the blocking oscillator operates and modulates the transmitter. The auxiliary contact in the program motor and an Olland cycle pressure modulator[4] also cause modulation of the transmitter. The transmitted signal is received on a Hammarlund Super-Pro 400X receiver[5] feeding a Brush pen oscillograph.[6]

APPARATUS

The BF_3 proportional counters used in these experiments were especially filled in this laboratory. Commercial tank BF_3 was found to be unsatisfactory for the purpose. In addition to containing 20 percent B^{10}, a percentage which was not desirable for our purposes, counters filled with this gas were found to exhibit poor plateau characteristics even after multiple distillation. The gas appeared to contain impurities which could not be driven out in the purification process. It was concluded that even a fraction of a percent impurity had noticeable effect on the behavior of the counters.

A complex of $BF_3(BF_3\cdot CaF_2)$ in powder form was obtained both in the 96 percent B^{10} form and in the 10 percent B^{10} form. The powder was heated in an electric oven to drive off the gaseous BF_3, which was then filtered, passed through a dry ice and alcohol trap to remove water vapor and other high freezing-point impurities, and passed into the distillation system. Here the gas was frozen out in a liquid air trap and the system pumped out carefully. The liquid air was then removed and the BF_3 permitted to return to the gaseous state. On the basis of experiment, this process was repeated five or six times to be sure that most impurities were removed. The gas was then stored in a flask from which counters were filled. After pumping out, counters were outgassed in an oven for periods up to 24 hr. and then filled to a pressure of 17.6 cm Hg with the purified BF_3.

Each counter was calibrated in the following manner. First, a plateau check was made to be sure that each counter operated in the correct region and exhibited acceptable plateau characteristics. Counters were then checked for contamination background inside a boron shield. In all cases this background was found to be less than $\frac{1}{4}$ c.p.m. Counters were then given a long run close to a neutron source at their operating voltage using the same amplifier and scaler with which they would be flown. The counting rate was computed and compared with the counting rate of a standard reference counter given a similar run with the same equipment immediately thereafter.

It was not deemed feasible to make an absolute calibration of counters, since the distribution of neutron energies in paraffin or any other usual moderator is not the same as encountered in the atmosphere. Short of using a velocity spectrometer or some other device, it did not seem possible to make a calibration which would be of any value in determining the absolute sensitivity to atmospheric neutrons. Instead, one counter was used as a standard and others checked against it. When counters operated correctly there was never a deviation from the standard greater than the statistical fluctuation.

At the operating voltage deemed most suitable, the average pulse developed by a neutron is approximately 0.01 volt and 10^{-5} sec. in duration. The amplifying

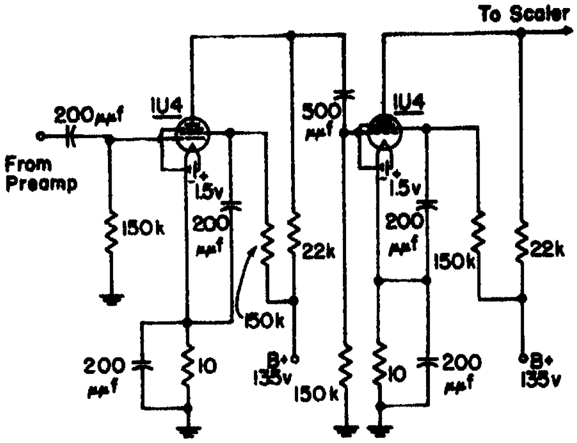

FIG. 3. Two-stage resistance-coupled amplifier.

system must therefore favor pulses of this size and discriminate against smaller and faster pulses.

The preamplifier (Fig. 2) chosen is a cathode follower. It meets the necessary requirements of providing a high impedance match to the proportional counter and a low impedance match to the amplifier. Other advantages of the cathode follower are that the output pulse is almost identical to the input pulse and of the same polarity. In addition, its degenerative feedback results in good stability and improves the circuit performance with respect to the variations in supply voltage. Its one disadvantage, however, is that it has less than unit voltage gain.

With a grid resistor of 10k ohms, an excellent reproduction of the input pulse was found at the output of the preamplifier. If a grid resistor of higher resistance were to be used, the pulses would be lengthened considerably. For example, a one-megohm grid resistor was found to lengthen the pulses by a factor of ten. This caused a large build-up of gamma-ray pulses from the source used for calibration, with the result that even though the bias of the amplifier was set to eliminate gamma-ray pulses, many large build-ups were occurring which rivaled neutron pulses in size.

The cathode follower consists of a 1*U*4 tube with a filament voltage of 1.5 volts and a filament current of 50 ma. The plate voltage is 67.5 volts with a plate current of 0.2 ma, and the over-all gain of the preamplifier is 0.8.

The resistance-coupled amplifier (Fig. 3) consists of two 1*U*4 tubes with plate voltages of 135 volts and plate currents of 0.1 ma. The maximum gain of the amplifier is found at 50 kc with its half-power points at 25 kc and 150 kc.

Because of possible feedback, each section of the amplifier has its own filament supply with the bias voltages developed across the cathode. The rise time of the amplifier is 1.1 μsec. while the delay time is 0.65 μsec. These small time constants are an advantage in that they allow the amplifier to recover quickly from a pulse, thus permitting fast resolving times.

The scaling circuit (Fig. 4) is a form of the Eccles-Jordan circuit consisting of two 3*A*5 tubes which are directly heated 1.5 volt dual triodes. Each tube makes up a scale of two. The filament current is 220 ma and the bias voltage for each section of the tube is developed across a common cathode biasing resistor in the filament circuit. The plate voltage is 135 volts with 1.2 ma flowing in the conducting tube and 0.6 ma flowing in the non-conducting tube. The circuit will handle approximately 10^5 evenly spaced pulses per second.

Without exception, all components in this scaling circuit are very critical. The components which are to be given extra special consideration are the plate resistors which have to be within 10 percent of each other and the grid and feedback resistors which have to be within five percent of each other. Another important factor that was taken into consideration in the design of the scaling circuit is the constant decrease of battery voltage with time during a flight. It was found that the circuit would work efficiently with a decrease of 20 percent in its voltage supply.

The output of the scaling circuit is passed through a differentiating circuit and on to the grid of the univibrator trigger circuit (Fig. 5). The univibrator is used to modulate the transmitter. It consists of one 3*A*5 tube with a plate voltage of 135 volts. The bias voltage is developed across the 2500-ohm resistor in the filament.

Individual trigger units sometimes were found to have a tendency to oscillate. When the mutual coupling between the plates and grids of the univibrator is purely capacitive, the bias voltage for both triodes is developed across the common cathode resistor. If the capacitor only had a resistance of 50 megohms, there was found to be current flow through the grid resistor, thereby adding an additional bias to the grid of the tube. This additional voltage caused the circuit to oscillate. There-

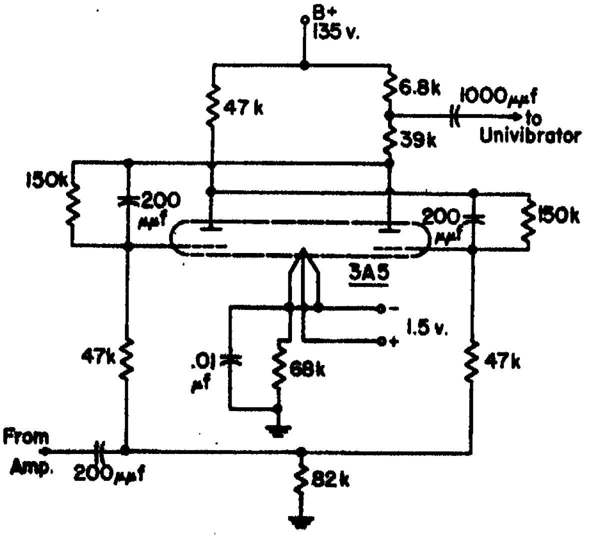

FIG. 4. Scale of two. A scale of four can be made by adding an identical scale of two to the output of the first scaler.

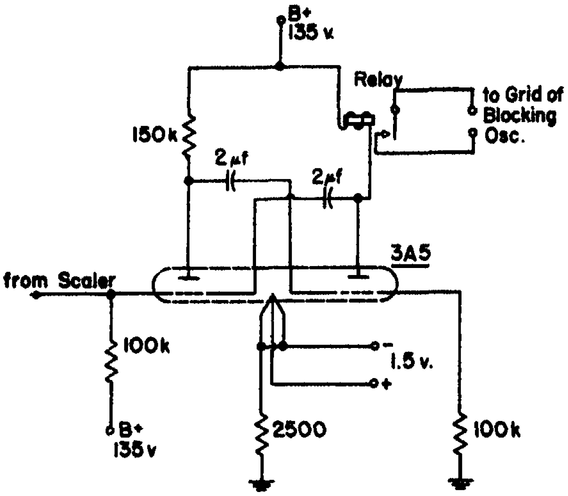

FIG. 5. Trigger circuit (univibrator).

fore only condensers with very high internal resistances, of the order of 1000 megohms, could be used.

A Sigma[7] relay (41*R*-5000G) is placed in the plate circuit of the second triode. The secondary of the relay is connected to the grid circuit of the blocking oscillator. The blocking oscillator is used to audio-modulate the transmitter. The length of time that the transmitter is modulated depends upon the time constant of the univibrator. The lightweight *AM*-1 transmitter used was designed especially for long-range flight by L. Hillman[8] of the New York University, College of Engineering, Research Division.

Two ground stations were used where possible, one at the launching site and one several hundred miles downwind, so that data could be recorded for a maximum possible time. These stations were identical, each consisting of a Hammarlund Super-Pro receiver feeding a Brush oscillograph. It is also necessary to receive information regarding the pressure at every moment during flight. The Olland cycle modulator is used for this purpose. The Olland cycle pressure modulator, as presently designed, contains a standard Signal Corps *ML*-310*E* radiosonde aneroid unit, a rotating cylinder of insulating material with a metal helix wound around the cylinder, and a 6-volt electric motor which rotates the cylinder. There are two contacting pens which ride on the cylinder and conduct electrical current when they touch the helix. One pen is fixed in position and makes a contact at the same time in each revolution of the helix. This contact is used as a reference point for measuring the speed of rotation of the cylinder. The time that the second pen, which is linked directly to the aneroid cell, makes contact with the spiral is dependent on the cylinder speed and on the pen position which is determined by the pressure. By an evaluation chart, the atmospheric pressure can be determined as a function of the relative position of the pressure contact as compared to the reference, thus eliminating all rotation effects other than short term motor speed fluctuations. The advantage of this system of modulation over the conventional type normally used for meteorological observations is that one can detect smaller fluctuations in pressure without ambiguity. The conventional type of Diamond and Hinman[9] apparatus adopted by the U. S. Weather Bureau does not allow one to know, when the balloon has been floating, whether it is ascending or descending until it crosses a reference point, which may be after a considerable length of time.

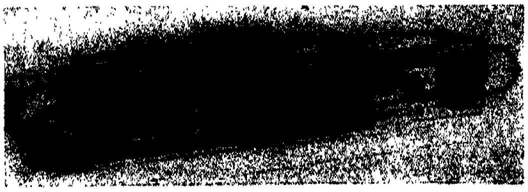

FIG. 6. Flight set.

As a result of a number of tests, it was determined that for consistent results without spurious counts the counters and high voltage system should be pressurized. Lack of this is evidenced by extra counts at atmospheric pressures corresponding to about 40,000 ft. or higher. These spurious counts can be traced to a corona discharge taking place between some point of the high voltage system and the frame. In addition, it has been noticed that within high voltage batteries themselves there appears to be a corona discharge when the pressure of the air surrounding them is less than 185 mb.

The method shown in Fig. 6 was used as the simplest expedient for obtaining a pressure tight system for these units. As it shows, the high voltage batteries are mounted in an aluminum box on the lower shelf of the frame. The circuit batteries are mounted on the same shelf so that all heavy materials are in the center and below the two counters. The pressure system, except for connecting tubing, is constructed of welded aluminum. Pressure gaskets are used to seal the lid on the box and the end plates on the counter containers. The high voltage leads to the counter cylinders from the battery box are contained in copper tubing sealed by means of standard flare pressure fittings. The low voltage leads from the central wire of the counter emerge through pressure fittings sealed by Neoprene gaskets and are fed to the microswitch through metal braid shielding.

The flight frame was designed to provide a minimum of scattering or star-producing material in the hemisphere above each counter, and in addition, the counters are mounted with their longitudinal axes in line so that a minimum solid angle is subtended by one counter upon the other. The entire circuitry is on one shelf above the batteries. Units are mounted individually so that in case of malfunction in the field any element may be removed and replaced without detailed trouble-shooting being required at the time. This precaution has proved invaluable on field trips, enabling changes to be made where necessary without requiring elaborate laboratory facilities on the spot. Batteries are connected to individual components by means of chassis connectors and spare packs are available so that in case of doubt a complete circuit battery change can be made instantly.

[9] Diamond, Hinman, and Dunmore, J. Research Nat. Bur. Stand. 18, 73 (1937); 20, 369 (1938); and 25, 327 (1940).

The frames themselves are of aluminum angle stock and are of all welded construction to insure strength and good electrical bond. A common point is chosen to which all circuits and the counter batteries are grounded. This is essential for proper operation of equipment which cannot be connected to an earth ground.

The transmitter, blocking oscillator, and Olland cycle modulator are a self-contained unit in a separate box which is bolted to the flight frame. The entire unit weighs approximately 57 lb. and is suspended from the balloon by means of four eyebolts on the top of the frame. To shield against outside electrical noise pick-up, the entire circuitry is surrounded by copper screening. Before flight the entire apparatus is wrapped in double Cellophane to maintain batteries at above freezing temperatures by means of the "greenhouse" effect.

MULTIPLE-LEVEL TECHNIQUE

The use of non-extensible balloons has become common in the past three years because of the large load they can lift and their inherent stability when floating at their maximum altitude. A non-extensible open-appendix balloon will tend to float at the altitude where it has just valved enough gas to make the lift equal to the load. In this work, it was desired to utilize this characteristic to obtain long times at two constant levels.

Flights were launched carrying a large amount of liquid ballast in the form of aircraft compass fluid which has excellent low temperature viscosity characteristics. The balloon would then level off at an altitude corresponding to a lift just equal to the total load, including the ballast. After a desired time interval, a chronometric switch would fire electrically operated explosive squibs to open a drain in the bottom of the ballast reservoir and permit ballast to drain out. After all ballast has gone a second squib was used to cut the supporting line and permit the ballast reservoir to descend by parachute. As a result of this loss of weight the balloon would then ascend to a new equilibrium altitude where it would again float.

In this manner it was possible to compare counting rates at two different altitudes with excellent statistics. The spread in altitudes obtainable by this process is about 10,000 to 15,000 ft. at 50,000 ft. with the payloads used in these experiments. For smaller payloads the spread could be made greater. The advantages of this method for application to specific measuring problems are obvious. The major disadvantage is that the launching of large plastic balloons calls for experienced crews, large launching areas, and low surface winds.

The authors would like to express their appreciation for the guidance and assistance of Professor S. A. Korff, Director of the New York University Cosmic-Ray group. In addition, they would like to acknowledge their indebtedness to the New York University Balloon Project, under the technical direction of William Murray and J. R. Smith, for making the balloon flights, and to M. J. Swetnick, H. Neuburg, and L. G. Collyer for assistance in the filling of counters and the construction of flight sets.

Announcement

From time to time, the Institute has received inquiries from subscribers for information as to where and how they may have their copies bound. After investigation the Institute has found that this may be best accomplished by selecting a capable bindery that will work to our specifications and produce a well-bound volume at as low a price as possible. The necessary arrangements have been completed with the Book Shop Bindery, 308 West Randolph Street, Chicago 6, Illinois.

The volumes will be bound in the best grade of washable buckram with facsimile gold stamping on the spine and the subscriber's name in gold on the front cover. A distinctive color for each of the Journals has been selected as listed below. Advertising matter and covers are removed before binding. The price of $3.00 per volume applies to any of these journals regardless of size. Issues, comprising complete volumes, should be sent by prepaid express or parcel post to the Book Shop Bindery. Bound volumes will be shipped approximately 30 days after receipt. Return transportation will be prepaid when remittance accompanies order.

No deviation in color or specification can be allowed in view of the favorable price.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 6 JUNE, 1950

Nuclear Emulsions and the Measurement of Low Energy Neutron Spectra*

Norris Nereson and Frederick Reines
Los Alamos Scientific Laboratory, Los Alamos, New Mexico

(Received March 8, 1950)

An experiment was performed with Ilford Type *C2* nuclear emulsion to determine the usefulness of photographic plates for measuring neutron fluxes and spectra by proton recoils in the region of the low energy limit of the emulsion. The results show that the plates give valid data for neutron flux determinations and energy distributions down to a neutron energy of about 0.5 Mev. Below 0.5 Mev the proton recoils give low values for the number of incident neutrons but approximate results can be obtained down to 0.3 Mev by applying a correction factor in this energy region. The experimental results permit a range-energy curve for protons in *C2* emulsion to be determined for the energy region from 0.2 to 1.5 Mev. Finally, recoil proton energy distributions obtained from neutron irradiations of *C2* plates at various low energy values are presented and discussed.

INTRODUCTION

SEVERAL recent experiments at the Los Alamos Scientific Laboratory have involved the measurement of neutron spectra by means of nuclear emulsions. Frequently, the interesting part of the spectrum has occurred in the 0.1 to 1 Mev energy decade which contains the low energy limit above which nuclear emulsions can be used for measuring neutron or proton energies. Some investigations have been made of the high energy limit of nuclear emulsions but very little information has appeared on the reliability of nuclear plates at low energies. Therefore, the chief purpose of this investigation has been to determine the practical low energy limit of proton recording nuclear emulsions and the reliability of these emulsions at low energies for measuring neutron spectra. The work has been restricted to measurements of proton recoils making a small angle with the direction of the incident neutron.

EXPERIMENTAL TECHNIQUE

In order to ascertain the usefulness of nuclear plates at low energies, the plates were given neutron irradiations at various energies from 0.24 to 1.54 Mev. The Los Alamos Van de Graaff machine and the reaction $H^3(p,n)He^3$ were used for the exposures as shown in Fig. 1. The plates were placed at 0° with respect to the proton beam, with their emulsion surfaces parallel to the beam. Each plate was exposed to the same number of neutrons as monitored by a long counter[1] placed $1\frac{1}{2}$ meters from the target. This type of counter has a response which is flat to within 10 percent over the range of neutron energies used in this experiment.

The spread of neutron energies arising from the target assembly of the Van de Graaff was minimized by having the tritium at a low pressure equal to 15 cm of mercury. This resulted in a tritium thickness to protons of about 30 kev or a proton energy spread of ±15 kev. A thin aluminum foil of 1.4 mg/sq. cm separated the tritium from the proton accelerating tube. The aluminum foil thickness was determined by carefully weighing about ten samples of the foil material used in the target and then averaging these values. The energy spread arising from variations in the thickness of the aluminum foil was difficult to determine; consequences of this phenomenon are mentioned later in the section on Conclusions. Neutron energy degradation and scattering in the target were negligible since the tritium container walls were of 10-mil steel. Since the initial proton energy was accurately known, the average energy of the protons reacting with the tritium could be obtained by subtracting the aluminum foil thickness and one-half the tritium thickness from the bombarding proton energy. The neutron energy is then computed from the conservation of energy and momentum and the known Q of the reaction.

Care was taken to minimize the number of scattered neutrons entering the emulsion by holding the plate at the back with a very light support. Also, the tritium target was well in the clear and distances to large scattering objects were great compared with the distance from the target to the plate. However, in spite of the above precautions, scattered neutrons seem to have slightly influenced the results.

Ilford *C2* plates (batch number *Z2283*) were used in the experiment. The average thickness of the emulsion measured about 85μ before processing and between 34 and 37μ after processing. The plates were analyzed with microscopes using a 90× oil immersion objective (N.A. of 1.3) and a 12× compensating eyepiece. One of the eyepieces contained a suitable measuring scale and the other a 20° angle with bisecting line. The area analyzed on the 1×3-in. plates was restricted to a small section 1 cm long by 2 mm wide about the center line of the plate; this section was started about 5 mm from the front edge of the plate. By confining the area studied to this region, the maximum angle which a neutron from the tritium target could make with the plate center line was 2°. The average angle of the incoming neutron was about 1° and this accuracy is well within the limits of error of the measurements described below.

[1] A. O. Hanson and J. L. McKibben, Phys. Rev. 72, 673 (1947).

The method of analysis was similar to that used by Richards[2] and consisted of measuring the proton recoil tracks about a small angle in the forward direction. The angle was restricted so that only tracks making an angle of less than 10° with the center line of the plate were measured. Due to film shrinkage during processing, the 10° angle limitation restricts the original azimuthal angle of the proton track to a maximum of 23° to 25°, depending upon the amount of shrinkage.

In order to select data containing a minimum number of tracks which penetrated the emulsion surface, tracks originating in a small thickness of emulsion on the top and bottom were ignored. For energy values above 1 Mev, two microns of emulsion thickness were skipped at the emulsion surface and for values below 1 Mev, the thickness ignored was one micron. Using this procedure, less than one percent of the total tracks measured were observed to leave the emulsion.

The plates measured in this experiment were purposely given a small neutron irradiation so as to present a useful or measurable track density of one to two tracks per microscope field (about 300,000 cubic microns). A small track density aids in several ways: (1) the possibility of obscuring short tracks by longer tracks is minimized; (2) the number of background grains produced by gamma-rays usually present with neutron sources is decreased by a short exposure; and (3) the tendency of observers to select long tracks and overlook short ones is minimized.

The difficulty in analyzing *low energy* (<0.5 Mev) proton tracks by the methods described arises not so much in measuring their lengths as in determining whether or not the azimuthal angle of the track is within prescribed limits. Since one micron is a practical limit[3] for the depth of focus in the microscopes in use here, the decision as to whether any track length less than 5.5μ (or 0.5 Mev) is within the 10° angle limit is subject to error. Therefore, measurements of proton energies below 0.5 Mev by different microscopists might be expected to differ as to the relative number of protons present in each energy interval. This difficulty might be eased by choosing a greater angle limit but such a choice would decrease the energy resolution of the method and the corrections to be applied to the observed proton energy become quite large. However, for spectra which vary slowly with energy, a large angle limit for the tracks is a less serious objection. Another aid for increasing the accuracy in determining the azimuthal angle of short, as well as long, tracks might be a tilting stage microscope.[4]

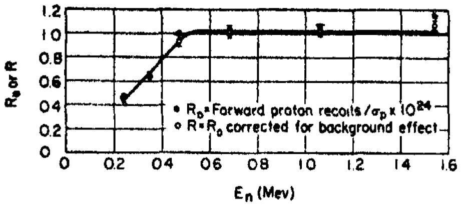

FIG. 2. Response of Ilford *C*2 nuclear emulsion to low energy neutrons.

Since the personal element enters into an experiment of this type, the more important results of the experiment have been based upon the findings of two experienced microscopists working independently.

EXPERIMENTAL RESULTS

1. Application to Flux Measurements and Monochromatic Neutrons

Since all the plates were bombarded with the *same* number of neutrons, each plate at a different energy, the number of recoil proton tracks in the forward direction should also be equal after being corrected for the variation with energy of the *n, p* collision cross section (σ_p) and background effects. These results are tabulated in Table I and are shown graphically in Fig. 2. The solid circles illustrate the nuclear emulsion response (R_0) to neutrons as determined by dividing the number of forward proton recoils (for equal emulsion volumes) by the *n, p* cross section. The open circles provide a better approximation for the emulsion response (R) to neutrons, as these points represent the R_0 values corrected for background effects (see the section on Conclusions). The two high neutron energy values at 1.54 and 1.06 Mev were analyzed in order to provide data in an energy region where the use of nuclear emulsions is known to be valid. However, the reliability of these two points is weakened to a certain extent since the background effect increased with energy. The values obtained below 0.5 Mev have been corrected to take into account the variation in response of the long counter monitor. The long counter used in this experiment had a sensitivity of 95 percent at 0.5 Mev and drops to 85–90 percent in the 0.2- to 0.4-Mev region.

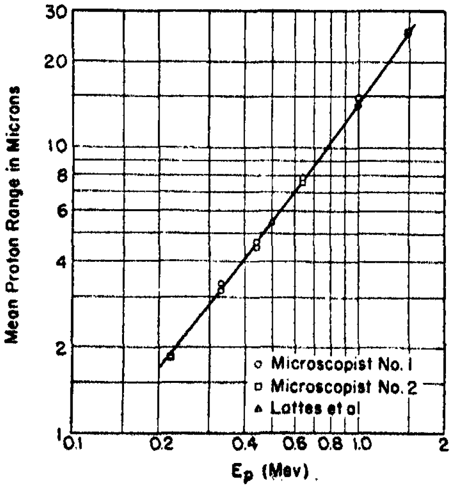

FIG. 3. Range-energy curve for protons in Ilford *C*2 emulsion at low energy values.

Figure 2 provides information on the reliability of nuclear plates for measuring neutron fluxes at various energy values, i.e., the point at a certain energy represents *all* the forward proton recoils, irrespective of their energy, arising from the bombarding neutrons of this energy. The results show that the corrected number of proton recoil tracks remains essentially constant until the 0.47-Mev point is reached. Therefore, one would conclude that nuclear emulsion data provide correct experimental values for the relative number of neutrons arising from monochromatic sources, except below 0.5 Mev. Data taken at neutron energies below 0.5 Mev by the above technique will be in error. It seems satisfactory to utilize as approximate data these low flux values in the energy region from 0.3 to 0.5 Mev if they are appropriately corrected according to Fig. 2. It should be emphasized that these corrected measurements at energies below 0.5 Mev are less reliable and subject to greater error than measurements at higher energies.

The result at 0.24 Mev is low by a factor of two. The agreement obtained here between the two microscopists is considered to be somewhat fortuitous. Comparison of spectral curves from different readers lends support to this contention. The use of the data obtained by the method of analysis employed here cannot be recommended for this low energy. In consequence, microscopists have also found that the determination of track acceptability in this energy range, that is, whether they fall within prescribed angular limits, is very time-consuming. Furthermore, there exists the possibility that the background grains may occasionally give the appearance of very short tracks.

2. Proton Range-Energy Relation

As a by-product of these investigations involving known neutron energies, it was possible to determine a proton range-energy curve in *C*2 emulsion in the region from 0.2 to 1.5 Mev. For each neutron energy, a plot was made of the number of proton recoil tracks (in the forward direction) measured at each division of the microscope eyepiece scale. Each division was equal to approximately 0.5μ. The peak of this curve was taken as an uncorrected mean range. The proton range obtained from this curve corresponds to an energy less than the neutron energy from the Van de Graaff, since most of the proton recoils are measured at a small angle to the incident neutron direction and hence are less energetic than the incident neutrons. The theoretical energy value at which a maximum occurs in a graph of proton recoil tracks per unit energy interval *versus* proton recoil energy is determined in Appendix II.

This energy value is taken to be associated with the uncorrected mean range value as determined above. The results of the analysis show that this energy is 5±1 percent lower than the neutron bombarding energy.

The data for the proton range-energy curve in the region from 0.22 to 1.48 Mev are listed in Table I and a curve is illustrated in Fig. 3. The agreement above 0.5 Mev between values from this experiment and from those of Lattes and others[5] is good. Range-energy values below 0.5 Mev obtained from the curve in Fig. 3 are listed in Table II.

3. Use of $N^{14}(n, p)C^{14}$ Reaction to Check Emulsion

Before discussing the proton recoil distributions obtained from the Van de Graaff exposures, it is appropriate to mention a side experiment which was performed in connection with this investigation as a check on the properties of the emulsion. This experiment consisted of exposing an Ilford C2 100μ plate in the thermal neutron flux of the "water boiler" at the Los Alamos Laboratory. The result should be tracks representing the sum of ranges of the proton and C^{14} arising from the nitrogen in emulsion by means of the reaction $N^{14}(n, p)C^{14}$. The energy of the protons should be 14/15 of the Q of the reaction. If an average Q value of 0.62 ±0.01 Mev is taken for this reaction,[6] 0.58-Mev protons should be observed. Previous calculations indicate that the C^{14} track comprises ~2 percent of the combined proton and C^{14} range.[7] Since the proton range was only measured to an accuracy of ±3 percent, the C^{14} track would hardly be detected in the present experiment. In this experiment, the proton source was unquestionably monochromatic so that any irregularities in the shape of the proton distribution could be traced to properties of or techniques associated with the nuclear emulsion rather than to the source.

The plate was analyzed by measuring all tracks with azimuthal angles in the processed emulsion less than 10°. The horizontal projections were measured rather than the actual track lengths. However, since the average inclination angle of the measured tracks is only 5°, the consequent error in the range is less than 0.5 percent.

The proton energy distribution derived from a measurement of about 400 tracks in this check experiment is shown in Fig. 4. The curve indicates a maximum at 0.58±0.01 Mev which agrees with the expected value. A plot of the number of tracks *vs.* range shows a maximum at 6.7±0.2μ for the combined proton and C^{14} range. This is in good agreement with the combined range value of 6.6μ obtained by Cuer.[7] The proton distribution in Fig. 4 shows a Gaussian-type curve having a half-width at half-maximum of 0.05 Mev. Evidently, this half-width must be accounted for by proton range straggling in the emulsion, the size and spacing of the grains, and observational error. Only the proton range straggling is felt to be important. The curve is quite symmetrical,[8] a result to be expected from natural range straggling. These results indicate that the nuclear emulsion yields the expected distribution curve from a measurement of monoenergetic protons.

[8] The reason for the few low energy tracks on the extreme left side of the distribution is uncertain. A possible explanation is that they are alpha-tracks arising from some (n, α) reaction with the oxygen or nitrogen present in the emulsion.

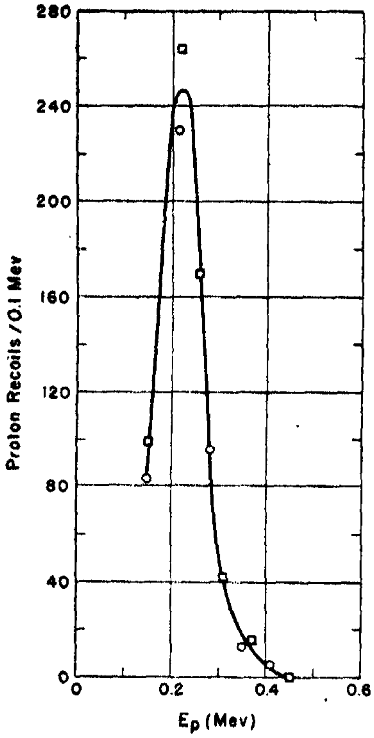

FIG. 5. Proton recoil distribution from $E_n = 0.24$ Mev.

from the Van de Graaff neutron exposures are plotted in Figs. 5 to 10 inclusive. Each graph gives the measured number of recoil proton tracks per 0.1-Mev interval as a function of the proton recoil energy. In each case the results of two microscopists are illustrated. Each set of data from a reader comprises a total of about 300 measured tracks except in Fig. 10, where, due to the larger energy spread, each microscopist measured a total of 600 tracks. Except for Figs. 5 and 6, the general shape of these curves is asymmetrical with a disproportionate number of tracks on the low energy side.

In order to determine whether the above-measured proton recoil distributions are reasonable, it was necessary to know the shape of the proton recoil spectrum admitted by the experimental geometry, i.e., by the prescribed angular limits referred to in the method of analysis. This proton recoil spectrum has been calculated in Appendix I. The result represents the proton recoil spectrum which would be obtained if range straggling or missing grain phenomena discussed below did not exist. However, the experimentally measured spectrum will be the admitted proton recoil spectrum modified chiefly by range straggling. This problem is solved in Appendix II for different straggling magnitudes. It was found that if the straggling is represented by a Gaussian curve, the best fit to the distributions was obtained by using a Gaussian half-width of 0.05 ±0.01 Mev. It is encouraging that this corresponds to the half-width obtained in examining the protons from the $N^{14}(n, p)C^{14}$ reaction (Fig. 4). The calculated spectrum using a Gaussian half-width of 0.05 Mev has been superimposed as a dashed line on the experimental data for the neutron energies above 0.24 Mev. The height of the calculated spectrum was normalized to that of the experimental curve. The agreement between the experimental and calculated distributions is quite good for the lower energy distributions but only fair for the higher energy distributions (i.e., for 1.06 and 1.54 Mev).

In all cases the disagreement occurs on the low energy side of the curve below the half-maximum value. Probable reasons for this discrepancy will be mentioned at the end of this paper.

An examination of the proton recoil distributions for points below 0.5 Mev suffices to show why the values below 0.5 Mev in Fig. 2 are too low. In both of these low energy distributions, the left side of the curves extends into the region below 0.3 Mev or track lengths less than 2.8μ. This region contains tracks consisting of about five grains and less. Track lengths which should consist of five grains may, on account of straggling, result in only two or three grains and such tracks will certainly be missed. Furthermore, as shown in Appendix III, for tracks having less than a nominal five grains, the probability that the track will appear shorter due to the chance absence of grains at either end is not negligible. For example, if the probability that any one grain is missing is[9] x, the probability of observing a

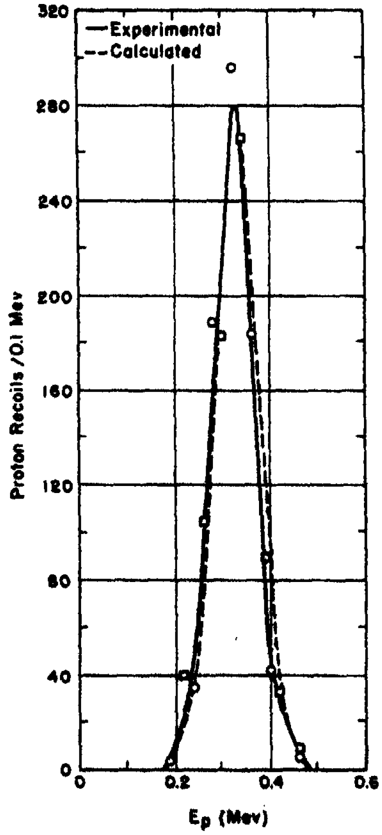

FIG. 6. Proton recoil distribution from $E_n = 0.35$ Mev.

---

[9] Direct evidence on the value of x is not available. However, it appears that in the case of alpha-particles, if development is delayed for 12 hr. as in the present work, the average grain density drops to ~80 percent of the value which obtains for

track shorter than the four-grain length it would have if $x=0$ is (cf. Fig. 17) 11 percent for $x=0.3$ and 20 percent for $x=0.5$.

Therefore, it is to be expected that distributions whose low energy regions extend below approximately 0.3 Mev will show an abnormally low track count. Note that the low energy portion of the proton recoil distribution from 0.47-Mev neutrons begins to extend into this region, and, therefore, might be expected to be in the neighborhood of the lowest energy at which a correct value could be obtained for a neutron flux measurement. Except for the case of the distribution at 0.24 Mev, no serious attempt was made to measure tracks containing less than a few grains because of the difficulty of distinguishing random background grain patterns from true tracks. More detailed study was made in the 0.24-Mev case chiefly to secure a point for the range-energy curve at this value.

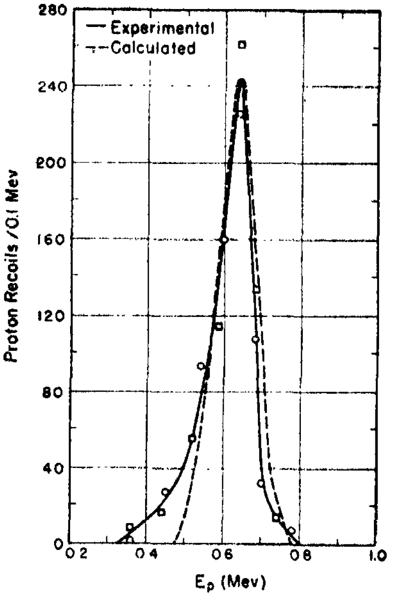

FIG. 8. Proton recoil distribution from $E_n=0.68$ Mev.

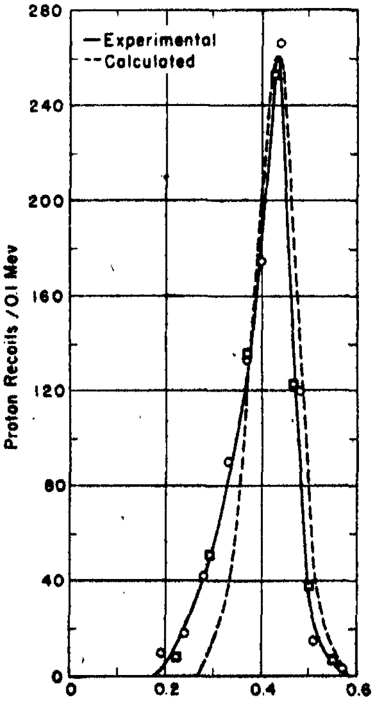

FIG. 7. Proton recoil distribution from $E_n=0.47$ Mev.

5. Application to Neutron Spectra Measurements

The results of this experiment can also be utilized to determine the usefulness of nuclear plates for measuring mixed monochromatic neutron sources or continuous spectra. In order to investigate the reliability of such measurements, suppose that a source consists of neutron groups having energies of 0.35, 0.45, 0.65, 0.85, and 1.05 Mev, with each group emitting the same number of neutrons per second. If a proton plate is exposed to such a source and analyzed by measuring recoils in the forward direction, the individual distributions from each energy value should closely resemble those drawn in Fig. 11; the measured or total proton recoil distribution curve obtained from this analysis should then be the sum of these individual distributions. The solid line distribution curves in Fig. 11 represent the Van de Graaff data (Figs. 4 through 10) which correspond best with the above-listed energies. Small errors arise from the facts that the experimental data do not exactly represent the energies in the assumed source and, where exact representation does occur, the observed maxima are slightly lower than the energies of the incident neutrons. Each of the solid curves in Fig. 11 has been normalized so as to represent data from the *same volume* of processed emulsion. The dashed curve at 0.85 Mev has been guessed, using the shape of adjacent curves as a guide.

One method of obtaining the approximate intensity distribution at the maxima of the neutron source assumed above is to determine the number of proton recoils (corrected for σ_p) occurring in 0.15-Mev[10] intervals taken about the peak of the curves. This number should be equal if the emulsion detector and the associated recording technique are energy independent. Since this is not the case, it is interesting to ascertain the useful energy range of this technique for correctly measuring neutron intensity of continuous spectra.

The number of proton recoils was obtained by summing the areas under *each* curve passing through the particular 0.15-Mev interval containing the energy value as midpoint. These sums are plotted as circles at the midpoint of each energy interval. The odd-spaced distribution at 0.35 Mev was included in order to determine the usefulness of spectrum measurements in the 0.3- to 0.4-Mev interval. The contribution to the

---

immediate development. Cf. H. Faraggi and G. Albouy, Comptes Rendus 226, 717 (1948).

[10] An analysis using 0.1-Mev intervals gave similar results.

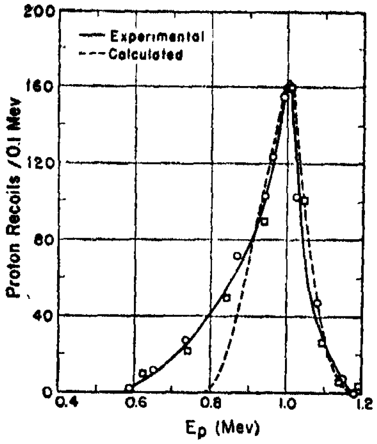

Fig. 9. Proton recoil distribution from $E_n = 1.06$ Mev.

0.35-Mev interval from the 0.55-Mev distribution is drawn as a dotted line at the base of the 0.275- to 0.425-Mev interval.

The numbers of proton recoils divided by σ_p are plotted as triangular points in Fig. 11; this curve exhibits a constant region at the high energy end and drops off at the low energy end. The curve is not plotted beyond the 0.85-Mev interval because the experimental data at higher energies are less reliable. (See the section on Conclusions.) The main point of this analysis concerns the low values obtained at 0.35 and 0.45 Mev as compared to the results at 0.65 and 0.85 Mev; this comparison demonstrates the decreased efficiency of the emulsion for measurements at low energies. In order to give the correct number of neutrons the point at 0.45 Mev should be increased by 10 percent and the one at 0.35 Mev by about 50 percent. Since the long counter has a sensitivity of around 90 percent at 0.35 Mev, this correction should be raised to 55 percent. Although no measured value is available for the point at 0.55 Mev, a reasonable interpolation indicates that this value should be increased by five percent or less. These results are similar to those discussed in connection with Fig. 2. The lack of proton recoils in the low energy distributions is due chiefly to the large straggling effects. These straggling effects produce tracks which will be missed either because they are too short or because they lack too many grains to be recognized as tracks.

6. Comparison of Emulsion with Cloud Chamber

The following independent experiment was conducted to provide additional data on the reliability of nuclear emulsions for measuring continuous neutron spectra in the region of the low energy limit of the emulsion. A well-collimated neutron beam having a spectrum which decreased rapidly with increasing energy in the region from 0.3 to 1 Mev was investigated with *both C2* nuclear emulsion and a hydrogen-filled cloud chamber. A total of 2000 proton recoil tracks taken within 15° of the forward direction were measured in the energy range from 0.1 to 0.8 Mev with the cloud chamber. The nuclear emulsion data covered the energy range from 0.3 Mev and upward and consisted of 4000 proton recoil tracks measured by two experienced microscopists who used the previously described technique. The cloud-chamber data were normalized to the film data in the 0.5- to 0.8-Mev energy region. Good agreement existed between the slopes of the two sets of data in the normalizing or matching region. However, below 0.5 Mev the film data fell below the cloud-chamber results. Table III shows the resulting corrections to be applied to the emulsion spectrum data as derived from a comparison with the cloud-chamber data and from the previous analysis (Fig. 11) using the Van de Graaff data.

Except for the 0.3- to 0.4-Mev interval, the correction factors as derived from the two experiments agree satisfactorily. The correction factors obtained from the cloud-chamber comparison are more reliable since they were derived in a more accurate and direct manner than those obtained from the Van de Graaff results. The influence of scattered neutrons on the Van de Graaff results is commented on in the section on Conclusions. Only the correction value for the 0.3- to 0.4-Mev interval can be appreciably affected by scattered neutrons and, to adjust for this effect, this value might well be increased from 55 to about 70 percent.

7. Straggling

The proton recoil distributions from the Van de Graaff and the proton distribution from the $N^{14}(n, p)C^{14}$ reaction show that a half-width (at half-maximum) of 0.05±0.01 Mev can be expected from straggling effects alone in Ilford C2 emulsion. Within the accuracy of these experiments, this width appears to be energy independent over the 0.5- to 1.5-Mev interval studied. If the half-width divided by the energy is taken as a measure of the straggling, then the proton energy straggling varies from 10±2 percent at 0.5 Mev to 3±1 percent at 1.5 Mev. The *latter value* can be compared with Bethe and Livingston's results[11] and is found to be in agreement within experimental error

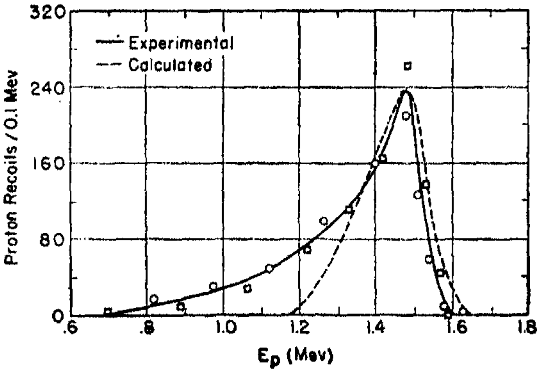

Fig. 10. Proton recoil distribution from $E_n = 1.54$ Mev.

---

[11] H. A. Bethe and M. S. Livingston, Rev. Mod. Phys. 9, 285 (1937).

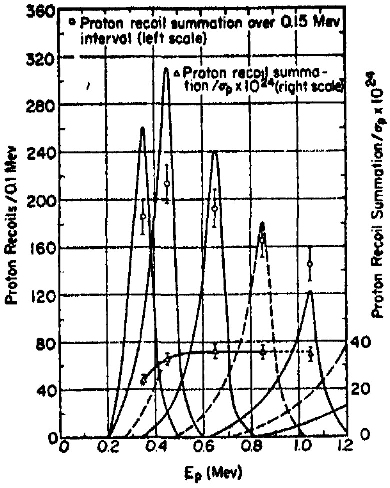

FIG. 11. Application of individual proton recoil distributions to determine usefulness of nuclear emulsion for low energy neutron spectral measurements.

with the energy straggling of ~2 percent as calculated from their curve. The above experimental straggling values are comparable with the results of Lattes *et al.*,[12] who have obtained a half-width of about 0.08 Mev at 3.2 Mev for proton straggling in *B*1 emulsion.

In the type of spectral analysis used in this experiment, that of counting recoils in the forward direction, the energy spread of the proton recoils as admitted by the experimental geometry becomes comparable with the energy spread due to proton range straggling at energies around 1 Mev. This causes the absolute magnitude of the energy width of the distribution curves to increase with energy in this type of analysis. It is, however, customary to express the width as a fraction of the energy or range. This has been done in Fig. 12 where the energy half-width of the distribution curves, expressed as a percentage of the mean proton energy, has been plotted against the energy (solid curve). It must be emphasized that this particular curve is of value for indicating proton recoil energy widths for neutron spectra only if the analysis is performed according to the technique used in the present work. The half-width to be expected from straggling effects alone is shown as a dashed curve in Fig. 12. For the energy range covered in this experiment, the latter curve is merely obtained by plotting 0.05/*E* expressed in percent *vs.* *E*.

TABLE III.

Neutron spectrum energy interval	Percentage increase to be applied to nuclear emulsion data From Van de Graaff results	 From cloud-chamber comparison
0.7–0.8	None	None
0.6–0.7	None	None
0.5–0.6	<5 percent	None
0.4–0.5	10 percent	10 percent
0.3–0.4	55 percent	75 percent

CONCLUSIONS

The present experiment provides information on the accuracy of proton recoil data from nuclear emulsions for determining numbers of neutrons and neutron spectra at low energies. Results show that correct data are obtained for energies above about 0.5 Mev and that approximate data can be obtained down to 0.3 Mev if suitable corrections are applied. The proton range *vs.* energy relation below 0.5 Mev is presented for *C*2 emulsion. Proton recoil distributions obtained from low energy neutron exposures and analyzed by the technique of measuring recoils in the forward direction are presented and discussed.

The experimental distributions from recoils in the forward direction can be approximately described by a function representing the admitted proton recoil spectrum on which is superimposed a Gaussian function of half-width equal to 0.05 Mev. Only the extreme low energy side of the experimental curves is in serious disagreement with the above composite function. A measurement of areas reveals that the experimental curve has an excess area over that of the calculated curve equal to 13 percent at 0.47 and 0.68 Mev, 20 percent at 1.06 Mev, and 25 percent at 1.54 Mev. The exact reason for the excessive number of these low energy tracks is not clear. The fact that the distribution from the $N^{14}(n, p)C^{14}$ reaction was as expected and that the above disagreement occurs consistently throughout the entire energy range would indicate that the surplus low energy tracks probably reflect the spectrum of the neutrons striking the film.

It seems most logical to assume that the excess low energy recoils arise from neutrons leaving the tritium target in the backward direction and then being subsequently scattered into the film by heavy materials surrounding the back of the target. Although the number of neutrons produced in the backward direction is not large,[13] the solid angle subtended for scattering of

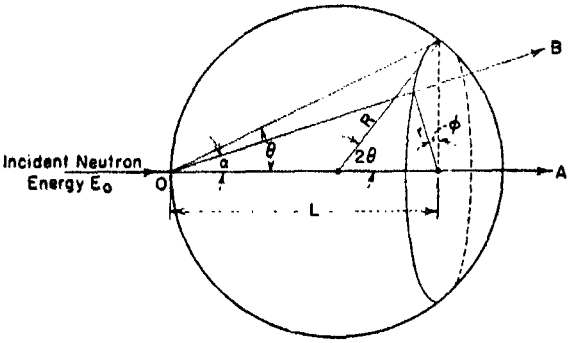

FIG. 13. Reference figure for calculation of proton recoil spectrum.

these neutrons by Van de Graaff components and structures is probably great enough to produce the observed effects. The following subsidiary facts also support this supposition. The disagreement between the calculated and experimental distribution increases with energy. This would be expected, since the yield of the T(p, n)He^3 reaction in the backward direction increases with proton energy.[13] The distribution curves show that the lowest energy is approximately one-half the highest energy observed. This result is consistent with the fact that the reaction produces a neutron in the backward direction with roughly one-half the energy of that produced in the forward direction. It is unfortunate that the nuclear emulsion detector exaggerates the number of scattered neutrons, since the cross section for proton recoil production is more favorable for the scattered low energy neutrons than for the higher energy neutrons coming directly from the target. Approximate corrections can be made for the effect of these scattered neutrons. However, in the important energy region of this experiment, namely, at low neutron energies, the number of scattered neutrons is small compared to the number of neutrons direct from the target.

It might be imagined that the aluminum foil in the target assembly could give rise to the observed straggling. This explanation is rendered unlikely by the reasonable agreement, at the high energy ends of the distribution curves, between the calculated and experimental results.

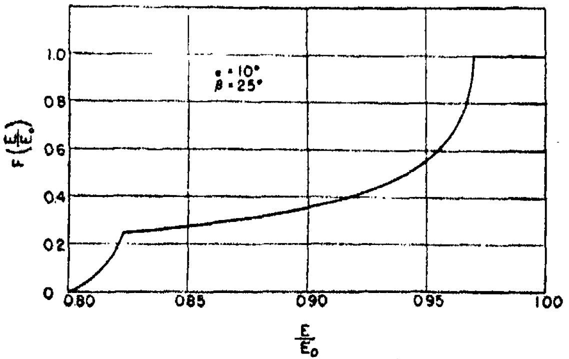

FIG. 14. Proton recoil spectrum, $F(E/E_0)$, admitted by experimental geometry.

In reference to Fig. 2, the corrections to the number of proton recoils due to the presence of the low energy scattered neutrons can be estimated from the following expression:

$$R=R_0\left(1-\frac{p_1}{p}\right)\left[1+\frac{1}{(\sigma_{p1}/\sigma_{p0})((p/p_1)-1)}\right], \quad (1)$$

where R is a measure of the film response; $R_0=p/\sigma_{p0}$ is the uncorrected response; p is the total number of proton recoils per unit volume of emulsion; p_1/p is the fraction of proton recoils ascribed to the scattered neutrons (this factor is estimated from the difference in area between the experimental and calculated curves); σ_{p0} is the $n-p$ cross section for the bombarding neutrons; σ_{p1} is the estimated average $n-p$ cross section for scattered neutrons. The correction is everywhere less than 10 percent.

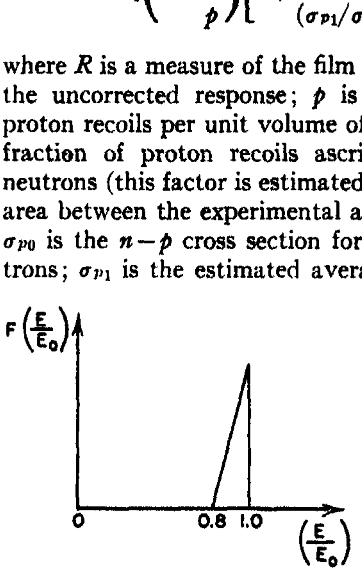

FIG. 15. Approximate proton recoil spectrum admitted by experimental geometry.

The range-energy relation is not influenced by the scattering since the experimental and calculated distribution curves agree well beyond the energy region where the maxima of the curves are located; from this it can be concluded that the peak of the curve is not shifted by the presence of the scattered neutrons.

The spectrum analysis presented in Fig. 11 may be appreciably influenced only in the 0.35-Mev result. The results as presented at the 0.45-, 0.65-, and 0.85-Mev points are derived from distributions which contain about[14] 15±3 percent scattered neutrons. If these spurious neutrons had not been present but instead their number was replaced by neutrons direct from the target, the effect would have been to increase the area in the above three intervals by approximately 15 percent. This area increase would, in turn, raise the portion of the curve marked by triangular points by the same factor, and the ordinates of the 0.45- and 0.55-Mev intervals relative to those for the higher energies would not change appreciably. It is more difficult to estimate the effect of the scattered neutrons on the 0.35-Mev point since the experimental and calculated distributions are in agreement. This agreement may be due either to the fact that the scattered neutrons are too low in energy to be recorded by the film, or because their number may be small (~5 percent) at this energy.

---

[14] Since no experimental measurement was made for the 0.85-Mev interval, an interpolation was used to give the percentage of scattered neutrons in this interval; the result, a value of about 17 percent.

Assuming the first statement is true and employing the same reasoning as given above, the 0.35-Mev point should also be raised but not as much as at the higher energies because of the smaller percentage of scattered neutrons at this energy. In either case, the 0.35-Mev point would not change significantly. Consequently, its value relative to the flat portion of the curve would be decreased, and the correction required to make it agree with the flat portion is raised from the previous 55 to ~70 percent.

The authors wish to thank Jewell Erickson and Dorothy Squires of the microscopy laboratory for their services in reading the nuclear emulsion plates used in this experiment. Appreciation is also expressed to the Van de Graaff group at Los Alamos for their cooperation and the use of their machine.

APPENDIX I. RECOIL PROTON SPECTRUM ADMITTED BY EXPERIMENTAL GEOMETRY

Consider a beam of monochromatic neutrons incident on the photographic emulsion from the left. The geometry employed in this experiment admitted all recoil protons within a vertical angle $\pm\alpha(\pm 10°)$ and a horizontal angle $\pm\beta(\pm 25°)$. We first consider the limitation on the spectrum set by the angle $+\alpha$ (Fig. 13). The angle α is the angle between diametral line OA and the plane indicated by OB.

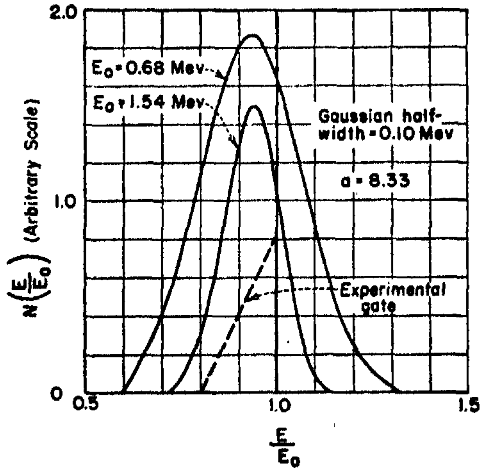

FIG. 16(a). Calculated proton recoil spectrum, $N(E/E_0)$, for a Gaussian half-width of 0.10 Mev at $E_0=0.68$ and 1.54 Mev. (Ordinates of the curves are not normalized.)

From conservation laws, the energy, E, of the recoil proton is

$$E=E_0\cos^2\theta. \tag{2}$$

From Fig. 13, elementary trigonometry, and Eq. (2),

$$\phi=\cos^{-1}\left[\left(\frac{E/E_0}{1-E/E_0}\right)^{\frac{1}{2}}\tan\alpha\right]. \tag{3}$$

The angle ϕ measures the fraction of the solid angle at energy E/E_0 which is excluded by the experimental geometry.

If we consider the intersection by two planes at right angles to each other and passing through point O at angles of α and β, respectively, with diametrical line OA, ϕ becomes

$$\phi=\cos^{-1}\left[\left(\frac{E/E_0}{1-E/E_0}\right)^{\frac{1}{2}}\tan\alpha\right]+\cos^{-1}\left[\left(\frac{E/E_0}{1-E/E_0}\right)^{\frac{1}{2}}\tan\beta\right]. \tag{4}$$

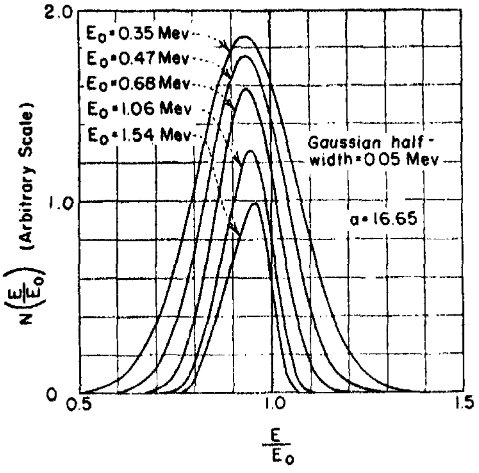

FIG. 16(b). Calculated proton recoil spectrum, $N(E/E_0)$, for a Gaussian half-width of 0.05 Mev at all experimental values of E_0. (Ordinates of the curves are not normalized.)

The fraction of the solid angle admitted by the experimental geometry is

$$F(\alpha,\beta,E/E_0)=1-(2/\pi)\phi. \tag{5}$$

Figure 14 gives the calculated spectrum for $\alpha=10°$, $\beta=25°$.

APPENDIX II. CALCULATION OF THE APPARENT PROTON RECOIL SPECTRUM

The true proton recoil spectrum as admitted by the geometry of this experiment from a monoenergetic neutron source is that given in Appendix I. The apparent or measured spectrum should be expected to differ from this because of the phenomenon of straggling. If the sum total of the straggling effects is taken to be Gaussian, as seems reasonable, it is possible to deduce an observed spectrum for any assumed half-width using the recoil proton spectrum admitted by the experimental geometry given in Appendix I. Judging by the spread of the experimental curves, the Gaussian half-width is about 0.05 Mev. In consequence, it was felt to be reasonable to replace the rather complicated function of Appendix I by a triangle, Fig. 15, so that

$$F(E_p/E_0)=C_1[(E_p/E_0)-0.8], \tag{6}$$

where E_0 = neutron energy, E_p = recoil energy, $1>E_p/E_0>0.8$, and C_1 is a constant.

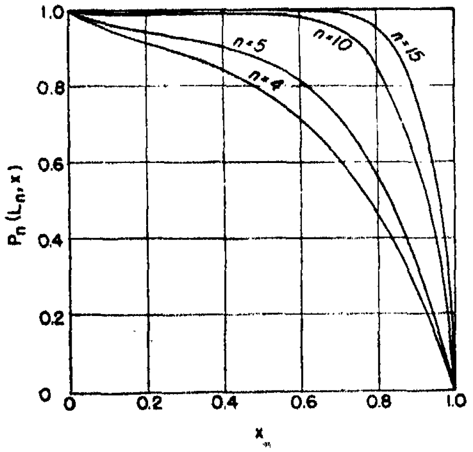

FIG. 17. $P_n(L_n, x)$ vs. x for $n=4$, 5, 10, and 15.

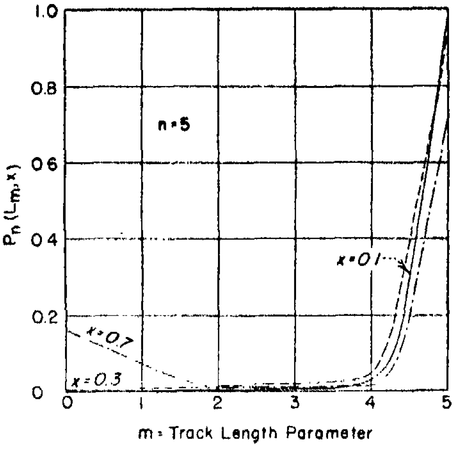

FIG. 18(a). $P_n(L_m, x)$ *vs.* m for $n=5$ and $x=0.1$, 0.3, and 0.7.

The measured spectrum, $N(E/E_0)$, should then be given by

$$N(E/E_0)=C_2\int_{0.8}^{1}F(x)\exp\left[(-a^2E_0^2)\left(\frac{E}{E_0}-x\right)^2\right]dx, \tag{7}$$

where the half-width of the Gaussian is determined by the constant a and C_2 is a normalization constant. Equation (7) has the virtue that it can be integrated in terms of tabulated functions. The result is

$$\frac{N(E/E_0)}{C}=\frac{(\pi)^{\frac{1}{2}}}{2}\frac{[(E/E_0)-0.8]}{aE_0}$$
$$\times\left[\frac{2}{(\pi)^{\frac{1}{2}}}\int_{aE_0[0.8-(E/E_0)]}^{aE_0(1-E/E_0)}\exp(-x^2)dx\right]+(1/2a^2E_0^2)$$
$$\times\{\exp-[aE_0(0.8-E/E_0)]^2-\exp-[aE_0(1-E/E_0)]^2\}, \tag{8}$$

where C is a constant.

The spectrum given by Eq. (8) has been plotted in Fig. 16(a) for two different neutron energies, $E_0=1.54$ and 0.68 Mev used in this experiment, and for a Gaussian with half-width$=0.10$ Mev. Figure 16(b) illustrates Eq. (8) plotted for all the neutron energies used in this experiment and for a Gaussian half-width$=0.05$ Mev. The experimental proton recoil distribution curves have been compared with these calculated curves in Fig. 16(b), i.e., the dashed curves in Figs. 6 to 10.

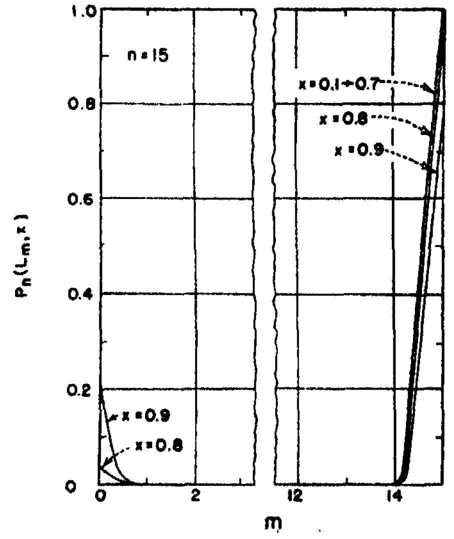

FIG. 18(b). $P_n(L_m, x)$ *vs.* m for $n=15$ and $x=0.1$ to 0.7, 0.8, and 0.9.

The spectrum has a maximum which is located no lower in energy than the center of area of the gate. This result is independent of the gate shape and follows directly from Eq. (7). As the Gaussian half-width is increased the spectrum maximum shifts to the left. From (7) the condition for the maximum as $a\rightarrow 0$ is

$$\int_{0.8}^{1}F(x)\left(\frac{E'}{E_0}-x\right)dx=0$$

so that

$$\frac{E'}{E_0}=\int_{0.8}^{1}xF(x)dx\bigg/\int_{0.8}^{1}F(x)dx. \tag{9}$$

Since for a triangular gate $E'/E_0>0.933$ and $E'/E_0=0.95\pm0.01$ for a half-width of 0.05 Mev, it is seen that the location of the maximum is insensitive to the Gaussian half-width. The lowest value of E'/E_0 is 0.930 for the actual experimental gate given in Appendix I.

We wish to thank the Los Alamos computing group under Bengt Carlson and Max Goldstein for performing the numerical work.

APPENDIX III. CHANGE OF APPARENT PROTON RECOIL SPECTRUM DUE TO LOSS OF GRAINS

It appears from the analysis given below that the apparent increase in the number of short recoil proton tracks due to the probability that a given grain along the track is not rendered developable is negligibly small except in the case of tracks having ~5 grains or less. We assume that the range of the proton in the emulsion is dependent only on its energy. This seems reasonable in view of the approximate equality of the stopping powers of the silver bromide grains and the remainder of the emulsion. Range straggling is neglected in this appendix.

Let $x=$probability of any one grain missing. Assume that x is independent of the number of grains.

Then $(1-x)^{n-\alpha}x^{\alpha}=$probability that α grains are missing and $(n-\alpha)$ grains are present.

Let $C_\alpha(L_m)=$probability that if α grains are missing and $(n-\alpha)$ grains are present, the track length will be $L_m=(m-1)a$. Assume equally spaced grains of spacing a. According to the convention adopted here, the length of a track is defined by the distance between the end grains without regard to the number of grains between them.

Then

$$P_{\alpha,n}(L_m,x)=C_\alpha(L_m)(1-x)^{n-\alpha}x^{\alpha}, \tag{10}$$

where $P_{\alpha,n}(L_m,x)=$probability that the track length will be L_m if x is the probability that any one grain is missing and α out of n grains are missing. Finally,

$$P_n(L_m,x)=\sum_{\alpha=n-m}^{n-2}P_{\alpha,n}(L_m,x), \tag{11}$$

where $P_n(L_m,x)=$probability that a track length L_m is observed when x is the probability that any one grain is absent in an assemblage of, at most, n grains.

Consideration of the combinations involved leads to the following expressions for $P_n(L_{n-\alpha},x)$:

$$P_n(L_{n-\alpha},x)=\frac{(\alpha+1)\alpha!}{n(n-1)(n-2)\cdots(n-\alpha+1)}x^{\alpha}(1-x)^{n-\alpha}$$
$$+\frac{(\alpha+1)(\alpha+1)!(n-\alpha-2)}{n(n-1)\cdots(n-\alpha)}x^{\alpha+1}(1-x)^{n-\alpha-1}$$
$$+\frac{(\alpha+1)(\alpha+2)!(n-\alpha-2)(n-\alpha-3)}{2!n(n-1)\cdots(n-\alpha-1)}x^{\alpha+2}(1-x)^{n-\alpha-2}$$
$$+\cdots$$
$$+\frac{(\alpha+1)r!(n-\alpha-2)(n-\alpha-3)\cdots(n-r-1)}{(r-\alpha)!n(n-1)\cdots(n-r+1)}x^{n}(1-x)^{n-r}$$
$$+\cdots+[2(\alpha+1)/n(n-1)]x^{n-2}(1-x)^2, \tag{12}$$

where $m=n-\alpha$ and $n-2>\alpha>n-m$.

For

$$\alpha = n-1: P_n(L_1, x) = (1-x)x^{n-1}$$
$$\alpha = n: P_n(L_0, x) = x^n.$$

So that

$$P_n(L_n, x) = 1 - \sum_{\alpha=n}^{\alpha=1} P_n(L_{n-\alpha}, x). \tag{13}$$

The results for $P_n(L_n, x)$ and $P_n(L_{n-\alpha}, x)$ are given as a function of x and for selected values of n in Figs. 17, 18(a) and (b).

In the above it was assumed that the length of the track was given only by the distance between the end grains. This assumption is somewhat unrealistic because of the fact that an "empty" track would not be recognized as a track at all and that a partly empty track might be mistaken for two short tracks. Judging from experimental experience, it is estimated that at least three or four grains would have to be missing in order to mistake one long for two short tracks. Given a nominal 10-grain track, the probability that three grains are missing and seven grains are present is much *less* than $(1-x)^7x^3$ because the three missing grains are postulated to occur in sequence and somewhere near the center of the track.

This quantity has a maximum value at $x=0.3$ of 2.2×10^{-4}, and, consequently, the apparent number of short tracks due to this cause is negligible.

The authors wish to thank Miss Lois Foster of the Rand Corporation for checking the derivation of Eq. (12) and assistance with the numerical computations.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 6 JUNE, 1950

A High Resolution Beta-Ray Spectrometer*

JOSEPH A. BRUNER† AND F. R. SCOTT
Indiana University, Bloomington, Indiana

(Received February 27, 1950)

A relatively inexpensive 180° magnetic focusing beta-ray spectrometer has been constructed, having a principle orbit radius of 15 cm. A radially inhomogeneous field provides essentially perfect focusing of electrons leaving the source within a 33° angle. In operation, with a 1-mm wide source, the transmission is 0.2 percent, the full width at half-maximum of an internal conversion line is 0.4 percent, and the effects of background and scattering are generally inappreciable.

INTRODUCTION

A MEDIUM-size, high resolution, 180° magnetic focusing beta-ray spectrometer has been constructed, patterned in many respects after that described by Langer and Cook[1] (hereafter referred to as the larger spectrometer), but differing in several important features. While the two instruments have transmissions, resolutions, and background counting rates of the same order of magnitude, the new instrument, because of its smaller size, has the major advantage of being easier and less costly to construct and minor disadvantages of necessarily narrower sources, a small (usually negligible) amount of scattering, and a shorter measurable energy range.

Essentially perfect focusing in the median plane is obtained by the use of a radially inhomogeneous magnetic field closely approximating the theoretically required field as determined by Beiduk and Konopinski:[2]

$$H = H_0(1 - 3\delta^2/4 + 7\delta^3/8 - 9\delta^4/16 + 51\delta^5/320 + \cdots),$$

where $\delta = (r - r_0)/r_0$, r_0 is the radius of the principal orbit, and H_0 is the field at $r = r_0$. In addition, a slight amount of axial focusing is obtained by accepting only orbits for which $\delta > 0$[2].

MAGNET

Except for the pole face profile the dimensions of the magnet frame are one-half those of the larger instrument. This fact alone, of course, reduces the cost of the iron by a factor of eight. The shape of the profile was determined by tests on a half-scale model, then applied to the full-size design. As a first approximation in calculating shape changes the pole faces (except near the edges) were assumed to be equipotential surfaces. The theoretically desired profile, as determined by these calculations, was approximated by means of angles and straight lines in order to facilitate the ma-

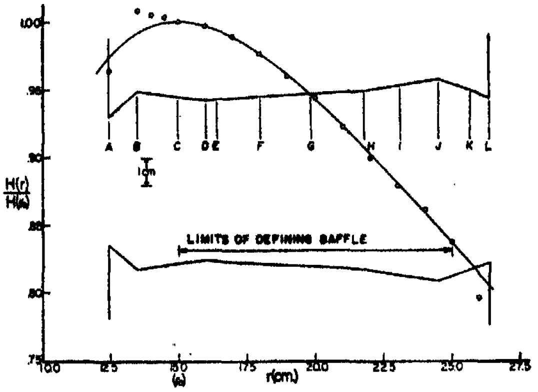

FIG. 1. Pole face profile and magnetic field distribution. The curve represents the field distribution theoretically required for perfect focusing. The points show the actual field. The pole face dimensions are given in Table I.

chining of the faces in the Physics Department shop. Figure 1 shows the profile of the finished pole faces (see Table I), the resulting field distribution, and a plot of the Beiduk-Konopinski curve for $r_0 = 15$ cm. The agreement is seen to be excellent over most of the region; the defining baffle is set so as to exclude from use the edges, where the agreement is poor.

The convection-cooled coil consists of 14,300 turns of No. 22 heavy Formvar wire and carries a maximum current of about 0.5 amp. This current produces a field in excess of 1000 gauss—sufficient to measure electron energies up to at least 4 Mev.

The magnet current is stabilized by four 807 tubes in parallel in a circuit similar to that described by Elmore and Sands.[3]

The magnetic field is measured by means of a flip coil and a ballistic galvanometer, the calibration of which is frequently checked in terms of a standard mutual inductance. The absolute calibration of the field is in terms of the internally converted 411.2-kev gamma-ray of Au^{198}.

FIG. 2. Two views of the completed spectrometer. Points of interest are: (a) A, Source supporting rod; B, G-M counter; C, counter slit control knob. (b) D, Background gate rod; E, exit to vacuum pumps; F, defining baffle control; G, flip coil.

At very low field strengths it is found that a particular cycling of the magnet is necessary in order to retain the desired radial distribution of the field; above 150 gauss, however, this precaution need not be taken.

VACUUM CHAMBER

The aluminum vacuum chamber was cast in a single piece in the form of a "pot," to which a $\frac{1}{4}$-in. sheet aluminum lid is screwed. Incorporated in the casting were several bosses (see Fig. 2) for convenience in attaching a source observation window, flip coil, movable defining baffle, background gate, etc. Fixed aluminum baffles were placed at the 30°, 60°, 120°, 150° positions to help prevent scattering. The edges of the adjustable detector slit were made of tungsten to provide an optimum combination of stopping power and geometrical thinness. Wilson-type vacuum seals were used for the defining baffle, background gate, and detector slit mechanism; and Neoprene gaskets were used for all other seals. No leaks occurred in the chamber.

SOURCES

Sources for measurement of beta-ray spectra are prepared as follows. Upon a 1-in. diameter aluminum ring are placed three 1.5-μg/cm^2 Zapon films. A line of insulin[4] 2 cm long and 1–3 mm wide (depending upon the desired resolution) is ruled on the Zapon by means of a simple machine, then permitted to dry. One or two drops of radioactive solution are then deposited on the same region. Because of the action of the insulin the solution spreads so as to cover completely the desired area. The source is then dried and covered with a single zapon film.

Sources for the measurement of gamma-ray energies are prepared in the manner described by Langer and Cook,[1] using a uranium radiator 2 by 0.3 cm.

The source ring is supported by a skeleton framework on the end of a rod and is inserted into the vacuum chamber through a vacuum gate. Positioning of the ring is accurate to within 0.1 mm both radially and vertically. The orientation of the source is determined by visual alignment with a machined vertical edge of the vacuum chamber.

DETECTION

End-window G-M counters, filled to 10 cm pressure with an argon-ethylene mixture, are used to detect the electrons. Two types of windows are employed, depending upon the energy of the particles to be observed: for very low energies a zapon window is used; otherwise, thin mica windows are adequate.

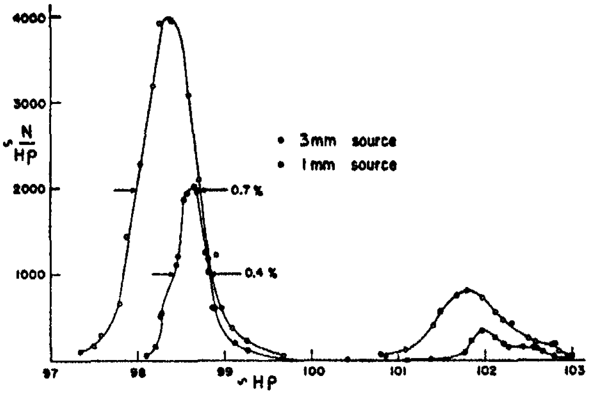

FIG. 3. Internal conversion K and L lines from Cs^{137} as measured using two sources of different widths.

Preparation of the zapon windows has already been described.[1] The supporting grid is made of Lektromesh.[5] Since these windows are unable to support atmospheric pressure, the counters are evacuated simultaneously with the vacuum chamber, then filled from a ballast tank. The connection to the ballast tank is left open during the operation of the spectrometer to maintain constant pressure in the counter against the slight diffusion through the window.

PERFORMANCE

Usually the source and counter slit are set 3 mm wide. The defining baffle is set with its inner edge at a 15-cm radius and its outer edge at a 25-cm radius, thus permitting the passage of a (1 in. high) beam which subtends an angle of 33° at the source, in the plane perpendicular to the field. Under these conditions the transmission[2] is calculated to be 0.2 percent, about twice that of the larger spectrometer. In practice, however, for a given specific source activity the counting rates of the two instruments are very nearly the same because of the difference in source areas.

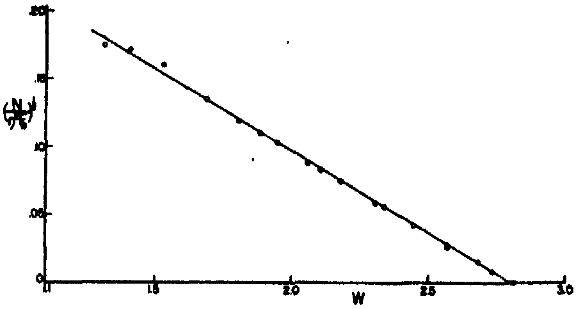

FIG. 4. Fermi plot of Pr^{143} beta-ray spectrum. Deviation from a straight line occurs at about 300 kev because of a relatively thick (0.5 mg/cm^2) source. Source and counter slit widths were each 3 mm.

The resolving power of the spectrometer is demonstrated in Fig. 3 for source widths of 3 and 1 mm. The full widths of the lines at half-maximum are 0.7 and 0.4 percent, respectively. The irregular shape of the narrower line is probably due to the fact that, in the preparation of this particular source, there was an accidental overflow of the source solution slightly beyond the region defined by the insulin.

Figure 4 shows a typical result from the measurement of a beta-ray spectrum. In this case[6] the experimental momentum spectrum of Pr^{143} is compared with that predicted for an allowed transition by the Fermi theory. The theory predicts a straight line when $(N/\eta^2F_b)^{\frac{1}{2}}$ is plotted against W, where N is the number of electrons counted per unit momentum interval, η is the electron momentum, F_b is the Bethe approximation for the Coulomb correction factor, and $W=(1+\eta^2)^{\frac{1}{2}}$ is the electron energy in units of m_0c^2.

The authors wish to express their gratitude to Dr. Lawrence M. Langer for his valuable advice and encouragement.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 6 JUNE, 1950

The Velocity of Propagation of the Discharge in Geiger-Müller Counters*

H. SALTZMANN AND C. G. MONTGOMERY
*Sloane Physics Laboratory, Yale University,*** *New Haven, Connecticut*

(Received March 8, 1950)

The velocity of propagation of the discharge in a Geiger-Müller counter has been measured in a counter with a divided cathode by the method of delayed coincidences. The parameters varied were the counter potential and the percentage of ethyl alcohol mixed with argon. The results are compared with Wilkinson's theory. Good agreement is obtained except for high velocities where the theory predicts values much too low.

THE propagation velocity of the discharge along a counter wire has been measured by several observers,[1] and rough agreement has been found among them. Recently Wilkinson[2] has proposed a theory of the propagation and derives a formula for the velocity which can be compared with experiment. Unfortunately none of the observations published are sufficiently detailed to allow a check of the theory. A series of experiments were therefore undertaken with this purpose in mind.

The counter used had a divided copper cathode 1 cm in diameter; one part was 20 cm long, the other part 3 cm in length. The wire was tungsten of 0.003-in. diameter and the envelope was Pyrex glass. A discharge was started at one end of the long cathode by gamma-rays from Co^{60} collimated by a small hole in a lead block. The discharge traveled along the counter wire and after a short time interval reached the short end cylinder. The start of the discharge was recorded by a pulse taken from the long cathode; the arrival of the discharge at the other end produced a pulse from the short cylinder. The two cylinders were shielded from each other to some extent by copper foil wrapped around the outside of the counter and connected to ground. The time interval between the two pulses was measured by delayed coincidences using the circuit described by Schultz and Beringer.[3] The first pulse was passed through a variable calibrated delay line and mixed with the second pulse in a coincidence circuit with a resolving time of about 3×10^{-8} sec. The length of the delay line was varied until a maximum number of delayed coincidences was recorded with a counting-rate meter. Preamplifiers placed next to the counter cathodes were used and hence only a very small initial portion of the counter pulse was necessary to actuate the circuit. The leak resistors were 1 megohm. The counter was permanently connected to a filling system with a manometer and various mixtures of tank argon and ethyl alcohol vapor were used. In addition the average charge produced in each counter discharge was obtained from measurements of the counting rate and the current through the counter. The counter voltage was measured with a potentiometer.

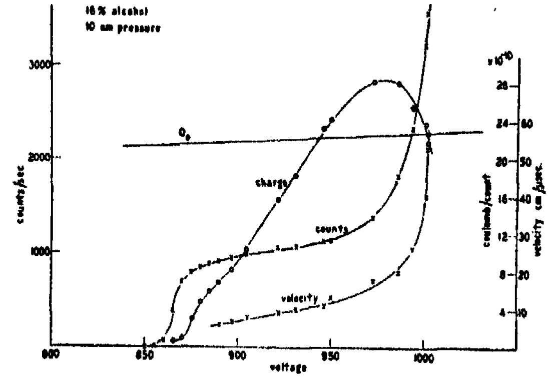

FIG. 1. Typical set of observations.

A typical set of data is shown in Fig. 1. The characteristic curve shows a plateau with a considerable slope and a steep rise just below 1000 volts caused by spurious counts. The charge formed in each count increases linearly with voltage but reaches a maximum at voltages corresponding to the end of the plateau. For higher voltages the charge decreases again. This decrease is also to be attributed to spurious counts which seem to contain, on the average, less charge because of incomplete recovery of the counter. The velocity of propagation of the discharge increases with counter voltage, slowly at first but later with increasing rapidity. The percentage of alcohol vapor in the counter was varied, keeping the total pressure constant at 10 cm Hg. The variation of the velocity that resulted is shown by the curves in Fig. 2. It should be noted that the curve for 14 percent alcohol shows two sets of points. These observations were taken at different times and with different gas in the counter tube. The agreement of the two sets is excellent. Since these four curves have nearly the same shape, but are displaced to higher voltages the higher the alcohol content, the velocity can be regarded as a function of the over-voltage (counter voltage minus starting voltage) alone in the first approximation. Systematic deviations from

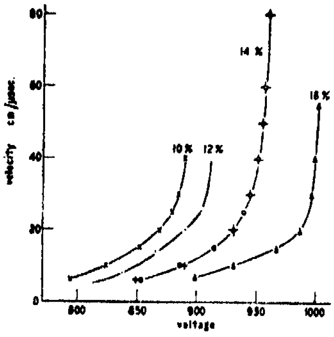

FIG. 2. Discharge velocity as a function of counter voltage for different alcohol percentages. The total pressure is constant at 10 cm Hg.

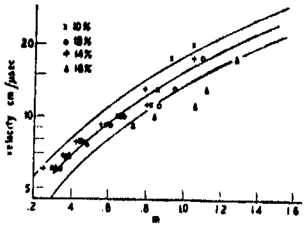
this approximation are evident, however, particularly in the data for 16 percent alcohol.

The calculations of Wilkinson[2] resulted in the following expression for the velocity v of discharge propagation:

$$v=\frac{4}{\pi}\left[1-(\tfrac{1}{2})e^{m}\right]\left[\frac{e^{m}-1}{\ln(Q_0\epsilon/e')(1-e^{-m})^2}\right]^{\frac{1}{2}}v_e,$$

where the notation is $m=Q/Q_0$, the charge formed in the discharge divided by the charge on the counter wire, e' = the electronic charge, v_e = the mean electron velocity in the immediate vicinity of the wire, and ϵ = the probability per ion that one avalanche give rise to a succeeding one. The quantities v, Q_0, and m are determined from direct measurements and fortunately the expression for v depends insensitively on the value of ϵ. The most probable value of $Q_0\epsilon/e'$, according to Wilkinson, is about 10^4. Since Q_0 varies only slightly (see Fig. 1) it was assumed constant for these computations. Unfortunately too little is known about the velocity of electrons in the extremely high fields near the counter wire to choose an experimentally determined value for v_e. We can regard it as a parameter to be determined from the present observations. It is obvious that the rapid increase of the velocity at high values of the overvoltage is not reproduced by Wilkinson's formula. For lower values, the agreement with the formula is shown in Fig. 3. The three curves have been calculated assuming a value of v_e = 31 cm/μsec. The ordinates in Fig. 3 are plotted on a logarithmic scale so that the theoretical curve corresponding to a different

FIG. 3. Comparison of theoretical curves with the experimental points. The velocity v_e was chosen as 31 cm/μ sec., and the quantity $Q_0\epsilon/e'$ was taken to be 10^3, 10^4, and 10^5 for the three curves, the smallest value pertaining to the uppermost curve.



value of v_e can be obtained by a vertical shift of the curves. The parameter $Q_0\epsilon/e'$ was given three values: 10^3, 10^4, and 10^5 for the three curves. For values of m of less than 0.6, the observations are well represented by Wilkinson's formula. At larger values the divergence between the formula and the observations increases more and more. Somewhat better agreement for values of m near 1.0 might be obtained by the choice of a different value of v_e for each pressure, although the agreement between theory and experiment would then be destroyed for low m values. It should be noted that velocities as high as 100 cm/μsec. were observed which are much too large to fit the theory. No very large variations of v_e with counter voltage are to be expected.

Several investigators have derived the velocity of propagation from observations of the build-up of the counter voltage during the discharge. Such determinations do not measure the same velocity as measured by the present experiments. The voltage rise of a counter pulse is determined by the time necessary for the space charge to be formed about a unit length of counter wire. It is not essential that the successive avalanches be contiguous. On the average they will be separated by the mean range of the photons producing them. If a large number of photons are produced in an avalanche, one photon may travel an appreciable distance down the counter wire before it is absorbed. Thus the velocity of propagation as measured by experiments of the type described here should show large fluctuations and yield somewhat greater values than those derived from pulse shape. Such fluctuations in time of traversal of the discharge were observed but no quantitative measurements were made.

The radioisotopes used in this investigation were obtained through the courtesy of the AEC.

End and Wall Corrections for Absolute Beta-Counting in Gas Counters

A. G. ENGELKEMEIR AND W. F. LIBBY*
Argonne National Laboratory, Chicago, Illinois

(Received February 6, 1950)

A^{37} (2.8 kev Auger electrons) and Kr^{85} (0.74 Mev β) were used to determine end corrections for gas counters with flat ends and brass walls. The corrections were found to agree with those published previously for C^{14} (0.154 Mev). Argon-alcohol fillings were used with small quantities of the active gas being studied. Wall loss corrections were measured for Kr^{85} and calculated for A^{37}, C^{14}, and Kr^{85}. It appears from the results that absolute beta-counting for energies from about 0.01 to 0.8 Mev to an accuracy of one or two percent can be accomplished by the use of flat end Geiger counters applying the corrections indicated.

INTRODUCTION

THE intrinsic limitations to the efficiency of argon-alcohol filled Geiger counters in which the active sample is incorporated in the gas mixture are the weakening of the field near the ends of the counter sufficient to prevent a large part of the ionization formed in that region from starting an avalanche and the possibility that particles from disintegrations occurring near the wall will escape from the counter before forming an ion pair.

During the course of measuring the half-life of C^{14} using brass wall counters with flat Lucite ends,[1] the loss in counting efficiency because of the inhomogeneity of the field, i.e., the end loss, was determined. It was assumed as a first approximation that for a given volume of active gas, the difference between the counting rates of two counters of the same diameter but of different lengths was a measure of the end correction. The results obtained fit this hypothesis and indicated that the end loss is principally a function of the length to diameter ratio of a counter.

Further investigation of the end loss was undertaken with A^{37} and Kr^{85} as the active gases to determine whether particles of different energies would show different end losses and also to determine whether weakly ionizing radiations would show an appreciable wall loss.

PROCEDURE

The same counters were used as in the C^{14} determinations with the exception of two counters of smaller length to diameter ratio which were employed to obtain larger end corrections and greater accuracy. The same counting mixture was used also, 1.2 cm Hg of ethanol and 7 cm Hg of argon. The active samples were introduced into the counters with the argon, the radioactive argon and krypton of high specific activity having been diluted several hundredfold with inactive argon.

The radioactive argon was obtained by bombarding KCl with 8-Mev deuterons in the University of Chicago cyclotron;[2] its decay was followed for slightly more than one half-life to show the absence of contaminant activities. The krypton was obtained by dissolving a 10 g piece of an "old" irradiated uranium slug and condensing the noble gases on activated charcoal at liquid nitrogen temperature. Although the slug had been irradiated so long ago that it could be assumed that all other gaseous fission product activities had completely disappeared, the identity of the radioactive gas was demonstrated by running an absorption curve in Al on a sample contained in a brass cell with a mica window. The curve showed only a single beta-component and no gamma-radiation; a Feather analysis gave an energy of about 0.8 Mev. This is in good agreement with 0.74 Mev obtained by Hoagland and Sugarman.[3]

The counting procedures were similar to those described in the C^{14} work. For each counter filling the counting rate of the sample was determined at 25 volt intervals and the counting rate of an external standard plus the sample measured at 50 volt intervals, thereby providing two criteria of counter behavior.

END LOSS

A. Results

The end correction data obtained may be represented by an equation of the form

$$y = K/(L/D - K),$$

where y is the end correction, L the length and D the diameter of any counter, and K is a constant. This equation may be derived as follows by making the assumption that the effective insensitive length, l, of any counter is proportional to the diameter: Let R = observed counts/min. for any given volume of active gas in any counter of length L and diameter D, ρ = disintegrations/min for the same volume and v = insensitive volume $= l\pi D^2/4$.

If the end correction be called y, then

$$y = (\rho - R)/R,$$

or

$$y=\frac{l\pi D^2/4}{(L-l)\pi D^2/4}=\frac{l}{L-l}.$$

Assume

$$l=KD.$$

Then

$$y=K/(L/D-K).$$

A consequence of this assumption is that for any counter in which the total gas volume is that volume enclosed by the cathode and flat ends the end correction is a function only of the length to diameter ratio.

The end corrections obtained with A^{37}, C^{14}, and Kr^{85} are almost identical. Table I is a tabulation of the specific counting rates for the counters with A^{37} and Kr^{85}, corrected for coincidence losses, and in the case of the argon, for decay on the basis of a 34.1 day half-life.[4]

Table II consists of the end corrections calculated from the data in Table I. Part A lists the end corrections for individual counters, and Part B the end corrections for counters of the same length to diameter ratio. The wall correction discussed below was applied to the krypton data to make possible the averaging by length to diameter ratio. Part C gives the average of the corrections in Part B together with the average for C^{14}.

Figure 1 shows the average end corrections (Part C, Table II) for each gas as a function of the length to diameter ratio.

B. Discussion

The end loss has been ascribed to a weakening of the field near the ends which makes that region less sensitive. In addition to the bowing or distortion of the field at the counter ends characteristic of a cylindrical condenser, there is probably some effect due to the accumulation of charge on the insulating ends.

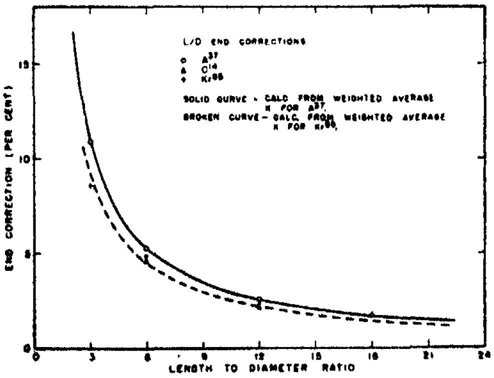

FIG. 1. The end corrections obtained from the average specific activity for counters of the same length to diameter ratio with A^{37}, C^{14}, and Kr^{85}. The curves represent the average corrections calculated for A^{37} and Kr^{85} from the equation $y=K/[(L/D)-K]$, where $K_{A^{37}}=0.298\pm0.014$ and $K_{Kr^{85}}=0.259\pm0.012$.

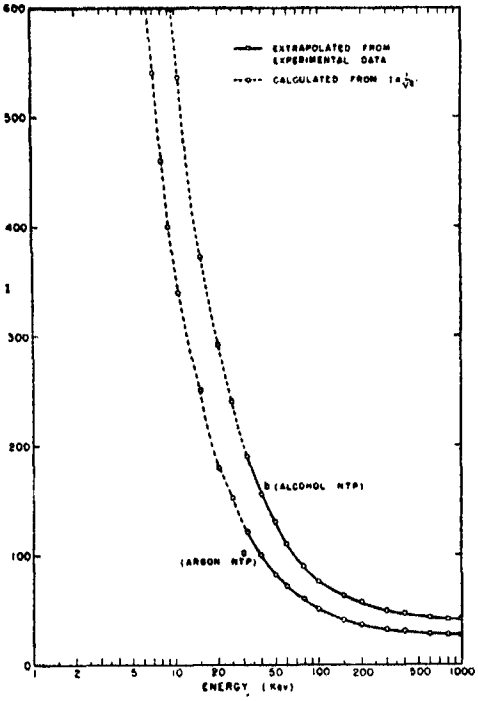

FIG. 2. Primary ionization as a function of energy for argon and ethanol at N.T.P. The solid lines were extrapolated from experimental data on the primary ionization in argon[8] and alcohol[9] on the assumption that I_A and I_{alc} differ from I_{air}[7] by a constant factor independent of energy. The dotted curves were calculated from $I=\alpha/V^2$ with α chosen to fit the solid curves in the region of 50 to 100 kev.

It is by no means obvious that the end losses should be the same for the A^{37} radiations which consist principally of 2.8 kev K-capture Auger electrons[5] as for C^{14} (154 kev, maximum energy of the beta-spectrum)[6] and Kr^{85} (740 kev maximum). The average lengths of the dead volumes, assuming them to be cylindrical, obtained for C^{14} and Kr^{85} are very much less than the range of either radiation in the gas mixture in the counters, whereas the length of the dead volume for even 1 in. diameter counters is of the order of the A^{37} range under these conditions. The ranges of the three radiations are listed in Table III together with the lengths of the dead volumes calculated from the end corrections obtained for each gas.

C. Conclusions

Since all known beta-emitters have ranges greater than that of the A^{37} Auger electrons and since the end effect for even this low energy radiation is essentially identical with that for C^{14} and Kr^{85} one assumes that the present corrections apply for all absolute beta-counting in counters with flat ends for beta-emitters with maximum energies below 0.75 Mev.

* Experimental wall loss correction applied.
** Data from reference 1.

WALL LOSS

A. Results

Since the loss for particles escaping from the counter before any ionizing collision approximates a surface effect, it might be expected to vary as the ratio of surface to volume for different counters, or inversely as the diameter. On the basis of this assumption the correction in the krypton measurements was found to be approximately 6.9±1.1 percent for 1 in., 4.6±0.7 percent for 1½ in., and 3.4±0.5 percent for 2 in. diameter counters. No wall loss was observed with A^{37} as the active gas.

B. Discussion

The loss for particles which penetrate the walls before forming a single ion pair was calculated by considering the probability that a particle emitted from a differential element of volume in the gas would reach the wall without causing ionization. An integration of the losses over the entire volume of the counter was carried out to give the total loss. For counters of diameter 1 in. or larger, the fractional loss due to this effect equals $1/ID$ where I is the number of primary ion pairs per unit path length. In obtaining the primary ionization in the gas mixture in the counters, it was assumed that the primary ionization in the mixture used differed from that in air by a factor which was independent of energy. The values of I for air obtained

TABLE IV. Loss due to non-ionization.

Isotope	Wall loss For $D=1''$	Wall loss For $D=2''$	Compensated wall loss For $D=1''$	Compensated wall loss For $D=2''$
A^{37}	0.3%±0.2	0.15%±0.1	0	0
C^{14}	5.5 ±1.4	2.8 ±0.7	3.1%±0.8	1.5%±0.4
Kr^{85}	10.7 ±2.1	5.4 ±1.1	7.1 ±1.4	3.5 ±0.7

by Graf[7] for energies from 50 kev to 1000 kev were used to calculate the relative primary ionization for the mixture as a function of energy. The absolute values were obtained by using the value for I for argon obtained by Curran and Reid[8] at 420 Kev and the higher value of I calculated for alcohol by Hazen.[9] Curves *a* and *b* of Fig. 2 give the primary ionization of argon and alcohol at N.T.P. as a function of energy.

The wall loss to be expected for the different energy radiations was then calculated by integrating over the beta spectra. Columns 2 and 3 in Table IV give the percent of the total disintegrations in the 1 in. and 2 in. diameter counters which will not cause counts because of their occurring in the vicinity of the walls.

The loss due to "non-ionizing" particles is in some part compensated by the emission of secondary electrons from the cathode. For very low energies the ratio of secondary electrons to primary is about one for a brass or copper surface; for higher energies the multiplication factor is less than unity, approaching 0.3 above 100 kev, so that the wall loss is not completely cancelled. By interpolating between the data recently published by Trump and Van de Graaff[10] for high energy primary electrons and data for the very low energy range,[11] and integrating over the β-particle spectra, ratios of secondary to primary electrons of about 0.4 for C^{14} and 0.3 for Kr^{85} were determined and applied as a correction to the calculated wall losses. The corrected values are given in Table IV, columns 4 and 5.

Figure 3 is a plot of the ratio of secondary electrons to incident primaries *versus* energy for brass surfaces.

C. Conclusions

From these considerations it appears that the wall loss is entirely negligible for counters of 1 in. diameter or greater for β-energies less than 10 kev. For example, the wall loss compensated by secondary emission for H^3 (average energy approximately 6 kev)[12] in a 1 in. counter at 0.1 atmosphere pressure is of the order of a tenth of a percent. For higher energy radiations it should be possible to calculate the wall loss for any brass wall Geiger counter with an argon-alcohol filling from the curves in Figs. 2 and 3 since the wall loss is inversely proportional to counter diameter and to pressure for any energy β-particle and since secondary emission is a function only of energy.

Having completed the calculations for the wall loss for C^{14} it appeared of interest to re-examine the data obtained in the half-life determination, particularly since it had been noticed that the counters of smallest diameter yielded results considerably lower than the average for a given length to diameter ratio. Calculations based on the assumption that the wall loss is inversely proportional to the diameter gave the following results: for 1 in. diameter counters, 3.5±1.2 percent, for 1½ in. counters, 2.3±0.8 percent, and for 2 in. counters, 1.8±0.6 percent. Because the errors in the respective values are large it is possible that the agreement between the experimental and the calculated corrections is fortuitous, although highly suggestive. It is also significant that application of the empirical correction decreases the root-mean-square deviation from the average of the half-life data for all the counters by a factor of two. It is to be noted that applying these corrections to the half-life data lowers the published value of the half-life of C^{14} by about 2½ percent to 5580±45 years.

The principal limitation to the calculated wall loss corrections arises from uncertainties in the values for the primary ionization in argon and in alcohol. While the value for argon is probably approximately correct there may be considerable error in the value for alcohol (cf. Curran and Reid).[8] It is to be seen, however, that even a factor of two change in the absolute value of I_{alc} means a change of less than twenty percent in the calculated corrections because of the small partial pressure of alcohol in the counters.

A second limitation to the calculation of the wall loss is the possibility that the exact nature of the brass surface may exercise some effect on secondary emission. The evidence seems to indicate, however, that the

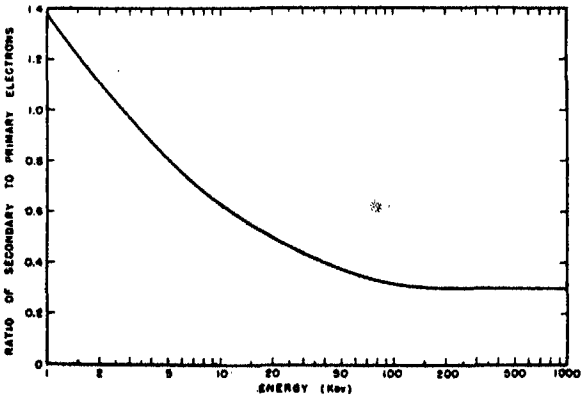

FIG. 3. Secondary emission from brass surfaces as a function of energy. The curve was obtained by plotting secondary emission as a function of atomic number at energies from 0.25 to 2 kev[11] and from 40 to 1000 kev[10] and interpolating in the region between.

treatment of the surface affects the ratio of secondary electrons to primary greatly only for very low energies, i.e., those below 1.5 kev.

SUMMARY

For flat end brass wall Geiger counters containing active gas samples the end loss presumed due to inhomogeneity of the field has been measured for A^{37} and Kr^{85}. The loss was found to be approximately the same for them as for C^{14} despite the differences in energy, and to be proportional to the length to diameter ratio.

The counting loss for particles which escape from the counter without causing ionization was measured with Kr^{85} and calculated for A^{37} and C^{14} as well as for Kr^{85}. The experimental and calculated losses agree well within the limits of error and show the loss to be inversely proportional to diameter.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 6 JUNE, 1950

Scintillation Type Alpha-Particle Detector

A. S. Goldin, E. R. Rohrer, R. L. Macklin
Carbide and Carbon Chemicals Division, Union Carbide and Carbon Corporation, K-25 Laboratory Division, Oak Ridge, Tennessee

(Received November 28, 1949)

A portable scintillation detector for alpha-survey work is described. The instrument can detect as few as 16 alpha-counts (32 disintegrations) per minute because of the virtual elimination of spurious background. The upper limit of 50,000 counts per minute is not inherent and can be raised by appropriate circuit changes. The instrument is stable and is unaffected by most atmospheric conditions other than strong sunlight. Gamma-radiation up to 14,000 mr/hr gives no detectable response on this alpha-meter. The probe is the size of a GT type radio tube with a shield, allowing access to relatively small spaces. The sensitive area is about 1 in.×⅜ in. when a 931-A photo-multiplier is used.

INTRODUCTION

DETECTION of ionizing radiation by scintillation counters has been developed by Kallman,[1] Deutsch,[2] Coltman and Marshall,[3] Bell,[4] Hofstadter,[5] and others. Coltman and Marshall,[6] in particular, have developed scintillation counters for alpha-particles.

A scintillation type radiation detector consists essentially of a sensitive screen, a photo-multiplier tube, an amplifier, and a counter or rate-measuring instrument. The detection of alpha-particles differs from that of most other ionizing radiation because of the short range (three to five mg/cm²) and the high specific ionization. The short range makes it necessary to have the alpha-source very close to the instrument and to provide a light-tight window of some material sufficiently thin that the alpha-particles can penetrate it. The high specific ionization makes it possible to use sensitive screens of such materials as commercial zinc sulfide fluorescent powder in very thin layers.

Presently available field alpha-detection instruments are of either the ionization chamber (Zeuto) type or the proportional counter (Poppy) type. The Zeuto types are stable, have satisfactorily low drift rates, and are sensitive to about 100 to 500 alpha-counts per minute. (Throughout this report, the words "counts per minute" are used to refer to a counting rate as measured on a 50 percent geometry ionization chamber.) Poppy types are sensitive to individual alpha-particles, but are also sensitive to moisture, and have backgrounds so high that they are not able to detect with certainty a source of less than 100 counts per minute. Both types are somewhat sensitive to high intensities of beta- and gamma-radiation. Previously, in this section of the laboratory, we have built scintillation counters capable of detecting alpha-particles, but only when the alpha-source was enclosed in the same light-tight housing as the detector. It would be desirable to have a field type alpha-detector which would be sensitive to sources weaker than 100 counts per minute, and which would also be stable, have a low drift rate, and be insensitive to atmospheric conditions and to radiations other than alpha.

CONSTRUCTION

Probe

Because of the high specific ionization of alpha-particles, it was felt that the fairly inexpensive type 931A or type 1P28 photo-multiplier tube could be used rather than the more expensive type 1P21 or type 5819. Also, the rather less efficient commercial zinc sulfide powder could be used in place of crystalline anthracene or similar phosphors. A thin scintillator, such as a zinc sulfide screen would reduce the gamma-ray absorption while completely absorbing the alpha-rays.

It is found necessary to select the tubes used for low background rate. This was done on the regular scintillation counter equipment in this laboratory, consisting of a voltage divider for the photo-multiplier tube, a type A-1 linear amplifier with pulse-height selector,[7] and a scale-of-64 unit. The tube background was measured at several pulse-heights and then the alpha-counting rate was measured at the same pulse heights. If the background was low (e.g., 0.01 sec.$^{-1}$) at a pulse height at which the alpha-counting rate was still high, the tube was accepted.

After considerable experimentation, it was found to be more satisfactory to use dry adhesives rather than liquid for attaching the phosphor and light shields to the tube. The type of probe now in use was made in the following manner.

Scotch Tape was put around the cylindrical surface of the photo-multiplier tube, sticky side out, and was fastened at the side opposite the cathode. A mask around the cathode area was made by applying Scotch Tape sticky side down, leaving the sticky Scotch Tape surface uncovered over the window itself. A fluorescent screen could then be applied by rolling the tube in Patterson Type "D" fluorescent powder* which adhered to the Scotch Tape in a thin layer. The mask was then removed and the screen covered with aluminum Dutch leaf** having a thickness of approximately 0.16 mg/cm². This thin leaf has pinholes and so it was necessary to use two layers of it as a coating. This double coating was more satisfactory when the two layers were in close contact. Usually a piece was cut large enough for both layers. This was then folded and rolled between two sheets of tissue paper to insure close contact. By rolling the tube over the aluminum, the leaf adhered to the Scotch Tape. It was, of course, necessary to make the outer layer somewhat larger than the inner layer. The tube was then made light-tight with black Scotch electrical Tape and with Apiezon *Q* wax. In the probes so far constructed, the dome-shaped part of the tube was blackened by applying four or five coats of a solution of Apiezon *W* wax in trichloroethylene, allowing thorough drying between coats, but this method failed to give complete opacity and had to be supplemented by use of Apiezon *Q*. In view of this, it is felt that the preliminary coating with Apeizon *W* is unnecessary.

A case was made for the probe by machining out the inside of a 1¼ in. copper solder cap until it was a fairly loose fit for the probe, soldering to this a skirt of 0.012 in. brass to cover the tube except the window area, and then soldering copper screen over the window area. This screen was ordinary copper screen which had been etched in dilute nitric acid until the wires were reduced to about 0.006 in. in diameter. It is desirable to supply this case with a grounding wire.

Circuit

The circuit developed was a five-stage device consisting of an inverter, a discriminator, a second inverter, and a multivibrator. Subminiature tubes of the types CK 571 AX and CK 512 AX were chosen because of their small physical dimensions and tube characteristics, such as low current drain and relatively high amplification factor. The circuit diagram is shown in Fig. 1.

The photo-multiplier tube operates with a negative potential of 600 v. applied to the photo-cathode. A ten-

stage voltage divider between this point and ground provides for equal voltage drops between successive deflecting dynodes.

Output pulses are developed across the 22 megohm resistor between the collecting anode and ground. These pulses are negative and need to be reversed in polarity before they reach the discriminator. The first stage provides an amplified signal of the proper polarity to the discriminator grid. The second stage is biased just beyond the cut-off point for applied signals due to photo-multiplier dark current noise. Under this condition, alpha-pulses drive the tube into conduction, producing relatively large negative pulses on the plate. The third stage inverts the pulses from the discriminator and couples them to the grid of the first stage of the multivibrator.[8]

The final two stages make up a one-kick multivibrator which operates statically with the first tube cut off and the second conducting. When a positive pulse initiates the multivibrator action, a constant plate current flows through the meter and charges the shunting capacitor for a period of time determined by the grid leak resistors and coupling capacitors. The time constant can be changed by varying the value of the coupling capacitor. This variability provides the increased range of the rate meter. After the multivibrator has returned to static condition, the charge developed across the 500 μfd capacitor leaks off slowly through the meter and the series 25,000 ohm resistor. The time constant of the meter circuit is such that the current through the meter is proportional to the rate at which pulses activate the multivibrator.

With the low voltage supplies on, the plate load resistance of the first stage of the multivibrator is adjusted to provide a reasonable plate current. This varies with individual tubes and resetting is necessary only when the tubes or tube characteristics are changed. This adjustment is made in conjunction with the setting of the bias of the first multivibrator stage. The bias control is adjusted for cut-off and acts as a zero adjustment for the rate meter. The high voltage is then turned on and the discriminator bias is adjusted so that dark current background pulses are rejected.

PERFORMANCE

The probes were first tested on this laboratory's scintillation counter equipment, previously described. With this equipment, it was possible to set the acceptance level at such a height that background was only 0.001 or 0.002 count per second while the over-all counting efficiency was still about 30 percent as high as a 50 percent geometry ionization chamber. The sources used were disks about 0.5 in. in diameter placed about one-eighth in. from the fluorescent screen, giving a geometry of some 16–28 percent.

When used with the portable rate-meter circuit, the discriminator bias could be set at such a level that background counts occurred at the rate of one every ten minutes or so. Under these circumstances, the meter needle will swing at the occurrence of this background impulse and will slowly return to zero. The *RC* time of the meter circuit is about 18 sec., so that it takes almost a minute for the needle to return substantially to zero. The probability of a second background impulse occurring before the needle has returned to zero can be calculated from the Poisson distribution law. It is the probability of more than one impulse occurring in any minute, and is 0.018 for an average background rate of one impulse in five minutes, or 0.005 for an average background rate of one impulse in ten minutes. It is thus clear that if the background rate is kept to these values, it will be extremely unlikely that the meter reading will exceed the value caused by a single impulse which is about one microampere.

---

[8] The third and subsequent stages of the circuit are essentially the same as the portable alpha-detector circuit developed by Mr. Clyde Warram of the Instrument Engineering Department.

On the other hand, it can also be calculated from the Poisson distribution law that there will be a 95 percent probability of two or more impulses occurring in a single minute if the average rate of impulses is 4.74 per min. Assuming an efficiency of 30 percent compared to a 50 percent geometry counter, this means that a source with a strength of 15.8 counts per minute will give a second impulse, before the needle has returned substantially to zero, 95 percent of the time. A source with a strength of 15.8 counts per minute could, therefore, be detected by the fact that the maximum meter reading would be greater than one microampere.

In actual tests using scale 1, the most sensitive scale, results were obtained at various discriminator settings, as shown in Table I.

The average of the maximum readings for the 16-count-per-min. source is 3.3±0.9 microamperes; for the 40-count-per-min. source, it is 5.8±1.4 (95 percent confidence interval). The ratio of these averages is 1.76, compared with a theoretical ratio of 2.5. Of course, it must be remembered that at these extremely low counting rates, the data are inherently poor.

When used with stronger sources, over the range from about 100 counts per min. to 48,000 counts per min., results were obtained as shown on the accompanying calibration curve (Fig. 2). The scales are numbered in order of decreasing sensitivity.

A ten milligram radium source, within one inch of the probe, did not cause a meter reading; neither did holding wet hand immediately in front of the window.

The detector was checked for sensitivity to light. Its background is not changed outdoors in the shade; however, in the bright sun, the detector could not be used. The light intensities as measured on a G-E photographic type light meter were: indoors 24; outdoors in shade, 180; outdoors in sun, 3000–7000. Probably this light sensitivity could be completely removed by using more layers of aluminum leaf and by making a better light seal between the edge of the aluminum leaf and the tube blackening material. However, for instruments intended for indoor use, it is felt that this is undesirable because of the difficulties in adding more layers of leaf.

TABLE I. Performance of detector at various discriminator settings.

Discriminator setting (volts)	Background		Time for 10 impulses (sec.)	Max. reading (μa)†
	Impulses/min.	Max. reading (μa)		
−6.5	Continuous	20	—	—
−7.0	0.6 (5 min.)	1.2	203 (16 c/min.)	2.3*
			295 (16 c/min.)	1.5

			45 (40 c/min.)	6.5*

† In runs marked (*), the meter reading did not return to zero after the first swing.

CONCLUSIONS

A scintillation type alpha-particle detector is now available which is capable of detecting alpha-sources as weak as sixteen counts per min. It is stable, insensitive to gamma-radiation and to atmospheric conditions other than strong sunlight. The probe can be used with various modifications for various types of field service.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 6 JUNE, 1950

The Theory and Properties of Low Voltage Radiation Counters[*]

J. A. SIMPSON, JR.
Argonne National Laboratory and Institute for Nuclear Studies, University of Chicago, Chicago, Illinois

(Received December 27, 1949)

The behavior of permanent gas mixtures which lead to low breakdown potentials is discussed, and criteria are established for attaining minimum threshold and operating potentials for G-M counters. Curves showing the dependence of counter characteristics upon pressure and electrode parameters have been obtained for various mixtures of neon and argon. The properties of cathode surfaces have been investigated and the criteria for obtaining suitable surfaces for counter operation were found.

Two classes of counters were observed using these permanent gas mixtures. The first class possesses the lowest range of threshold potentials (approximately 115 to 135 volts) at pressures up to approximately 7 cm Hg. They require quenching circuits having relatively long time constants. The second class of counters have threshold potentials in the range of approximately 135 to 210 volts corresponding to pressures from 7 to 50 cm Hg. They operate with fast quenching circuits.

Miniature portable radiation detectors and meters have been made using these detectors.

I. INTRODUCTION

RADIATION counters operating in the proportional and Geiger-Müller counting regions have been prepared and studied[1] which have unusually low operating potentials. Although the original purpose of the experimental investigation was to devise small portable radiation meters for personnel protection, the behavior of permanent gas mixtures at moderately high pressures for producing low voltage counters is of experimental and theoretical interest. Therefore, this paper emphasizes certain aspects of the theory of this class of counter and describes a series of measurements through which the properties of these counters have been determined.

For many years various methods have been used to reduce the operating potentials of Geiger-Müller and proportional counters. These methods may be reviewed briefly as follows:

1. Reduction of Gas Pressure

This method has been widely used,[2,3] but is extremely limited by the rapid decrease in counter efficiency and inadequacy of counter performance[2] with decreasing pressure. Threshold potentials as low as 375 volts have been obtained in helium[2] at pressures of about 1 cm Hg. The well-known minimum in permanent gases such as argon which occurs at about 0.1 to 0.8 cm Hg pressure has been used giving threshold potentials of 300 volts. The efficiency is low, and the counters possess poor characteristics.

2. Changes in the Relative Diameters of the Electrodes

About 20 percent reductions in counter threshold potentials are possible under optimum conditions. The range downward in size of center wires is limited by mechanical difficulties.

3. Triode Counters

By using a screen grid around the counter center wire[4] with the outer cathode 10–200 volts negative with respect to the grid Korff and Ramsey[5,6] have been able to reduce the operating potentials of large counters approximately 40 percent.

4. Mixtures of Permanent Gases

Counters filled to moderate pressures have been used in which the threshold potentials V_t were lower than for the principal gas alone.[7,8] The threshold potentials, however, were not less than 70 to 90 percent those of the principal gases. These mixtures operated as counters down to 400 volts or more. A mixture with V_t of approximately 300 volts at high pressure (53 cm Hg) has been reported[3] using a neon-helium mixture of unstated proportions, but counter performance was not satisfactory. Argon-oxygen,[9] neon-hydrogen, and impure argon have been used extensively as counters at somewhat higher potentials. Attempts have been made to use low voltage neon glow lamps as counters for radiation meters.[10,11] [*Note.*—More recently Present[1a] has proposed the use of halogen plus permanent gas mixtures for self-quenching counters. Liebson[1b] and Friedman[1c] have prepared counters of this type which operate successfully down to at least 250 volts. It would appear that these counters may be superior to permanent gas counters for radiation meters except where an instrument of unusually small size and weight is required.]

The following discussion will show that it is possible to obtain reproducible permanent gas counters having operating potentials ranging from approximately 130 to 250 volts, representing gas pressures ranging from approximately 5 to over 50 cm Hg.

II. THE THEORETICAL BASIS FOR LOW THRESHOLD POTENTIALS

A considerable amount of information is available on the behavior of the breakdown potentials for gases with different systems of electrodes as a function of the properties of the gases and gas mixtures. The discussion will be limited to permanent gases. The gas discharge regions useful for proportional counting and Geiger counting lie within a few volts of the breakdown potential of a mixture of permanent gases. It is thus desirable to consider the problem of obtaining minimal breakdown potentials using data in the literature before considering the more restrictive conditions for counter operation. It is not to be expected, therefore, that the determination of minimum breakdown potentials will necessarily at the same time determine sufficient conditions for the adequate performance of a counter. These additional conditions for counter operation will be presented later in the discussion concerning the counter tubes and will be supported by experiments.

A

As the potential difference is increased between two electrodes in a gas the current which flows is at first caused by residual ionization in the volume and photoemission at the cathode. This is the ion chamber region in which, under optimum conditions, all ions formed in the volume are collected at the electrodes. By further increasing the applied potential, electric fields may be obtained in which an electron formed in the gas may acquire sufficient energy to produce an ion pair by collision. This may lead to a self-sustaining discharge. The potential for which the discharge current increases by a factor of 10^7–10^8 and becomes self-sustaining is called the breakdown potential V_B for that particular system. This represents the beginning of the corona discharge region. The discharge regions of interest in this paper are: (1) the electron avalanche region near the breakdown potential which determines proportional counter characteristics; and (2) the breakdown potential and the corona current region immediately above V_B which determines G-M counter characteristics.

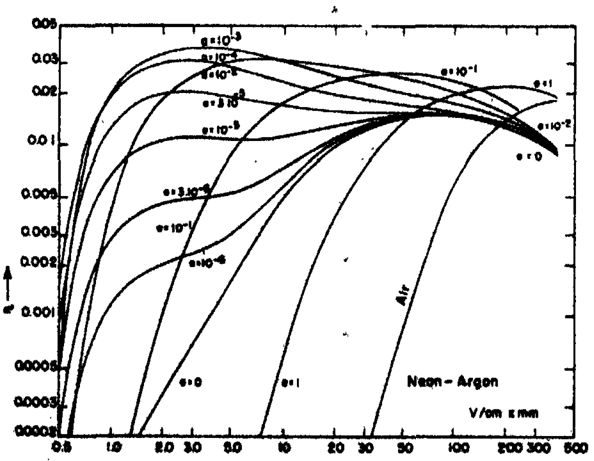

FIG. 1. Values for $\eta=\alpha/E$ as a function of E/P for various gases and gas mixtures. (See reference 14.)

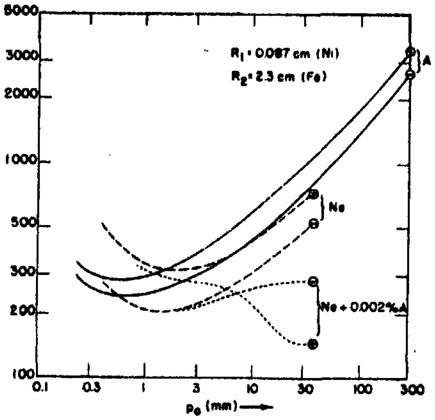

FIG. 2. The breakdown V_B between coaxial cylinders of radius $R_a=R_1$; $R_c=R_2$ in neon, argon, and neon plus 0.002 percent argon. (See references 17–20.)

For a coaxial electrode system it may be shown[12] that the condition for reaching a steady minimum current with a corona discharge beginning around the positive center wire is:

$$\gamma \exp\left(\int_0^{V_B} \eta dV\right)=1 \qquad (1)$$

provided $R_a \ll R_c$; $E_a/P \gg E_c/P$ and $E_c/P<1$ (R_a and R_c are radii of anode and cathode respectively).[13]

Thus, gases or gas mixtures which have high values for η produce low breakdown potentials. Extensive measurements of η have been reported in the literature.[14–16] Figure 1[14] shows the values of η for some gas mixtures as a function of E/P.

---

[12] L. B. Loeb, *Fundamental Processes of Electrical Discharge in Gases* (John Wiley and Sons, Inc., New York, 1939).

[13] For reference, several parameters of electric discharges are defined as follows: α—Townsend coefficient, the number of ion pairs formed per cm path length traversed by an electron in a field E. P—gas pressure in millimeters of mercury. $\eta(E/P)=\alpha/E$—a function of the energy of the ionizing electron; the ionization per cm path length per volt potential difference. i—electron current in amp. i_0—electron current as $V\rightarrow 0$. γ—the number of secondary electrons from the cathode surface per ion pair formed in the gas. This emission is principally caused by: (a) Emission of electrons by positive ion bombardment at the cathode. (b) Photo-electron emission by incident radiation quanta. (c) Emission of electrons by metastable atoms approaching the cathode.

[15] A. A. Kruithof and F. M. Penning, Physica 4, 430 (1937).

[16] M. J. Druyvesteyn and F. M. Penning, Rev. Mod. Phys. 12, 87 (1940).

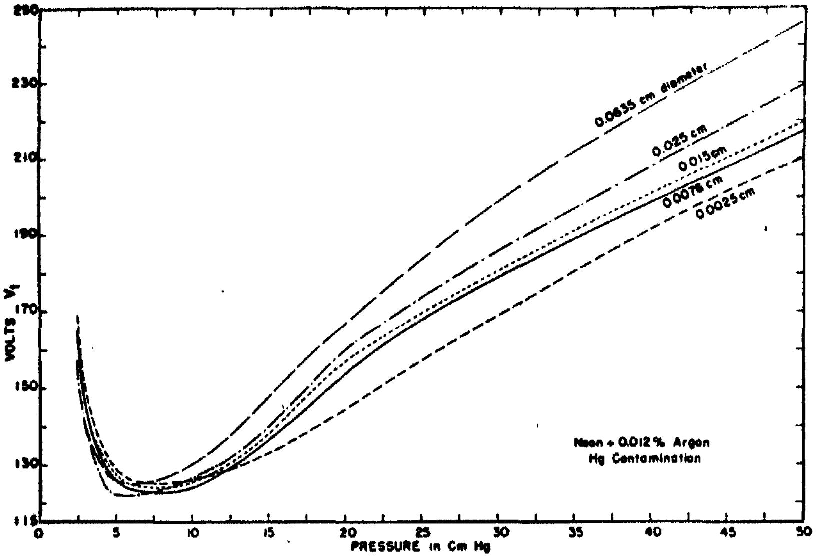

FIG. 3. The G-M pulse threshold potential V_t for a mixture of neon plus 0.012 percent argon as a function of the gas pressure. With a copper cathode radius $R_c=0.61$ cm. V_t was determined for values of $2R_a=0.0025$, 0.0076, 0.0152, 0.0254, and 0.064 cm.

The values of $\eta(E/P)$ for mixtures of pure neon and argon shown at low values of E/P are among the largest experimentally determined. Therefore, these special mixtures should demonstrate unusually low breakdown potentials, and they will be used as representative of this class of gas mixture throughout the discussion which follows.

Penning and his co-workers[17–20] have determined the breakdown potentials for coaxial electrode systems (Fig. 2) as a function of pressure using both pure gases and neon with small admixtures of argon.

B

An examination of the properties of this mixture reveals the reasons for the observed high values of η or low values of V_B.

Electrons in collision with gas atoms G_1 such as pure neon may excite the atoms and leave them in metastable states $G_1{}^m$ for considerable periods of time. Thus, large amounts of energy removed from the electric field by electrons are used to produce excitation and not ionization. This will result in small values of η or large values of V_B for such gases. When, however, a small quantity of a second gas G_2 is admixed with gas G_1 the mean life time of metastable atoms $G_1{}^m$ may be reduced to a very small value.

This will occur provided the second gas has a first ionization potential V_2 which is less than, but close to, the potential $V_1{}^m$ of the metastable state of the principal gas G_1. The following collision process will take place between an atom of kind G_1 in its metastable state $G_1{}^m$ and a neutral atom G_2.

$$G_1{}^m+G_2\rightarrow G_1+G_2{}^+ + \text{electron}; \text{ provided } V_1{}^m > V_2. \quad (2)$$

It is evident that for a given production rate of metastables $G_1{}^m$ in gas G_1 at pressure p_1 there is an optimum amount of G_2, say p_2, to provide for complete removal of metastable states in a time t to give a ***minimum*** breakdown potential $V_{B\text{ min}}$.

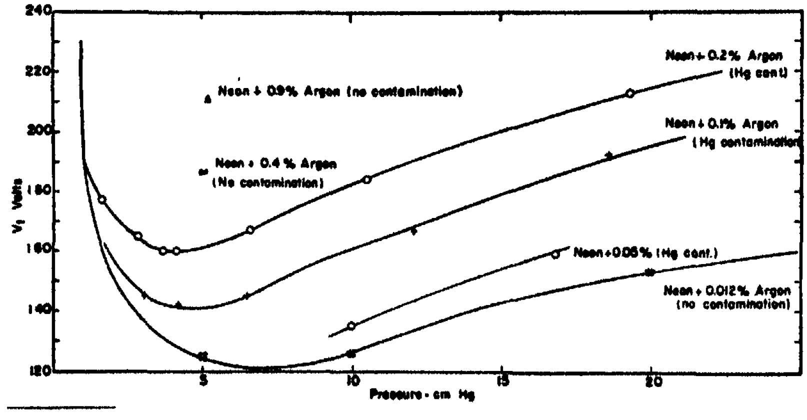

FIG. 4. The G-M pulse threshold potential V_t as a function of pressure for neon mixed with 0.012, 0.05, 0.1, and 0.2 percent argon, respectively.

[20] F. M. Penning, Zeits. f. Physik **46**, 335 (1927).

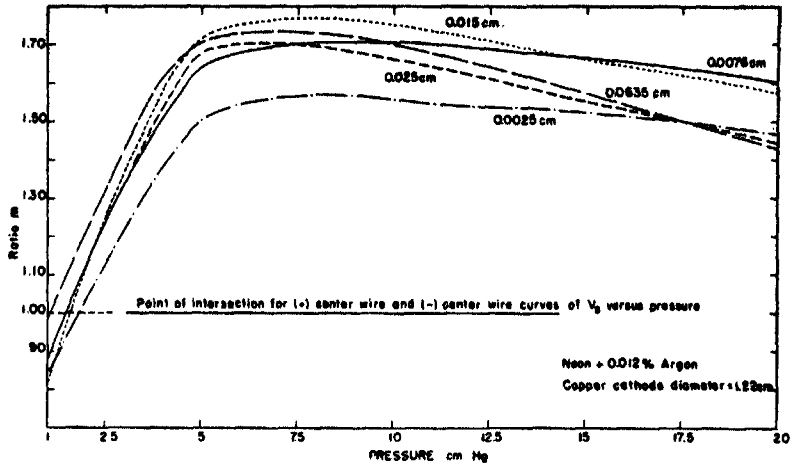

FIG. 5. To demonstrate that the counters are operating in the anomalous low voltage region, the ratio $m=(V_B$ to negative wire$/V_B$ for positive wire) has been determined. Compare these curves with Fig. 2.

For the particular case of neon gas mixed with small amounts of argon,

$$V_1=21.47 \text{ ev.}$$
$$V_1^m=16.6 \text{ ev.}$$
$$V_2=15.7 \text{ ev.}$$

These values satisfy condition (2).[20a] Amounts of argon greater than 0.0004 percent will measurably change the V_B of pure neon gas.

It should be noted that Hg vapor is about ten times more effective than argon in minimizing V_B in neon. At room temperature, however, insufficient amounts of Hg vapor are available for neon above one centimeter Hg pressure.

The very low values for η in Ne-A mixtures at $E/p<1$ are due to electron energy losses resulting from collisions with the atoms.

C

There is an additional, important factor which contributes to the lowering of V_B in the mixtures of neon and argon when the coaxial electrode system is to be used as a pulse counter since the center wire is positive with respect to the outer cylinder. It is apparent from Fig. 2 that at higher pressures the breakdown potential is lower for an anode center wire than for a cathode center wire. The theory of the anomalous lowering of V_B when the potential difference between electrodes approaches V_B has been described by Druyvesteyn and Penning.[16]

III. THE PROPERTIES OF LOW VOLTAGE G-M COUNTERS

A. Experimental Procedures

All counters used in the studies were constructed with Pyrex glass envelopes containing cathodes composed either of thin metal films, or of tubing. The center wires were made of tungsten so they could be heated by an electric current during the outgassing periods on the vacuum system. A group of counters which do not conform to the above specifications will be described later. Sets of identical counters were used for all measurements. The components of the vacuum system included a three-stage oil diffusion pump, a large manifold to which 30 counter tubes could be attached and a manifold on which were sealed flasks of gases to be used for the studies. The manifolds were separated by appropriate liquid nitrogen traps. A large furnace for outgassing the array of counters was provided so it could be rolled around the manifold containing the counters. Constant temperature controls protected the array of counters during the outgassing period. All data on counter characteristics were taken at 21°–24°C, and

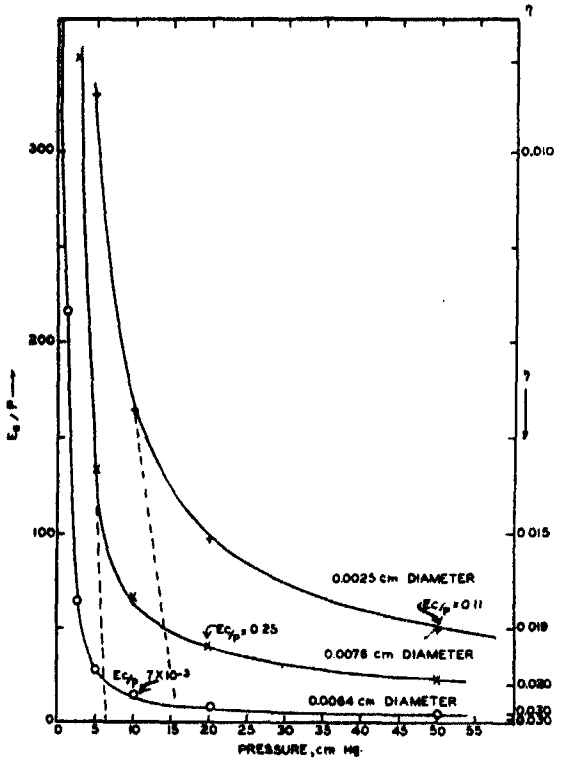

FIG. 7. Values for E_a/P at the surface of the anode have been calculated from experimental data as a function of the gas pressure. Each curve represents a different value for R_a. These values are obtained from Fig. 3. The gas mixture is neon plus 0.012 percent argon.

all data are obtained from the preparation of from 6 to 30 counters for a single measurement.

The outgassing process required at least 4 to 6 hours of pumping with the furnace at 300°C and included the use of an electrical discharge for "clean-up," a baking of the vacuum system parts which were outside the furnace and incandescent heating of the center wires. Liquid nitrogen cooled the traps after the removal of water vapor, air, and organic materials was complete.

Vacuum gauges covering several ranges of pressure were provided. Pirani gauges calibrated for the various gases were used when the gas pressures in the manifold were less than 0.1 cm Hg. Manometers calibrated in mm Hg were used for higher pressures.

All gases used were purified and stated to be "spectroscopically pure" by the manufacturer.[21] Neon gas was an exception since it contained not more than 0.1 percent helium. However, since Penning[15] has shown that helium up to 0.3 percent would leave the breakdown potential of neon unchanged from the value for pure neon the helium impurity was not important for these experiments. Break-off tips on the gas flasks were opened after proper outgassing of the manifold had taken place.

Pulse measurements such as threshold values V_t for the Geiger counting region were made with a conventional Neher-Harper[22] electronic circuit using a subminiature[23] type 512 Raytheon tube.

B. The Threshold Potentials for G-M Counters

With liquid nitrogen around the manifold traps a mixture of neon plus 0.012 percent argon was prepared in the counters. The pulse threshold as a function of pressure appears in Fig. 3 with center wire diameters as a parameter. The cathode was 1.22 cm in diameter and was made of chemically cleaned copper. Some Hg contamination might have been present on the copper surfaces. The change in threshold potential between 4 and 10 cm Hg is relatively small. Similar curves for 0.1 and 0.2 percent argon mixed with neon are shown in Fig. 4.

By determining the ratio $[V_B \text{ (wire negative)}]/[V_B \text{ (wire positive)}] = m$ as a function of pressure as in Fig. 5, it is easily shown that for pressures greater than 1.0 cm Hg the counters are operating in the anomalous low voltage region discussed in the previous section. Compare the position for $m=1$, Fig. 5, with Fig. 2 showing the intersection of the center wire positive and the center wire negative curves. Values for V_B with the center wire *negative* with respect to the outer cylinder may be determined from Figs. 3 and 5 as a function of pressure. (These data are of interest if the counter is to be used in a potential reversing circuit.)[24]

Other gas mixtures obeying condition (2) include He-argon and He-xenon, Fig. 6, and neon-Hg vapor.

Groups of counters with identical cathode diameters and surfaces but having different center wire diameters were used to obtain information on the variation of V_B with different values of R_a. Counters representative of each group were used for Fig. 3. At pressures above 16 cm Hg of neon plus 0.012 percent argon the characteristics are normal, that is, the pulse threshold potential is a direct function of R_a. Below approximately 16 cm Hg and extending down to about 2 cm Hg the V_B-pressure curves for different values of R_a cross to make V_B an inverse function of R_a. Haines[3] has reported such a phenomenon for H_2 and helium at low pressures but with high threshold potentials; no explanation of the effect was given. Brown[25] has predicted this kind of cross-over for helium by developing the theory of breakdown potentials in helium.

It appears that for the case of neon plus argon a satisfactory explanation of the effect may be made. From Fig. 3 it may be seen that the V_B *vs.* pressure curves for concentric electrode systems having different values of R_a cross at low pressures and that it is not the minimum R_a which produces the minimum values for V_B. The explanation of these characteristics depends upon a knowledge of the field intensity E_a near the surface of the anode and the effective mean-free-path λ of the ionizing electrons in neon-argon gas mixtures. Since $\lambda \sim 1/p$ then the ratio E/p may provide information to aid in interpreting the cross-over as a function of p. Using the data from Fig. 3, calculations of E_a, and hence, E_a/p have been made with three different values for R_a covering the pressure range 10 to 500 mm Hg. For a stated R_a the corresponding values of E_a/p are plotted as a function of p in Fig. 7. Values for η are also given for corresponding values of E_a/p. The values of E/p are maximum values at the anode, and since the field varies as $1/r$ the values for E/p only short distances away from the center wire will be much lower. Spot values for E_c/p at the cathode are shown on the graph to emphasize the fact that E_c/p is so low that the corresponding values of η are practically zero.

---

[21] Linde Air Products Corporation, Tonawanda, New York. The neon and argon may contain several parts per million of H_2O, CO_2, H_2 and oxygen. In addition the argon may contain 1–2 parts per million nitrogen. Gases not meeting these specifications were discarded.

[23] The use of subminiature tubes was desirable since they would find direct use in portable radiation meters.

[24] J. A. Simpson, Phys. Rev. 66, 39 (1944).

[25] S. C. Brown, Phys. Rev. 62, 244 (1942).

With the above information the crossing-over properties of Fig. 3 may be predicted. At pressures above 20 to 25 cm Hg values of E_a/p for all R_a shown are in a region where η has values which are near the maximum for the gas mixture. For example, at E_a/p for $r_c/r_a = 480$ the value for η is low, but a short distance r from the anode still within the avalanche region η will have reached its maximum value. Therefore, at the higher pressures the electrode systems behave normally as predicted in electrical discharge theory where V_B varies *directly* with r_a and r_c.

However, as the pressure is decreased Fig. 7 indicates that observed values of E_a/p begin to increase more rapidly for small values of R_a than for large values of R_a. This upward break occurs because the region of the $1/r$ electric field in which η is large is moving away from the region of the anode. It is, therefore, necessary to increase the field intensity distribution in the region around the anode where the avalanche processes occur to compensate for this average decrease in η. This appears as an increase in V_B. Thus, both decreasing p and increasing E_a results in a large increase in E_a/p. Since this increase of E_a/p begins at higher pressures for small r_a then a cross-over of the V_B-pressure curves for two different but *small* values of r_a should result at a higher pressure than for two different but *large* values of r_a. This is in accord with the experimental results.

An approximate value for the pressure at which cross-over would take place for two values of r_a may be estimated by extrapolating the steep slope portion of the E_a/p *vs.* P curve to intersect the pressure coordinate. Thus, the pressure range for cross-overs is approximately 2.5 to 16 cm Hg for values of r_c/r_a between 10 and 500 with this neon-argon gas mixture.

Figure 7 shows that increasingly great differences in E_a/p at constant P exist between any two values of r_a for pressures below 5 cm Hg. This arises from a continuation of the shift of maximum η away from the avalanche region as already described. As a result V_B in this low pressure region is an *inverse* function of r_a.

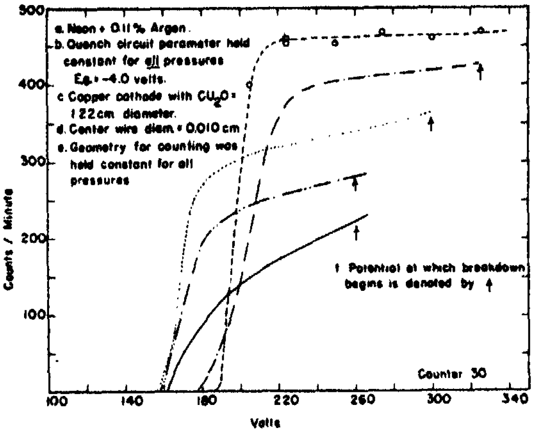

FIG. 8. Characteristic curves of a counter operating with an electronic quenching circuit having parameters which are *not* at optimum values for all counter pressures.

The optimum value of r_a required to achieve minimum V_B for any particular pressure of the neon-argon mixture may be determined approximately from Fig. 3.

It has been shown[22] that near the anode

$$\frac{dE_a}{dr_a} = \frac{V}{r_a^2 \ln(r_c/r_a)}\left[\frac{1}{\ln(r_c/r_a)} - 1\right],$$

and that only for dE_a/dr_a *decreasing* can the corona region exist. This requires that $r_c/r_a > e$, a condition that exists for all the experiments which are being described. It follows that as $r_c/r_a \rightarrow e$ the maximum current drawn by an avalanche discharge will increase.[26] The data presented in Figs. 3 and 7 may be used to further test the validity of Brown's theory[25] for determining

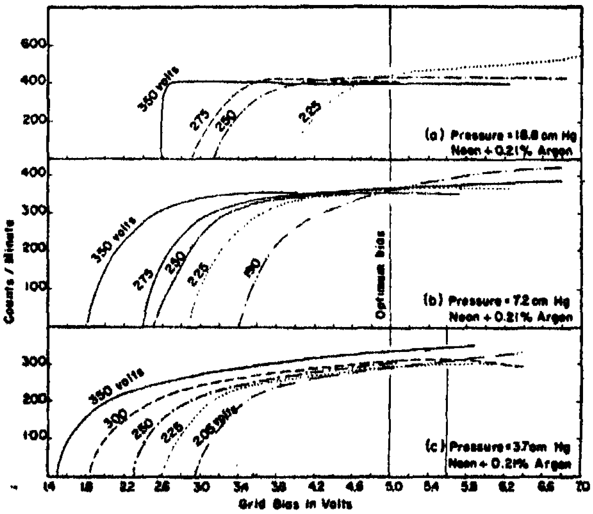

FIG. 9. Family of plate potential curves with counting rate as a function of grid bias, e.g., on the "quenching" tube.

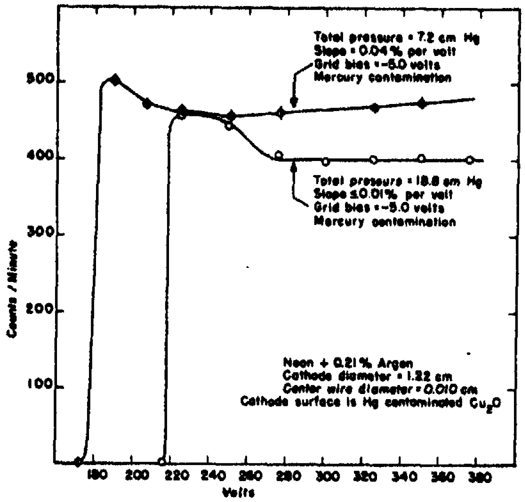

FIG. 10. Characteristic curves determined by using the optimum bias shown in Fig. 9.

the breakdown potential of a helium counter when applied to the case of a *mixture* of permanent gases.

C. Counter Measurements in the Geiger-Müller Region

The principal features of the counter discharge mechanism of permanent gas mixtures have already been described.[27, 28] *A necessary condition* for a counter to return to its operating potential without spontaneously continuing the avalanche process is that the counter remain below V_B for a time t sufficient for the removal of all ions and metastable atoms in the counter gas. This time t is minimized to decrease the insensitive time of the counter.

With the experimental verification of regions of low threshold potentials for Geiger counters it is important to examine the characteristics of these mixtures under counter operating conditions and examine the additional limiting conditions placed upon the choice of gas mixtures and cathode surfaces by the G-M discharge mechanism.

One conventional method for displaying G-M counter characteristics is to determine the counter response in counts per unit time as a function of applied potential. These so-called characteristic curves have been plotted for a variety of pressures and gas mixtures in Figs. 8, 10, 11, and 12. However, since the counter characteristics are not independent of the external electronic "quenching" circuit the indiscriminate use of these curves to study the counter tube alone is meaningless. For example, in Fig. 8 the characteristic curves of a counter filled with neon plus 0.11 percent argon are plotted for pressures of 18.6, 12.1, 6.5, 4.2 and 3.1 cm Hg using an electronic circuit with the *same* parameters for *all* pressures of the gas mixture. The circuit was initially adjusted for the counter operating at the highest pressure. As will be shown below, these changes in counter characteristic curves with decreasing pressure are *not* due alone to changes in the counter pulses but are also due to *improper* use of the electronic quenching circuit.

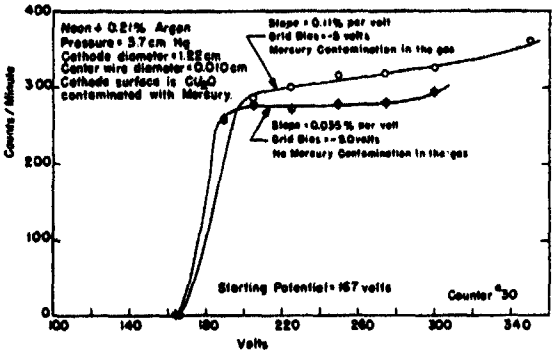

FIG. 11. The effect of mercury vapor and organic vapor impurities on the counter characteristics at a low pressure.

A set of counters was filled with neon plus 0.21 percent argon with Hg contamination to a pressure of 18.8 cm Hg. Counting rates as a function of the grid bias $-E_g$ on the N-H circuit were obtained as in Fig. 9 with plate supply potential as a parameter. This set of curves is more important than the "plateau" curves for determining the characteristics of a permanent gas counter tube. Not only are the slope characteristics of the counting region determined for any grid bias $-E_g$ but also the uniformity of pulse height, freedom from multiple pulses and freedom from momentary corona breakdown determined from these curves. For any given plate supply potential the region in which the counting rate is constant for a range of values of $-E_g$ provides a measure of the uniformity of counter pulse heights. An example of counter performance in which the pulses were of uniform height is shown in Fig. 9a with plate potential = 350 volts.

At high operating potentials permanent gas counters which produce spurious discharges due to impurities in the gas, may break down at random into corona discharges for long intervals of time. Consequently, a low counting rate is observed at high operating potentials. This behavior of counters has been discussed by Neher and Harper[22] and appears as a negative slope on the above curves for high values of $-E_g$. Such an effect is just becoming detectable at a pressure of 3.7 cm Hg for grid biases of about -6 volts as shown in Fig. 9c.

The selection of the optimum bias from Fig. 9 is approximately -5.0 volt. It is to be expected that the counting rate at 225 volts will be high as shown because the over voltage does not produce pulses large enough to operate the quenching circuit hence multiple pulses arise. This peak near the counter threshold potential is observed in Fig. 10. At 18.8 cm Hg the characteristic curve slope was less than one percent for a 100 volt interval. No multiples or discharges were observed even

[28] A. Nawijn, Physica, 's Grav. 9, 481 (1942).

at 400 volts. The threshold potential was 214 volts. At 7.2 cm Hg the counting rate slope was 4.5 percent in a 100 volts interval, but otherwise the counter characteristics were the same as at higher pressures. The threshold potential was 167 volts.

A further reduction in pressure to 3.7 cm Hg still with mercury and stopcock grease vapor contamination present resulted in the curves of Fig. 11. At optimum grid bias the counter plateau slope increased to 11 percent in a 100 volt interval. The addition of liquid nitrogen traps for a period of 10 hours left the threshold potential unchanged at 159 volts. However, a remarkable improvement in operating characteristics was found with the slope being reduced to 2.5 percent in a 70 volt interval. Removing the liquid nitrogen traps resulted in the system returning to the original characteristics with the 11 percent slope. Many groups of counters have shown the same shift of characteristics with reduction of pressure whenever these contaminants were present at room temperature.

In all cases the addition of mercury vapor was made by saturation at room temperature; hence as the total pressure in the counters was reduced the proportion of mercury vapor increased in the mixture. In general it was found that only with pressures of neon-argon mixtures below 7 to 10 cm Hg do counter characteristics become seriously dependent on mercury and stopcock grease vapor contamination.

A plateau curve from a counter with neon-argon mixture at 4 cm Hg having a threshold potential of 118 volts is shown in Fig. 12. As will be seen from the more detailed discussion which follows counters with such low threshold potentials require longer recovery times than counters with over approximately 135 volts threshold potentials.

D. Pulse Characteristics

Using a driven sweep circuit,[29] and cathode follower input to a wide band amplifier with an oscilloscope the rise times of counter pulses have been measured for various pressures and amounts of argon in neon. Counters with 0.1 percent or more of argon at pressures of about 10 cm Hg or above had rise times of approximately 2×10^{-6} sec. The formation of the peak of the pulse required 10^{-5} sec., and the total pulse width was 10^{-4} sec.

Counters filled with approximately 4 cm Hg of neon plus 0.1 percent argon had rise times of 10^{-4} sec. and a pulse width of about 3×10^{-4} sec.

However, counters filled with neon plus the order of 0.01 percent argon to about 5 cm Hg pressure producing minimum threshold potentials of 115 to 135 volts have different pulse characteristics. The rise time as measured on the plate of the quench circuit was $1\text{–}3\times10^{-4}$ sec. but the pulses had a recovery time of approximately 10^{-3} sec.

All pulse measurements were made with an overvoltage of 20 to 25 volts; overvoltages higher than this improved rise time characteristics appreciably as predicted by theory.[27] In all cases copper cathodes prepared to give optimum results have been used with the counters described. The determination of these satisfactory cathode surfaces is discussed later.

The constancy of counter characteristics has been determined for several mixtures of neon and argon over a period of two years. Threshold potentials have remained within one percent of their initial value and pulse shapes have remained unchanged. Many small counters were constructed simply by using a 0.95 cm diameter length of Kovar tubing as a cathode with small glass seals on both ends. These counters maintained their initial characteristics over two years with threshold potentials of 115 to 125 volts. See Fig. 12.

The background counting rates for these counters agree well with the number of ionizing events expected per unit volume.

E. Cathode Surface Characteristics in Neon-Argon Counters

Evaluation of the secondary effects at the cathode of permanent gas counters is difficult. The function γ which represents these effects has been defined as the

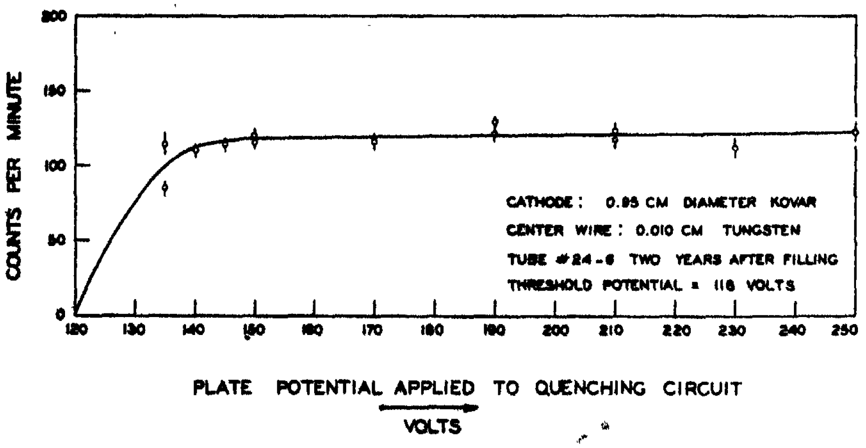

FIG. 12. Characteristic curve of low voltage neon-argon counter using quenching circuit.

---

[29] H. G. Stever, Phys. Rev. 61, 38 (1942).

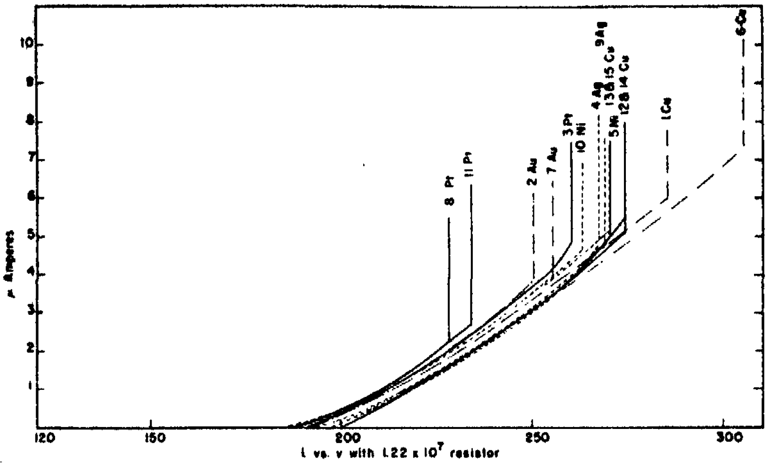

FIG. 13. These curves show the potentials at which the corona current sharply increases. All counters are identical except for the material used for the cathode surface.

number of electrons which are ejected from the cathode per ion pair formed in the gas. Although no attempt has been made to measure this quantity for any cathode surface in these experiments several interesting trends have been observed.

From the approximate expression (1) for a coaxial system of electrodes,

$$\int_0^{V_B} \eta dV = \ln(1/\gamma),$$

and it is seen that the breakdown potential V_B varies inversely with γ. If two electrode systems S_1 and S_2 in the same gas mixture are identical except that their cathode surfaces have values of γ_1 and γ_2, respectively, then since η is almost exactly the same for both gases:

$$\int_0^{V_{B^1}} \eta dV - \int_0^{V_{B^2}} \eta dV = \ln(\gamma_2/\gamma_1).$$

Thus

$$\int_{V_{B^2}}^{V_{B^1}} \eta dV = \ln(\gamma_2/\gamma_1) \approx \eta(V_B{}^1 - V_B{}^2), \qquad (3)$$

if the values for $\gamma_2 - \gamma_1$ are small and $V_B \gg (V_B{}^1 - V_B{}^2)$. Both these assumptions are satisfied in the data presented below.

Expression (3) indicates that even for moderately large differences of γ_1 and γ_2 the value of $(V_B{}^1 - V_B{}^2)$ will be very small. Therefore, the cathode surface cannot contribute appreciably to the lowering of breakdown potentials and from this point of view would not be important in achieving low voltage counters.

TABLE I.

Type of cathode surface	Threshold potential	Relative photo-sensitivity	Counter performance
A Mechanically cleaned	190 volts	11	Unsatisfactory
B (CuO)	189 volts	14	Unsatisfactory
C (Cu_2O)	192 volts	1	Excellent

However, the secondary effects at cathodes *are* important in determining other operating characteristics of G-M counters. An ionizing event within the counter gas is followed by multiplication of the initial ion pairs near the anode center wire. Photons produced in this process may eject electrons from the cathode which then extend the avalanche process at random along the length of the counter. A positive ion sheath[27] soon forms, and the center wire may drop rapidly below V_B. For high values of γ the positive ions or metastable atoms approaching the cathode surface have a high probability for ejecting electrons. These secondary electrons may either continue the discharge so that the counter cannot recover or, if a long-lived metastable atom approaches the cathode, may produce a spurious pulse. Thus it is important to use cathode surfaces with *low* values of γ to insure adequate counting characteristics.

To study the change in V_B with γ and the change in performance of G-M counter tubes with γ a series of different cathode surfaces was prepared from otherwise identical sets of counters. Since all the surfaces were mercury contaminated results cannot be compared with studies of V_B made with clean cathodes. In fact, considerable variations in cathode properties were found among groups of supposedly identical surfaces, and it should be understood that some aspects of the following measurements are little more than qualitative.

Three groups of counter cathodes were prepared.[30] Group *A* had mechanically cleaned copper, group *B* had a thick layer of CuO on copper, and group *C* had a thick layer of Cu_2O (brick red oxide) on copper for cathode surfaces. Table I gives a comparison of the three groups of counters with a gas mixture of neon plus 0.2 percent argon. A mercury light source with slit aperture was used to illuminate the interior of a counter cathode from each group under fixed geometry conditions. The background counting rate was determined for each counter, and then the counting rate with illumination was determined. The values of relative photo-sensitivity should not be considered to show more than the trend in values.

---

[30] These were prepared according to J. Strong, *Procedures in Experimental Physics* (Prentice-Hall, Inc., New York, 1939), pp. 268–270.

The increase of threshold potential with decreasing photo-sensitivity of the cathode is in agreement with the assumption that photo-sensitivity is a function of γ.[31]

A comparison of G-M counter performances for the three types of surfaces shows that spurious and non-uniform pulses occur with group *A* and *B*, and at moderate overvoltages they will break down in random discharges that may last a second or more. Group *C* on the other hand had uniform pulses free from spurious discharges, and the counter overvoltage could be used over a wide range without a breakdown occurring. The dark backgrounds of all three counters were low.

This provides tentative confirmation for the statement made earlier that only counters having a low value for γ will show satisfactory characteristics in the counter operating region.

Another experiment was performed in which groups of two or three cathodes were used having heavy plated coatings of platinum, nickel, gold, silver and two different copper surfaces. All surfaces were originally chemically cleaned, but it must be assumed that some mercury contamination was on the surfaces. These groups of counters were operated under identical conditions. With 1.22×10^7 ohms resistance in series with each counter the potential was increased until an almost discontinuous increase in the corona current was observed. This was apparently the beginning of the glow discharge region. The potential at which this abrupt shift in corona current occurred is dependent on the γ of the cathode surface. The potentials at which these current breaks are observed along with the magnitude and sharpness of the breaks are shown in Fig. 13. The greater the average corona current required to supply photons and metastable atoms at the cathode for breaking into the glow discharge region the lower must be the effective γ of the cathode surface. From Fig. 13 the cathode surfaces tabulated in order of decreasing γ were platinum, gold, nickel, silver, clean copper and Cu_2O. The deviations of a few individual counters in Fig. 13 were probably attributable to unclean surfaces. The counter operating characteristics ranged from severe random breakdowns with the platinum cathodes to normal counter performance for copper oxide cathodes.

In making large numbers of counters it was found useful to use the measurement of the corona current break in predicting satisfactory counter operation before sealing off the counters from the vacuum system.

Assuming that this explanation of the behavior of the breaks in the corona currents is correct, it follows that for any given cathode surface the corona current breakpoint must be a function of E_a/P. Selecting a platinum cathode the corona current at the breakpoint was determined as a function of the gas pressure. The calculated values of E_a/P near the center wire were evaluated for these pressures, and the shapes of these two curves are compared in Fig. 14.

The characteristics of counters employing very thin silver or copper films were highly dependent on film thickness, uniformity and oxides. Many of these counters displayed spurious background effects such as those described by Malter and Roggen and Scherrer.[32]

IV. LOW VOLTAGE PROPORTIONAL COUNTERS

The proportional counting region for noble gas counters lies between the potential at which ion multiplication begins to occur at the center wire and extends to the breakdown potential V_B. Therefore, all discussions of the threshold potential for G-M counters which have been presented also define the approximate

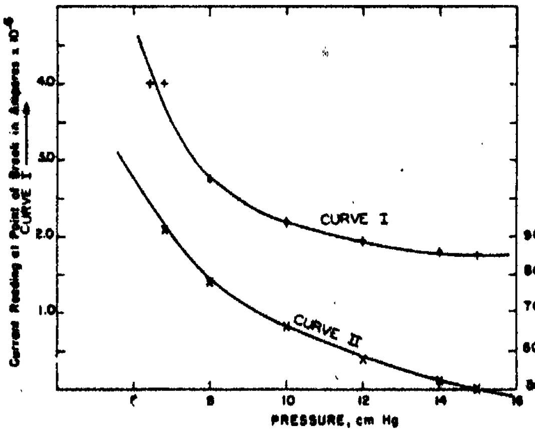

FIG. 14. The two curves show the dependence of the corona current at the breakpoint on the value of E_a/P. The counter cathode was plated platinum.

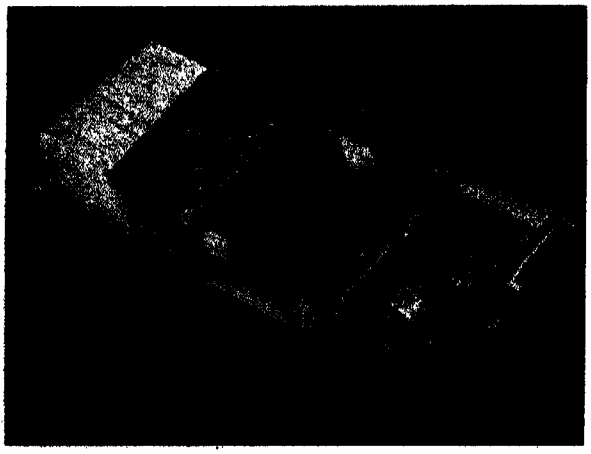

FIG. 15. A complete G-M counter radiation detector, for use with headphones, weighing less than 300 g. Case dimensions are 1×3×6 in.

---

[31] D. H. Hale and W. S. Huxford, J. App. Phys. 18, 586 (1947), and references therein.

[32] F. Roggen and P. Scherrer, Physica 15, 497 (1942).

operating potentials for proportional counter performance.[33] Counters with pure boron films deposited on iron cathodes have been prepared using neon-argon gas mixtures. Their characteristics have been studied by using the alpha-pulses from the $B^{10}(\eta, \alpha)Li^7$ reaction to produce the ionizing events. The maximum usable gas amplification factor[34] is more stable in neon-argon counters when pressures above 10 cm Hg are used, but the amplification factor is critically dependent on operating potential.

V. APPLICATIONS FOR LOW VOLTAGE G-M COUNTERS

Since the operating potential requirements of these neon-argon counters are modest it is convenient to use batteries which have been recently developed for hearing-aids and radiosonde equipment.[35] Several pocket radiation detectors have been constructed[1] using thin-wall counters having a threshold potential of 125 volts. An electronic quenching circuit utilizing a subminiature tetrode or pentode supplied a pulse signal for a high impedance head-phone. The dimensions of the aluminum instrument case were $1\times3\times6$ in., and the total weight was less than 300 g. The detector unit parameters were calculated so that 25×10^{-3} roentgen unit per hour of gamma-radiation produced an output signal in which the individual pulses could barely be audibly resolved. An early design is shown in Fig. 15.

Another type of radiation meter was constructed utilizing approximately 160 to 200 volts threshold counters.[1] The output of the quenching circuit operated a two tube counting rate meter and a single tube vacuum tube volt meter using a 1 in. diameter 0–100 microammeter. A movable absorber over the counter window provided a method for separating beta- and gamma-radiation. The dimensions of the instrument case were $1\times3\times10$ in. and it weighed 600 g.

Boron-coated cathodes used in neon-argon proportional counters produce convenient slow neutron detectors of small size using subminiature vacuum tubes in pulse amplifiers.

VI. SUMMARY

Conditions have been found for the adequate performance of low voltage counters. It is assumed that the additional factors essential for the adequate performance of all G-M counters in general are well known from the literature and need not be described. Thus, it has been shown that neon with small amounts of argon added is at least one combination of a class of gas mixtures which will successfully produce low voltage counters. They have the following counter characteristics: 1. A selection of G-M counter threshold potentials ranging from 115 to above 250 volts depending upon pressure, gas mixture and electrode dimensions is possible. 2. Counters with threshold potentials of 145 volts or more have "plateau" slopes of approximately 1 to 2 percent in a 100-volt interval. These counters have pulse rise times the order of 2×10^{-6} sec. and may be used with fast quenching circuits (Figs. 10 and 11). 3. Counters with threshold potentials *below* 135 to 145 volts require quenching circuits with long recovery times ($\sim5\times10^{-3}$ sec.) (Fig. 12). 4. The counters employ gas mixtures at pressures of 4 cm Hg ($V_t=112$–125 volts) to beyond 50 cm Hg ($V_t=210$ to 250 volts) having high specific ionizations. At pressures of 15 cm Hg or more the counter efficiency for ionizing events is very near 100 percent. 5. The counters appear to be stable for an indefinitely large number of counts and are essentially non-temperature dependent.

Neon-argon tubes with the characteristics described above have many applications in miniature radiation survey instruments. In general, only those counters with threshold potentials above 145 volts are useful for quantitative measurements. Improved electronic quenching circuits contribute greatly to extending the applications of these counters.

Laboratory and Shop Notes

A Useful Fast Coincidence Circuit

R. L. GARWIN
Institute for Nuclear Studies and Department of Physics, University of Chicago, Chicago, Illinois

February 17, 1950

IN connection with some work on beta-gamma-angular correlation[1] a reliable fast coincidence circuit was needed. It had to satisfy at least three requirements: (1) to be operable at resolving times shorter than 0.02 μsec. (μ=microsecond) and preferably as short as 0.002 μsec.; (2) to be absolutely reliable in rejecting single impulses and to count properly all coincident pulses; (3) to be operable on relatively small pulses so that the driving source for the coincidence circuit need not handle large power.

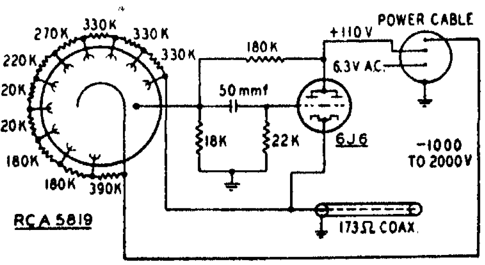
The circuit depicted in Fig. 1 fulfills all of the requirements and has been operating for more than eight months at resolving times of the order of 0.02 μsec. without failure or necessity of adjustment. The difficulty with the common Rossi circuit (Fig. 1 without the diode (a)) is that a coincident pair of negative pulses lasting 0.01 μsec. will allow the anode capacity to charge through the anode resistor to about 20 volts above the quiescent potential of 60 volts, during the coincidence. The tube characteristics, however, indicate that driving a single grid negative will allow the plates to reach some 90 volts, a 30-volt output pulse. Therefore, a long single pulse gives a larger output than the desired coincident pair. This situation is alleviated by the clamping diode (a) in Fig. 1. When the grids are not pulsed, this diode carries somewhat more than half the total plate current to the double triode, charging the fast ceramic 0.01-μf condenser to a potential determined by the tube characteristics (∼100 volts). The total tube current is then 30 ma, of which 18 ma flows through the diode. Since resistance of the diode in the forward direction is ∼20 ohms (1 Type IN56 or 3 parallel IN34) the positive output pulse arising from driving one grid negative is of amplitude 15 ma×20 ohm or 0.3 volt. The coincidence pulse, however, is not attenuated, remaining ∼20 volts for 0.01 μsec. Therefore, if the crude discriminator is set at one volt, no difficulty is observed with resolving times as short as 0.005 μsec.

In order to be able to use a conventional scaler, the pulse stretcher consisting of the diode (b) and the stray capacities C_s (∼3 mmf) lengthens the coincidence output pulse to 0.5 μsec.

The clamp diode (a) has also the advantage of eliminating active capacities between plate and grid. For fast pulses without the clamp, one may expect the plates to fall some 2 volts in view of the grid plate capacities if the grids are driven 3 volts negative. The charging during the coincidence time may or may not be large compared to 2 volts. The diode (a), however, reduces the initial drop due to capacitive feed-through to less than 0.2 volt, effectively removing this undesirable phenomenon. Little advantage is gained by using two pentodes rather than the triodes, except for somewhat larger output. However, the Type 6AH6 pentode with g∼9000 micromhos allows a considerable reduction in grid pulse amplitude. The flawless operation of the 6J6, however, makes the substitution of pentodes somewhat a matter of taste.

The circuit requires negative pulses of 3-volt amplitude for proper operation and has been tested with artificial pulses from a mechanical switch-coaxial line arrangement[2] down to coincidence times of 0.005 μsec. Since one wants to be able to use the coincidence circuit with fullest flexibility, the input should be transmitted through electrically smooth coaxial cable. The current needed from the driving source is about 15 ma for cable impedance of 173 ohms. It is fortunate that not much current is required since the obtaining of fast negative pulses from a cathode follower requires continuous passage of large currents through the tube. The driver and pulse shaping lines are also indicated in Fig. 1, the shorted stub lines in the grid circuits being 1 meter long for 0.01 μsec. resolving time. The impedance match in the grid circuit is only approximate and may be improved somewhat by placing 200-ohm resistors to ground from the cathodes of the cathode followers.

It should be noted that most photo-multipliers (RCA 5819) may be operated at voltages high enough (1500–2000 volts) to give pulses 3 v high from anthracene crystals with 50-kev ionization loss in the crystal. This enables one to dispense with amplifiers and to get the ultimate resolving times of which presently available photo-multipliers are capable. No refrigeration is used and the noise pulse amplitude is increased only to the equivalent of about 50-kev ionization loss in anthracene. The number of these noise pulses diminishes extremely rapidly with amplitude so that one can count all beta-rays of energy 100 kev with less than one noise pulse per minute. Of considerable help in reducing photo-multiplier noise is the operation of the photo-multiplier anode at only 10 volts positive with respect to the preceding dynode. This causes space-charge saturation on the fast noise pulses to a greater extent than on the slower signal pulse, improving the signal-to-noise ratio. With crystals faster than anthracene, the usefulness of this trick disappears. In cases of very low ionization loss, i.e., say 80-kev gamma-rays detected by Compton recoils in anthracene, distributed amplifiers will be used with lower photo-tube voltage.



PREAMPLIFIER AT EACH PHOTOMULTIPLIER

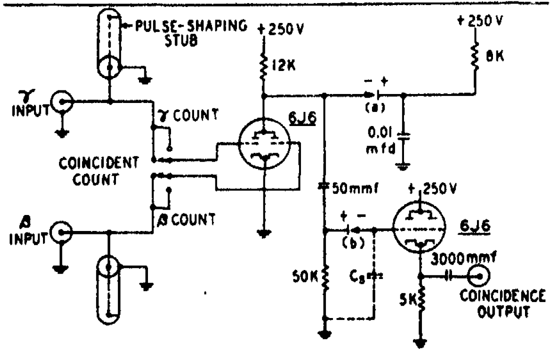


FIG. 1.

Care should be taken in absolute measurements with this coincidence circuit using the photo-multiplier pulses. If single counts are to be taken continuously with the coincidences, the biases should be set to be appropriate for the purpose of the experiment. This type of difficulty is not present with artificially generated (blocking oscillator) pulses.

The circuit of Fig. 1 has proved so trouble-free that it is now much used even in relatively slow coincidence applications. Until better photo-multipliers with less transit time spread and better crystals than stilbene become available, this circuit should be adequate for fast coincidence work.

An Effective Vacuum Cut-Off

G. W. Sears* and E. R. Hopke
Department of Physics, Duke University, Durham, North Carolina

April 18, 1950

It is frequently necessary to cut off gas flow from one part of a vacuum system to another. Particularly for the manipulation of condensed phases in vacuum a tight closure is demanded to avoid sample losses as well as contamination of the pumping system. A cut-off involving non-volatile components is desirable to facilitate outgassing.

This note describes a cut-off constructed of glass and quartz, which might equally well be constructed solely of either material. The particular form shown here served as a Rodebush gauge[1] for measuring small pressures. The device is shown graphically in Fig. 1.

A circular plate, *C*, of optically flat quartz 1 mm thick and 25 mm in diameter seats against the polished end of an 18-mm Pyrex tube, *B*, to cut off gas flow. A quartz eye sealed to the center of the disk is attached via a quartz fiber, *F*, to a quartz encased iron armature, *A*. This assembly is suspended via a quartz fiber, F^1, from a quartz cantilever spring, *S*, which serves to seat the disk against the opening of the tube.

The upward force of the spring is counterbalanced by a downward force of a solenoid on the armature when the cut-off is to be opened. In closed position a high pressure region outside of the Pyrex tube is sealed off from a low pressure region inside the tube. In fact, it is impossible to open the cut-off under these conditions. The pressure must be nearly equalized to open the cut-off. By weighting the plate the gate may be made to open against a larger pressure difference.

The annular surface of the Pyrex seat was prepared by successive grinding with *F* through *FFFF* carborundum grits. The surface was maintained normal to the tube axis with the aid of a jig. The finely ground surface was polished with a good grade of red rouge on a pitch lap until the surface appeared smooth as observed without magnification. Some care was necessary in sealing the eye on the quartz plate. A region no larger than 8–10 mm in diameter at the center of the plate could be distorted during the operation. The completeness of the cut-off can be judged by the observation that a vacuum of 10^{-5} mm Hg was maintained against a pressure of 1 atmosphere in one test.

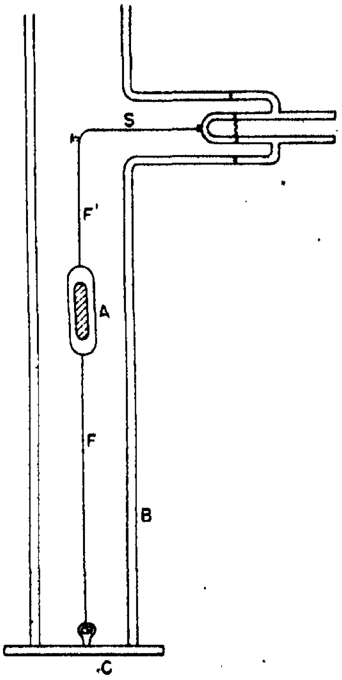

FIG. 1. Apparatus for vacuum cut-off.

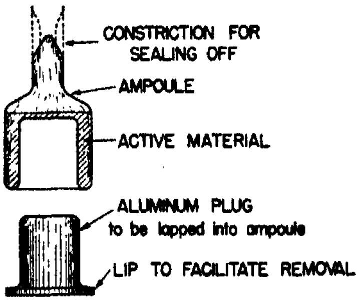
A Remote-Control Method of Opening Ampoules of Active Materials

Jesse E. Sherwood
National Bureau of Standards, Washington, D. C.

April 10, 1950

When working with highly reactive materials such as alkali metals, one is likely to require a method for opening an ampoule of such a material in a vacuum or some special atmosphere. In work with molecular beams, for example, such devices as magnetically operated hammers cannot be used because of space limitations. In case heating of the material is permissible, the following procedure may be used. It utilizes the effect of the high thermal expansivity of aluminum as compared to glass.



CONSTRICTION FOR SEALING OFF
AMPOULE
ACTIVE MATERIAL
ALUMINUM PLUG to be lapped into ampoule
LIP TO FACILITATE REMOVAL

FIG. 1.

The ampoule is made in the shape shown in Fig. 1. The cavity in the end of the ampoule is made to receive a cylindrical plug which is lapped into place with an abrasive. The plug is then removed and the ampoule filled in the usual way. After sealing off, the plug can be snugly set in place. The ampoule will break when the plug is heated. The ampoule should be placed with the plug uppermost.

In our work, the ampoule is of Pyrex glass and the plug is about 6–7 mm in diameter. The arrangement described has functioned in all cases on being heated to 100°C.

Regulated Low Voltage Power Supply

A. K. Solomon
Biophysical Laboratory, Harvard Medical School, Boston, Massachusetts

March 20, 1950

A regulated low voltage power supply has been designed for use with the direct current amplifiers in a mass spectrometer of the Nier type.[1] It is a series regulator with two stages of amplification; the circuit diagram is shown in Fig. 1. The output is 225 volts at a current of 190 milliamperes. The use of a battery instead of a resistance chain in the feed-back circuit imposes the whole error signal on the input grid of the 12AX7. There is no provision for adjustment of output voltage, since it can be varied by 1.5-volt steps by adjusting the battery potential. In a circuit of this type, any change in tube electrode potentials to alter the output voltage results in departure from the optimum conditions for operation. Should this be essential it would be possible to replace the 226.5-volt battery with a smaller battery and the conventional resistance chain. For best operation it is

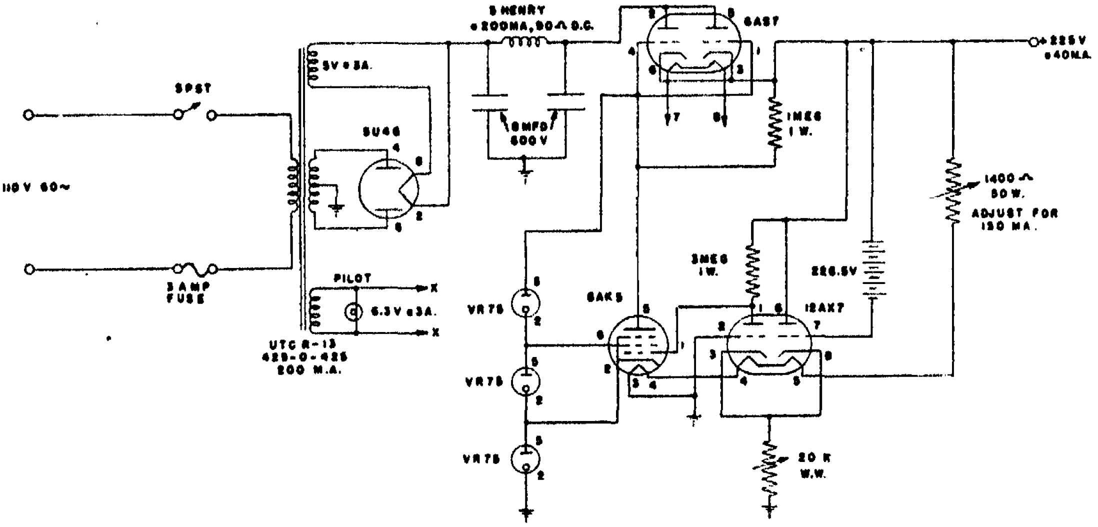


FIG. 1.

necessary to adjust the 20,000-ohm rheostat in the cathode circuit of the 12AX7 to set the voltage between the ground and the right-hand grid to a value between 1.5 and 2.0 volts. Direct current heating of the filaments of the 12AX7 and the 6AK5 improves the performance by a factor of two. The direct current amplifier, for whose power requirements the present circuit was designed, uses 150 milliamperes for filament heaters and 40 milliamperes for plate supply. When used in this connection, the 1400-ohm potentiometer is replaced by the series heaters in the amplifier and a much smaller resistance with which the current is adjusted to 150 milliamperes.

Data on the performance of the power supply follow. A change of input voltage from 108 to 135 volts results in a 10-millivolt change in output; a change from 93 to 135 volts results in a 20-millivolt shift. At 118 volts input, a change in load from 0 to 190 milliamperes results in a 20-millivolt shift in output voltage. Ripple is less than 1 millivolt between 93 and 135 volts.

In order to determine the expected operating characteristics of the power supply in the spectrometer, it was fed from a Sola constant voltage transformer, and the output was bucked by a set of batteries. A load drawing 150 milliamperes was supplied. The difference between the bucked potential and ground was then measured on a 4.5-second Brown Electronik Recorder with a full scale deflection of 10 millivolts. Since the input impedance of the Brown recorder is not high and is a function of the position of the carriage on the slide wire in the recorder, the current drawn from the batteries is not constant and a balance must be achieved between charging and discharging the batteries. This balance is critical and extends over a very narrow range; either side of balance the system rapidly becomes unstable. It will be seen from Fig. 2 that when a balance is achieved, the output voltage is stable to better than 50 microvolts. Any fast fluctuations do not, of course, appear. Standardization pips in the recorder account for the large apparent shifts in voltage; it can be seen that the battery-recorder system does not return to the same position after this momentary disconnection in the circuit.

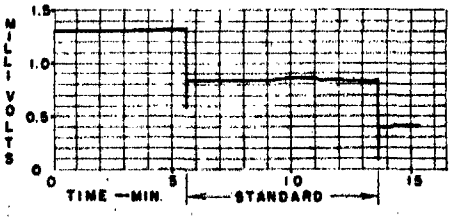

FIG. 2.

The author wishes to express his thanks to Mr. David Caton for his most valuable assistance. This work has been supported in part by the AEC.

Extension of the Low Pressure Range of the Ionization Gauge

ROBERT T. BAYARD AND DANIEL ALPERT
Westinghouse Research Laboratories, and Physics Department, University of Pittsburgh, Pittsburgh, Pennsylvania

April 13, 1950

THE ionization gauge[1] has been generally considered useful for the measurement of gas pressures ranging down to 10^{-8} mm Hg.[2] This low pressure limit is not the lowest pressure attainable with modern vacuum techniques, but has been shown to be a limitation of the conventional ionization gauge itself. An investigation made in this laboratory to determine the cause of this limitation has resulted in a new ionization gauge whose range has been considerably extended. The new gauge has been used to measure pressures of the order of 10^{-10} mm Hg.

The conventional ionization gauge resembles structurally the triode vacuum tube. The grid, however, serves as anode and is operated at a positive potential (100 to 250 v), while the plate is negative (10 to 50 v), both with respect to the cathode. Electrons from the cathode, before being collected at the grid, can create positive ions by collision with gas molecules. The number of ionizing collisions for a given electron current is considered to be proportional to the gas density. The current to the ion collector, or plate, is thus a measure of the pressure.

Dushman[3] has shown that the ion current for a given electron emission is indeed linearly related to the pressure between 3×10^{-6} mm Hg and 10^{-3} mm Hg. On the assumption that this relation continues to hold true, ionization gauges have been used to measure lower pressures. Workers in the field today, however, agree that while currents less than that corresponding to 10^{-8} mm Hg[4] could easily be measured, they are not observed. On the other hand many investigators[5] have had indications that considerably lower pressures than 10^{-8} mm Hg have actually been attained. This suggests the existence of a residual current to the ion collector which is independent of pressure. Nottingham[6] has suggested that this residual current is due to soft x-rays which release photo-electrons from the ion collector, the x-rays being created at the grid by the incidence of the thermionic electrons.

Independent evidence for the existence of a residual current comes from the observed characteristics of the ionization gauge itself. If for a given pressure and electron current, the ion collector current i_c is measured as a function of grid potential v_g, the plot of i_c *vs.* v_g, shown in Fig. 1a, has a characteristic shape for pressures above 10^{-7} mm Hg. The gas ionization curve shown (upper line) is typical of data taken on RCA type 1949 gauges. Note that i_c rises rapidly with v_g up to 200 volts and varies slowly with potential above this value. When the pressure is considerably lowered (ion gauge reading 10^{-8} mm Hg) the curve of i_c *vs.* v_g is radically different as shown (lower line). This residual curve continues to rise with grid potential, the slope on a log-log plot being between 1.5 and 2. In the intermediate range of pressures (10^{-7}–10^{-8} mm Hg) the characteristic corresponds to a superposition of the "gas ionization" curve and the "residual" curve. These results, obtained independently in this laboratory, are in agreement with data published in 1931 by Jaycox and Weinhart[7] and with unpublished findings of W. B. Nottingham.

With the explicit purpose of examining the hypothesis that this residual current is due to x-rays, a design was sought for an ion gauge which would operate in the usual manner but whose ion collector would intercept only a small fraction of the x-rays produced at the grid. The ionization gauge which evolved from these considerations is shown in Fig. 2. The new gauge has the usual three elements, but is inverted from the conventional arrangement; the filament *A* is outside the cylindrical grid *B*, while the ion collector *C*, consisting of a fine wire, is suspended within the grid. The volume enclosed by the grid is made comparable to that between the grid and plate of the ordinary ionization gauge. The positive potential on the grid forms a barrier to the ions formed inside the grid-enclosed volume so that they are eventually collected at the center wire. The ion collection efficiency is thus comparable to that of the conventional ionization gauge. On the other hand, the geometrical cross section of the ion collector to radiation from the grid is approximately one hundred times smaller than that of the conventional cylindrical collector.

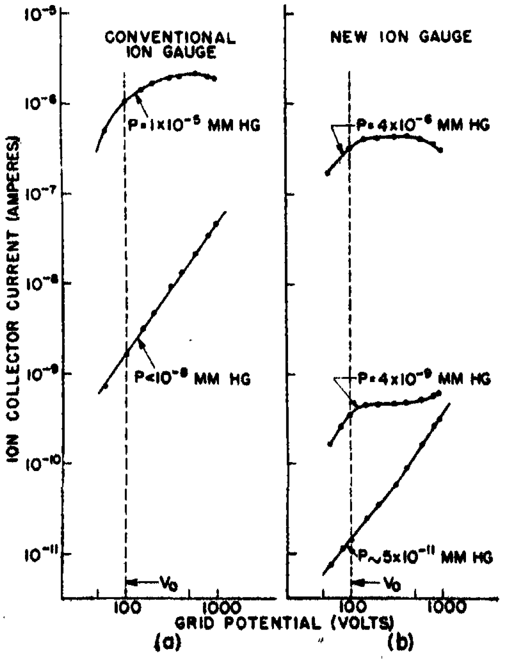

FIG. 1. (a) Typical data for RCA type 1949 gauge. (b) Typical data for the new type gauge. V_0 is the normal operating voltage.

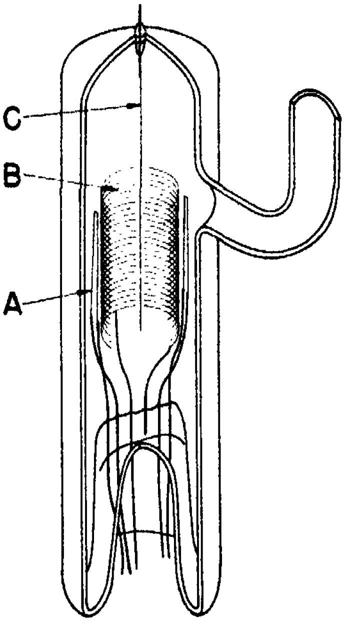

FIG. 2. Cutaway view of the new gauge showing filament *A* (an auxiliary filament is also shown), grid *B*, and ion collector *C*.

The properties of the new ionization gauge are shown by the curves of Fig. 1b. At higher pressures the characteristics of the new gauge are very similar to those of the RCA gauge, but it is evident that the new tube continues to have typical "gas ionization" characteristics at much lower pressures. At 4×10^{-9} mm Hg the collector current is predominantly due to gas ionization, and it is not until the pressure is less than 10^{-10} mm Hg that the residual current predominates.[8] Note that the slope of the residual curve is the same as that for the RCA gauge. On the other hand the value of the collector current for the new gauge, at a given grid voltage, is one hundred times lower than that for the RCA gauge. This ratio of residual currents for the two types of ion gauges is the same as the ratio of their geometrical cross sections to radiation mentioned above. These general characteristics of the new gauge clearly substantiate the x-ray hypothesis and indicate that ionization gauges can be built to measure even lower pressures.

The sensitivity of the new ionization gauge has been measured by calibration with a McLeod gauge at nitrogen pressures in the neighborhood of 10^{-4} mm Hg and by comparison with a standard ionization gauge at various pressures between 10^{-5} and 10^{-7} mm Hg. As seen from the typical curves in Fig. 1, the sensitivities of the two types of ionization gauges are essentially the same. The new gauge gives indication of pressures at least 100 times lower than the standard ion gauge. It has a minimum of metal surface, is easily outgassed, and is operated on a standard power supply. These characteristics make the gauge a useful tool for studies in the field of high vacuum.

---

[8] The pressure represented by the lowest curve, as judged by the deviation of the lower portion from a straight line, is estimated to be of the order of 5×10^{-11} mm Hg.

A Circumferential Recording Microphotometer

T. C. O'Connell* and A. G. Barkow
Physics Department, Marquette University, Milwaukee, Wisconsin

January 16, 1950

In preliminary experiments on the x-ray diffraction method of determination of fatigue in metals and the change in crystal structure in metals due to impact or shock, the need for a circumferential recording microphotometer was apparent.

The illumination system consisted of a line filament 32-candlepower automobile spotlight bulb which was supplied by a 6.3-volt transformer of heavy current capacity. The input to the transformer was controlled by a Variac to allow for a certain degree of light input variation. A double condensing lens of the Ramsden type was placed in front of the light source.

An adjustable micrometer slit was placed immediately in front of the condensing lens. The image of the slit was then projected forward on to the film by means of a microscope objective of 25.4 mm focal length. This system was used because of its relative simplicity and versatility. The slit width could be varied by placing the microscope objective in a focusing mount. Moving the film carriage back and forth, which was equivalent to changing the slit image distance, allowed the slit length to be varied enough to cover almost any diffraction ring encountered. As a matter of fact the slit could be made as small as necessary by means of a mask.

The film carriage consisted of a shaft mounted on a sheet metal stand which in turn was mounted on a geared track to allow for the centering of the diffraction ring under investigation. The photo-cell housing was located immediately behind the film, the latter being held flat against a flat faced cylinder by means of a pressure plate of highly polished aluminum under slight spring tension. The photo-cell was enclosed in an aluminum housing just large enough to fit over the photo-tube. A Type 917 (RCA) vacuum cell was used in the present equipment. This tube has the advantage of being relatively small in diameter (1.165 inch maximum at the base), allowing for the scanning of diffraction patterns of only 0.75 inch radius. Furthermore, the fact that it has an anode cap rather than an anode base lead, tends to reduce leakage currents. The vacuum photo-cell, in spite of its lack of sensitivity compared to the gas cell, is preferable for light measurement applications because of its higher internal resistance and more constant sensitivity. The cell was placed just far enough in back of the film so that the longest slit produced a spot of light which covered as much area as possible of the cathode element. Such coverage is necessary if maximum stability is to be had in the long time use of the photo-tube.

The socket is of the ceramic type to prevent leakage. The leads from the tube should be shielded and should have as high an insulation resistance as possible. These precautions must be taken if one expects to have response to small amounts of light and at the same time desires to maintain accuracy. The current supplied by the photo-cell developed an IR drop across two portions of a 10-megohm resistance (R_9 and R_{10}). Hence, any shunt leakage resistance is an erratic variable which may cover up the effect of small photo-tube currents. The complete schematic diagram is shown in Fig. 1.

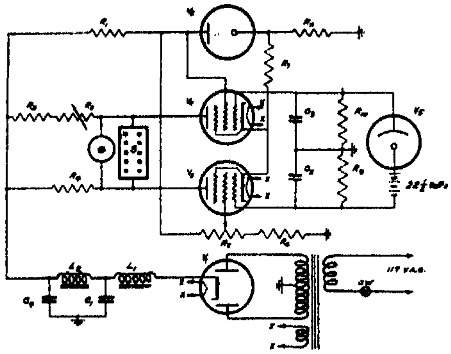

FIG. 2. Circuit diagram of the photo-tube amplifier.

Amplifier Part List

(All resistances in ohms and capacities in microfarads.)

C_1	8	400 v elect.
C_2	0.01	mica
C_3	0.01	mica
C_4	8	400 v elect.
R_1	5600	2 watts
R_2	47000	½ watt
R_3	1000 pot	vernier balance control
R_4	47000	½ watt
R_5	100000 pot	rough balance control
R_6	2400	1 watt
R_7	1200	1 watt
R_8	470	1 watt
R_9	5 meg.	½ watt
R_{10}	5 meg.	½ watt
L_1	10 henrys	
L_2	10 henrys	
S	0–100 shunt box	
T	Power transformer, 550 v C.T. 6.3 volts, 2 amp.	
V_1	6X5	
V_2	VR 105	
V_3	6J7	
V_4	6J7	
V_5	917 (anode cap) or 919 (cathode cap)	

The photo-tube amplifier (Fig. 2) used in this instrument consisted of a Wheatstone Bridge, two legs of which were made up of low μ-tubes. No more than 22.5 volts were applied to the photo-tube at any time. This low anode potential is necessary to prevent ionization of small amounts of residual gas which might lead to erratic operation of the cell.

For quantitative work, the entire system must be regulated to within 0.1 percent as far as applied voltage is concerned for consistent results. A Sola saturable reactor type transformer was used, the line voltage fluctuations being small enough to be kept within the limits suggested. A VR 105-voltage regulator tube was used to stabilize the screen voltage.

The output of the amplifier was supplied to a wall type galvanometer of moderate sensitivity and of a period of about three seconds. Since an amplifier of the type used has a sensitivity of about 0.3 volt full scale with a one-milliampere movement, the galvanometer whose resistance was 126 ohms was shunted by a 0–100-ohm shunt box. This allowed for a very wide range of sensitivity as well as the use of a very narrow slit in scanning.

The deflections of the galvanometer, due to the variations in film blackening, were recorded on the photographic enlarging paper which was fastened to a chronograph drum. This drum in turn was coupled to the film carriage in order that the diffraction ring to be scanned makes one revolution in synchronism with the drum itself. The coupling consisted of two rigid shafts connected to one another by means of a universal joint to prevent any strain on the film carriage. The speed with which the drum rotated was governed by means of a Variac controlled motor. A complete revolution could thus be made in about 20 to 30 minutes, depending upon the spot sizes on the diffraction ring. It should be mentioned that the galvanometer followed all variations in the film.

An astigmatic optical system was used to produce the trace on the enlarging paper (chloro-bromide). This system provided more than ample illumination due to the extreme speed of the paper used.

The procedure for operation of the densitometer was relatively simple. The amplifier was allowed to warm up for about twenty minutes to overcome any possible drift due to temperature changes. The x-ray film was centered on the carriage and the photographic paper placed on the drum.

The amplifier was adjusted to zero by means of the coarse control, R_4, and finally by the fine control, R_3. This adjustment was made with no light falling on the cell, in other words, this represented zero percent transmission. Next, the light source was turned on, and the slit made as narrow as possible. The slit image was then made to fall on a clear background region close to the ring being scanned. The intensity of the light source was then varied in conjunction with the slit and the galvanometer shunt in order to obtain a 100 percent transmission reference. This point was chosen arbitrarily at a particular distance from the zero reference and, of course, was a function of the dimensions of the drum.

The film was then moved so that the ring to be scanned was in the path of the slit image. The motor was then turned on and the trace made.

Applications.—The circumferential microphotometer was applied to the x-ray diffraction study of the changes in metals due to impact or shock. A sheet of Duraluminum, $14\times20\times\frac{1}{8}$ inches, was rigidly fixed at the four corners, or in terms of the coordinates at the points $(7, 10)(-7, 10)(7, -10)(-7, -10)$. An impact hammer capable of imparting 2000 ft. lb. per blow was allowed to strike the fixed plate at the coordinates $(0, 0)$. X-ray diffraction pictures of the plate were taken at two points, $A(3.5, 0)$ and $B(0, 5)$. These are two of several points analyzed by x-ray diffraction in an effort to determine the stresses set up in the metal. In analyzing the conditions, it was assumed that the vibrations set up in the aluminum were similar to those present in a vibrating plate fixed at the four corners. The points A and B were marked so that the plate could be removed from the impact machine, and set up in a frame on the diffraction unit in such a way that the two exact points could be irradiated. Preliminary pictures 1A and 1B were taken of the unstrained sheet while 2A and 2B were taken after the aluminum sheet had been struck forty times by the hammer or after 80,000 ft. lb. of energy were imparted to the plate. The diffraction pictures showed very little as to the nature of the change in the metal plate. In Fig. 3 it is immediately evident that a slight preferred orientation existed in the plate in the no fatigue stage. However, after the forty impacts a definite change in the orientation has manifested itself, especially at point B. These changes were hardly perceptible on the diffraction picture. Traces in Fig. 3 represent 360° or the complete diffraction ring of the second-order reflection from the (111) plane with copper $K\alpha$-radiation. The diameter of the chronograph drum was 6.7 inches; hence Fig. 3 is a reduction from traces approximately 21 inches in length. To check the accuracy of the preferred orientation, four India ink marks were placed at the quadrant marks on the diffraction film. These appeared as large "pips" on the microphotometer traces and help in orienting the pattern.

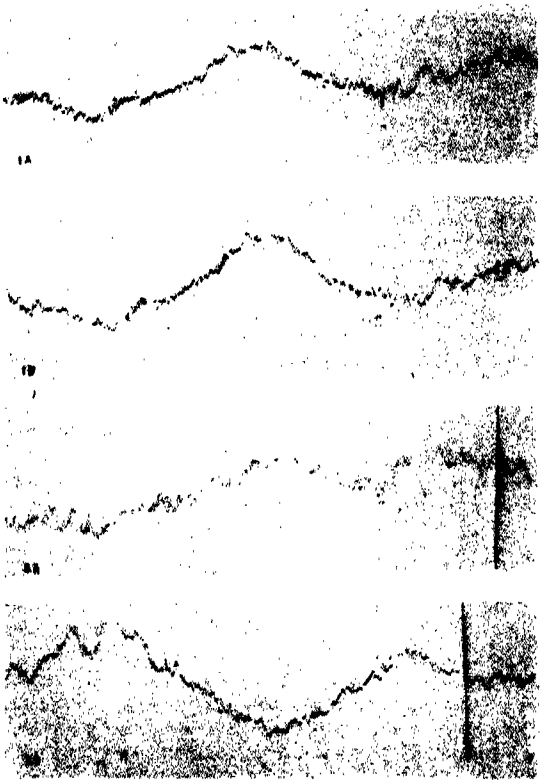

FIG. 3. Microphotometer traces of Duraluminum. 1A and 1B are of two points, 90° apart, of the unstrained plate. 2A and 2B are of the same two points after the plate was subjected to 40 impacts of 2000 ft. lb. each.

Water-Proofing Rocksalt for Infra-Red Absorption Cells

SCOTT ANDERSON, WILLIAM J. ANDERSON, AND MARTIN KRAKOWSKI
The Anderson Physical Laboratory, Champaign, Illinois

March 13, 1950

SOME time ago we had occasion to do some infra-red absorption work with vegetable oils prepared by a steam distillation process. The water content of the oils was sufficient that they attacked rocksalt vigorously. The region of the spectrum of interest to us was between 10–12μ which is beyond the useful transmission limit of CaF_2. Therefore, we sought a means of protecting the salt with a film of material. The requirements on such a film were as follows: it should (1) contain no characteristic absorption of its own between 4 and 14μ, (2) be capable of a highly polished surface, (3) have refractive index low enough that reflection losses would not be excessive, and (4) be uneffected by either water or carbon tetrachloride (or some other solvent that could be used to remove the oil). Evaporated selenium satisfied all these requirements. This note is to describe the technique and precautions necessary for the successful use of these cells.

Rocksalt plates were prepared in the usual manner by polishing with fine Alundum using alcohol for a lubricant. In this connection we found that durable selenium films were formed only when the polishing lap was of high quality hair felt. When a cotton lap was employed to do the polishing, the selenium invariably began to peel off the salt after two or three fillings of the finished cell.

Four salt plates were prepared each time, two plates drilled and two undrilled. This was done so we could make two cells alike and alternate them as standards and unknowns. The plates were mounted close together in the center of a brass plate. After mounting, the plates were rinsed with carbon tetrachloride to remove all dust and lint and placed in the evaporator eighteen inches above the evaporating filaments. These latter were molybdenum ribbons. Two were used to get a uniform coat of selenium on the salt.

Pieces of amorphous selenium were placed on the ribbons and evaporated onto the salt with a vacuum of the order of 10^{-5} mm of Hg. The evaporation was done in two stages. It is our belief that most pinholes in these thin films arise as a result of dust particles being present on the substrate surface. Consequently, the initial evaporation is carried out until the rocksalt plates are a pale orange by transmitted light. The plates are then removed from the holder, rinsed with carbon tetrachloride, and returned to the evaporator. It is hoped that this process removes the dust particles present during the first evaporation and other particles do not settle on the same spot. The second evaporation is carried out at the same pressure in the vacuum system. This evaporation is continued until the rocksalt plates transmit about the same as a Wratten No. 25 filter. Very seldom were pinholes detected in the selenium films.

The liquid absorption cells are assembled in the usual manner with the coated surfaces of the rocksalt plates toward the inside. The lead and tin foil spacer are amalgamated to insure a sealed contact. Care must be exercised not to move the spacer once it is placed on the selenium surface.

Cells prepared in this manner transmit between 80 and 85 percent of the radiation at 12μ. A single cell, made properly (i.e., polish the salt on hair felt and evaporate the selenium at 10^{-5} mm of Hg or better), can be used for between 700 and 1000 filling and rinsing cycles if the water content is below 4 percent. We had one cell that withstood 30 filling and rinsing cycles of water solutions without showing any deleterious effects. Our work with water solutions has not been as extensive as it was with the water-containing vegetable oils so we really can not say how well the properly made cells will withstand pure water.

Carbon tetrachloride is the only solvent we found which was satisfactory for rinsing the cells. Carbon bisulfide and alcohol remove the selenium films very readily and are unsuitable.

If the selenium coat is too heavy and the salt plates are polished plane, a Fabry-Perot effect is encountered. This is convenient for measuring the cell thickness but annoying when attempting to analyze the spectra. This effect can be avoided if the plates are polished slightly convex.

An Improved Electrode Cutter for Spectrographic Laboratories

Esther W. Claffy and Joseph G. Schumacher
Crystal Branch, Naval Research Laboratory, Washington, D. C.

April 13, 1950

CONSIDERABLE difficulty has been experienced in cutting and shaping spectrographic electrodes to uniform size, shape, and wall thickness for quantitative spectrochemical analysis.

Our equipment in the past has consisted of the motor-driven electrode cutter and saw, No. 2380, supplied by Applied Research Laboratories of Detroit, with a cutter-blade modified to produce a small crater with thin, sloping walls. This device is normally fitted with a mandrel having a guide hole of 0.246-in. diameter to accommodate ¼-in. electrodes.

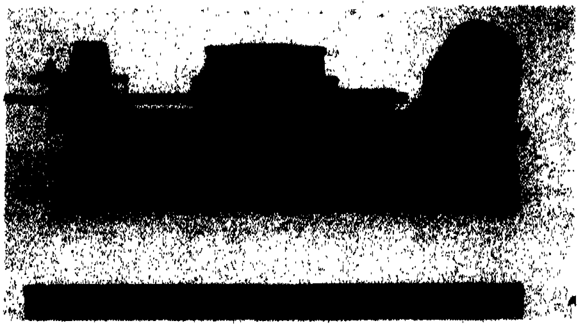

FIG. 1. Photograph of the modified tool, disassembled to show cutter-blade set in holder and chuck mounted on dust hood. "A" is a photographed series of 20 shaped electrodes, chosen at random, to show uniformity of cut.

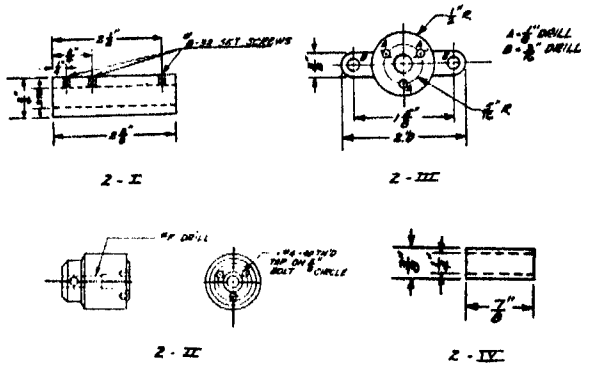

FIG. 2. Machinist's drawings: I, Modified cutter holder, material: drill rod. II, Modification of No. 1A Jacobs drill chuck. III, Support for Jacobs drill chuck, material: brass $\frac{1}{16}$ in. thick. IV, Spacers for Jacobs drill chuck, two required, material: brass tubing.

So-called ¼-in. electrode rods, however, were found to vary considerably in diameter. Some were too thick and became wedged into the opening. Others were thin, and in removing the shaped electrode slight random movements of the hand caused chipping of the crater walls. A certain amount of erratic play inherent in the rotating, axle-borne mandrel also contributed to our difficulties. Thus, there was considerable loss of time as well as waste of material. Moreover, even among the usable shaped electrodes there was noticeable variation.

An extensive but simple modification of the apparatus (Fig. 1) now permits the production of electrodes of remarkably uniform size and shape (Fig. 1A). These can be made with negligible breakage from rods of varied diameters.

The new cutter-blade (seen in Fig. 1) was designed to produce a thin straight-walled crater 3 mm wide and 3 mm deep. The crater holds 20–30 mg of sample. The original mandrel has been discarded and replaced by a small light-weight holder (Fig. 2-I) which is firmly seated on the axle. Cutter-blades can be inserted in the holder without removing it from the axle. Electrode rods are now fed through a modified Jacob's chuck (Fig. 2-II, IV) which is adjustable to the diameter of the rod. The chuck and its support (Fig. 2-III) are permanently attached to the dust hood (Fig. 1). Only the cutter-blade and its holder rotate. The accompanying diagrams are drawn to scale.

Pulsed Air Core Series Disk Generator for Production of High Magnetic Fields

Robert I. Strough and Erwin F. Shrader
Case Institute of Technology, Cleveland, Ohio

February 6, 1950

A HIGH current d.c. generator of the series unipolar type employing no iron in its magnetic circuit has been constructed and tested. The rotor of the machine serves as a flywheel for energy storage and is driven up to speed between current pulses by means of a jet of compressed air acting on turbine buckets cut in the face of the rotor. The present prototype model employing a 5¾ inch diameter forged beryllium-copper rotor weighing 11 pounds has been operated at 20,000 r.p.m. at which speed it stores 29,000 joules of kinetic energy.

The series field "winding" of the machine consists of two circular turns of conductor encircling the rotor and connected in parallel. The conductors are copper castings of 1 by 2 inch cross section. One end of each turn makes contact with the periphery of the rotor by means of a separate brush. The opposite end of each turn is connected by means of a shorting bar to the single center brush. This machine is operated short circuit to produce a large current in the series winding and hence a large useful magnetic field in the vicinity of the series coil of the machine. A separate starting winding consisting of a few turns of small conductor concentric with the rotor and energized by an external battery is also provided to supply the initial field necessary to start the build-up of current in the series winding.

To obtain the negative resistance characteristic required for current build-up in the machine it is essential that the brush resistance be kept extremely small since the e.m.f. generated by the disk per ampere in the series winding is very small (about 50 microvolts per ampere) at 20,000 r.p.m. for the machine described. For this reason a brush arrangement employing mercury flowing between amalgamated surfaces has been developed. The mercury brushes also provide a convenient switch since the series winding may be connected to the disk by starting the flow of mercury through the brushes.

To operate the machine, the rotor is brought up to speed, the mercury flow to the brushes is started, and the starting coil energized. The current in the series coil increases rapidly to a maximum and then decreases to a small value due to the slowing down of the disk as its kinetic energy is drawn off to provide the magnetic field energy and the resistive losses. The mercury flow and starting coil are then shut off and the machine is ready to repeat the cycle.

In preliminary tests the model described above developed a maximum field at the center of the disk of about 4000 gauss when operated at an initial speed of 19,600 r.p.m. This amounts to a total maximum current of about 45,000 amperes through the winding with a resulting current density of 40,000 amperes per square inch at the center brush. The time interval between the switching on of the starting coil and the maximum current is about 0.2 second. A check on the resistance of the series coil revealed a very poor conductivity for the copper castings (about ¼ that for commercial annealed electrical copper). It is estimated that remedying this defect would increase the maximum field obtainable with this particular machine to perhaps 15,000 gauss. The principal limitation on the maximum field obtainable with this machine is still brush resistance, however.

Mapping of the field produced is now in progress to determine the suitability of the machine as a cloud-chamber field supply. Also, the possibility of using such a machine as the source of magnetic field for an air core betatron or synchrotron is being investigated.

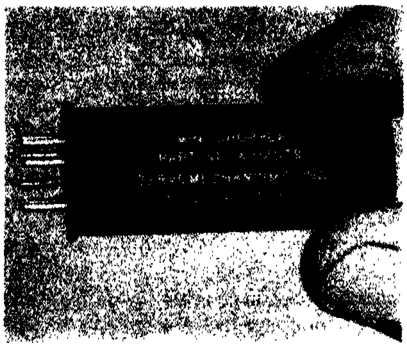
New Instruments

W. A. Wildhack: Associate Editor
in Charge of this Section
National Bureau of Standards, Washington, D. C.

These descriptions are based on information supplied by the manufacturer and in some cases from independent sources. THE REVIEW *assumes no responsibility for their correctness.*

Electron Microscope The new RCA permanent magnet electron microscope is expected to broaden greatly the field of application of this most modern tool of science. Employing for the first time permanent magnet lenses requiring no stabilization circuits and controls, this greatly simplified table model stands only 30 in. high and is expected to sell for less than $6000, about one-third the price of the well-known RCA Universal Model. The new instrument has the same 50,000-volt accelerating potential as the larger unit, and is more than 20 times as powerful as the best optical microscope, with a depth of focus 150 times as great. It will provide useful magnifications up to 50,000 diameters by photographic enlargement, with direct magnification in the instrument ranging up to 6000 diameters. Significant advantages of the new instrument are that specimens may be inserted and removed from the evacuated column without breaking the vacuum and photographic plates may be changed without admitting more than a small amount of air; as a result, pumping time between plates is reduced to only 90 seconds, which is just about enough time for the photographic development normally carried out between exposures. The simplicity of operation achieved in the new design, it is claimed, makes the instrument safe for operation in the hands of a high school student or unskilled laboratory personnel. With no more than an hour of instruction an operator generally familiar with the optical microscope should be able to insert specimens and produce well-focused pictures. Widespread application in the fields of metallography, bacteriology, and medicine is foreseen for this instrument, which has now been brought within the means of a much larger number of potential users.—RADIO CORPORATION OF AMERICA, RCA VICTOR DIVISION, *Camden 2, New Jersey.*

Mini-Chopper The Mini-Chopper, weighing 1.3 ounces and having less than one-eighth the volume of d.c.–a.c. choppers previously available, accomplishes all the functions of modulation, demodulation, rectification, and inversion of intelligence signals normally accomplished by electronic or electromechanical choppers. Despite the outstanding reduction in size and weight, all of these functions are accomplished with no loss of efficiency, and the Mini-Chopper has been proved to have a normal life expectancy of over 1000 hr. The Mini-Chopper is designed for installation in a standard seven-prong miniature electronic tube socket and for retention with a standard miniature tube retainer. Its use in airborne and other mobile systems will permit outstanding savings in both space and weight with the assurance of long trouble-free life.



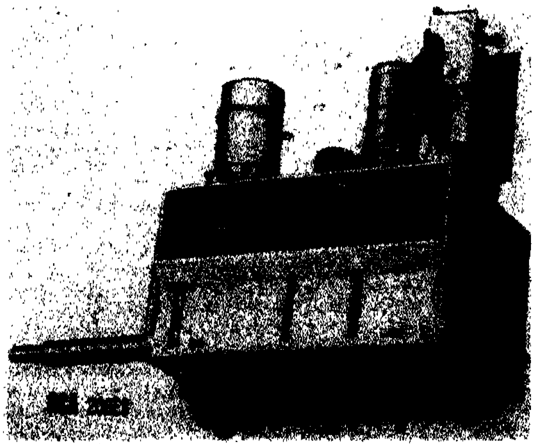
The Mini-Chopper will modulate to frequencies from 60 to 600 cycles at a rated input of 6.3 volts. A very simple provision is made for varying phase shift over an appreciable range during manufacture of these choppers. Extreme temperature tests have shown that the Mini-Chopper is unaffected by ambient temperature from −55°C to +120°C. Hermetic sealing renders it practically impervious to the effects of humidity and pressure.—Servomechanisms, Inc., *Old Country and Glen Cove Roads, Mineola, New York.*

"Printed-Circuit" TV Tuner

The television industry's first "printed-circuit" television tuner is a major development in home-receiver design which provides greatly improved performance, including superior reception in fringe areas as well as in receivers operated with built-in antennas.

A radical departure from conventional wound-coil units, RCA's new "printed-circuit" tuner utilizes a unique photo-etch process to reproduce the critical circuits. The process eliminates the complicated process of mechanically winding separate coils, and at the same time produces precision circuits of superior performance.

The new printed-circuit tuner provides high and substantially uniform gain of between 28 and 35 db on all channels under typical operating conditions. Other features include an excellent noise factor, high rejection of spurious responses, very low oscillator stability, and a low reflection coefficient in the transmission line.



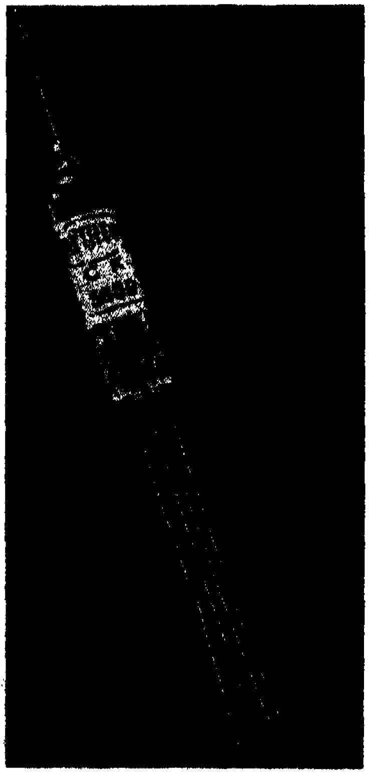
The photo-etch process developed for the RCA printed-circuit tuner begins with the photographing of a circuit drawing. A contact print is then made from the negative in a copper-clad sheet of phenolic plastic which is coated with a light-sensitive material. The print of plastic sheet is next developed and placed in an etching solution. The solution etches away that part of the copper not covered by the pattern of the circuit, leaving the required copper circuit on the plastic sheet. The sheet is then placed in a die and cut into separate sections and pierced.

Especially suited to television-tuner production, the photo-etching process is conducive to continued improvement and circuit development, since all that is necessary when a change is to be made in a circuit is to make a new photographic negative. Reproducibility is excellent, with detail and precision of the lines in the circuit approaching photographic accuracy.—RCA Victor, Division of Radio Corporation of America, RCA Tube Department, *Harrison, New Jersey.*

Subminiature Electrometer Type CK5889

The CK5889 is a new subminiature electrometer pentode having several new mechanical design features which have hitherto been unavailable in any subminiature tube designed for electrometer applications. The more important of these are the 7.5-ma low microphonic filament, the double-ended construction, and the guard ring. The maximum grid current is 3×10^{-15} amp., but the nominal value will be 1×10^{-16} amp., an unusually low value. The electrical characteristics include high transconductance, good emission stability, low drift, and low microphonics.

In the single-stage type of circuit, where the tube must actuate the indicating or recording device, the CK5889 has sufficient reserve emission, notwithstanding the extremely low filament current, to provide operation for several thousand hours. In multi-stage circuits, where the tube is operated at low space



currents in the high gain, pentode connection, the filament power may be reduced to 5 mw, or approximately 6 ma at 0.85 volt, with stable, long-life operation. The external leakage paths from the control grid lead at the top of the tube to the leads from other electrodes are broken by a metallic guard ring which is permanently bonded to the glass bulb.—RAYTHEON MANUFACTURING COMPANY, SPECIAL TUBE SECTION, *55 Chapel Street, Newton 58, Massachusetts.*

A Three-Stage Non-Magnetic Mass Spectrometer

A three-stage non-magnetic mass spectrometer, employing the principle of velocity selection, has been developed by Dr. Willard H. Bennett of the National Bureau of Standards. In the new spectrometer a radiofrequency field replaces the usual magnetic field. Combining unusually simple operation with small size, light weight, and high sensitivity, the instrument has promising applications in several fields of science and industry.

In ordinary mass spectrometers a high intensity beam of ions is bent in the field of a large iron magnet, passed through a narrow slit, and then focused accurately on a narrow receiving slit. The non-magnetic mass spectrometer uses neither bending nor focusing. Ions produced in the ionization chamber travel in parallel paths through the tube, a glass cylinder 8 in. long and 2 in. in diameter. Three sets of three tungsten-wire grids are spaced along the tube to form the three stages. A radiofrequency potential is applied to the middle grid in each stage. An additional grid, with a negative potential applied, follows the final stage and in the absence of r-f potential turns back any electrons that may have arisen anywhere along the tube. Following the final grid is a collector plate whose potential is sufficiently positive to repel all but the desired positive ions.

The distances between grids and between stages are selected very accurately so that for any particular ion mass there will be a single definite frequency of the radiofrequency potential which can speed up ions of that mass as they pass through each stage. The increased speed of these ions enables them to overcome the opposing potential on the collector while all other kinds of positive ions are turned back. Successive distances between stages must be chosen so that the r-f potential will complete an exactly integral number of cycles during the time it takes for an ion of the desired mass to travel between stages, picking up maximum energy in each stage. The best combination of these integral numbers for a three-stage tube turns out to be 7 and 5, and in actual operation the seven-and-five cycle tube has completely separated the isotopes of chlorine. From this observation it is estimated that a four-stage tube, using integral numbers 13, 11, and 7, should resolve masses differing by only one percent.

The spectrometer can make use of all the ions that can be made to emerge through a grid several centimeters in diameter, and a new kind of positive ion source has been developed to take advantage of this. A spiral filament delivers an ionizing electron current of 100 ma through a double grid attached at one end of a hollow metal cylinder 3 cm deep. The far end is closed by a grid and near it is another grid at a negative potential which turns back all electrons and draws positive ions out from the cylindrical enclosure. At a pressure of 4×10^{-5} mm of mercury the source delivers a positive ion current of 100 μa.

By an appropriate change in ion source and reversal of potentials, the spectrometer works well for the study of negative ions, an important feature of the new instrument. Since negative ions are in general much less abundant, when they exist at all, the unusual sensitivity of the Bennett spectrometer is a great advantage in the study of negative ions.

In the development of vacuum tubes as for example power transmitting tubes such a spectrometer can be very helpful in analyzing gases and vapors that are evolved from the heated electrodes.

Surface reactions are another group of processes for which the new spectrometer can be used, separately analyzing the positively or negatively charged components. In gaseous discharges, the instrument can be used for direct analysis of the ions without magnetically disturbing the discharge.

One of the urgent needs of the U. S. Bureau of Mines is an instrument which can be used in the field for the analysis of small percentages of hydrogen in the manufacture of helium. The new spectrometer has already demonstrated adequate sensitivity and resolution for this task, and it can be readily adapted to automatic operation. Similarly, the new instrument could be used for continuous observation of the air in an enclosed space, giving warning of the presence of dangerous components such as hydrogen or chlorine. In addition, an active project is now under way at the National Bureau of Standards to adapt this instrument for use as an extremely sensitive carbon monoxide detector.

The lightness and compactness of the non-magnetic spectrometer offers a way to settle the question of the chemical composition of the upper atmosphere. This is a problem which is directly related to work in radio propagation and stratospheric flight. Arrangements have been made with the Applied Physics Laboratory of the Johns Hopkins University to send one of the new spectrometers aloft in a rocket. Before it is mounted in the rocket, the spectrometer tube will be evacuated and sealed; when the rocket has reached maximum altitude, an arm of the tube will be broken open to the rarefied air. The relative densities of atmospheric components will then be telemetered back to the ground for recording.

The non-magnetic mass spectrometer is now being adapted to the rapid scanning of mass spectra. Present methods permit sweeping twice a second through the mass range from 10 to 50, displaying the measured mass components directly on the screen of a cathode-ray oscilloscope. The scanning is accomplished by sweeping the ion accelerating voltage from 50 to 250 volts while modulating the radiofrequency potential with a 1000-cycle signal. —NATIONAL BUREAU OF STANDARDS, U. S. DEPARTMENT OF COMMERCE, *Washington 25, D. C.*

Electrostatic Generator

Two recently revealed electrostatic generators of 6 and 20 kv are designed to replace cumbersome and short-lived batteries as a high voltage supply for "snooper-scopes," "sniper-scopes," and similar infra-red sighting equipment. In the photograph, the new equipment is shown on the right, and the old, on the left.

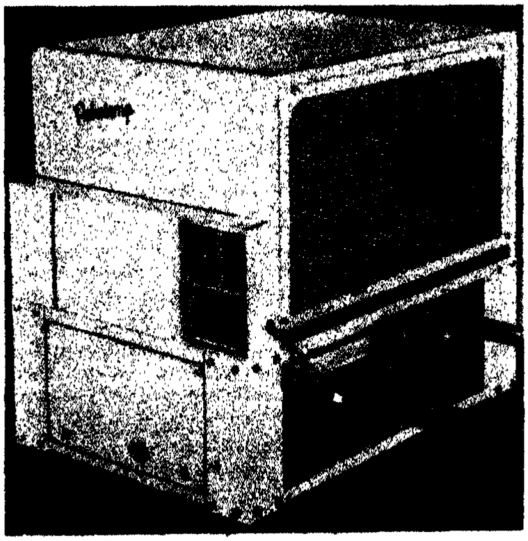
The generators are extremely compact, weigh only 10 lb., and are powered by a spring motor. Whereas batteries which were formerly used lasted 3 hr., these units operate indefinitely. One spring winding of the new unit generates for 20 min.

Special problems solved in design included development of new dielectric materials, a pressure-tight transmission and new techniques of hermetic sealing. A special variable speed governor controls the power from the spring motor to provide constant speed.

An interesting point about this type of generator is that, unlike most generators, constant speed results in constant current output rather than constant voltage. Constant voltage output is maintained with a corona discharge regulation tube. This type tube also eliminates the power wasting and extra power requirements of resistance-type voltage divider regulation.—Chatham Electronics Corporation, *Newark, New Jersey.*

Temperature Control

This new unit, named PAKOTEMP, automatically holds fluid temperatures within a range as narrow as plus-minus ½°F by circulating a tempering liquid rapidly through a jacket or tempering panels surrounding the critical fluid. Incorporated in the unit is a radically different stainless steel heat exchanger which automatically provides heat or refrigeration as required to hold the temperature of the critical fluid within pre-determined limits.



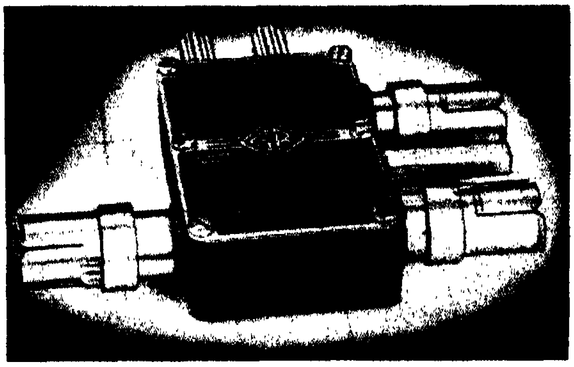
Since the tempering liquid is force circulated through a closed circuit extremely small temperature changes are corrected. This also avoids the setting-up of temperature zones within the critical fluid.

All thermostatic and electrical controls are conveniently located on the PAKOTEMP eliminating the hazards of electrical connections on solution tanks. Complicated mixing valves or manual controls are also eliminated. Only one electrical connection and two simple non-corrosive plumbing connections are required.

In addition to the standard models the PAKOTEMP may be modified for direct tempering and circulation of a critical fluid.—PAKO Corporation, *1010 Lyndale Avenue, N., Minneapolis, Minnesota.*

Diode Modulator for Video Frequencies

Useful in the laboratory, in TV-receiver production testing and in the TV service shop, the General Radio Type 1000-P6 crystal diode modulator converts an oscillator, standard-signal generator, or other r-f source into a test-signal generator for television-receiver testing. It modulates the oscillator signal after attenuation, so that reaction on the oscillator frequency is negligible. Thus it produces an amplitude-modulated signal with no significant incidental f-m.



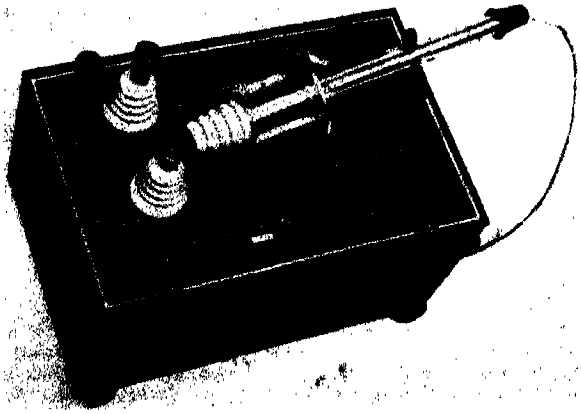
Range of modulating frequencies is 0 to 5 Mc and carrier frequency range is 20 to 1000 Mc, covering the proposed new u.h.f. television bands, as well as all currently used frequencies.

For receiver testing, a video signal can be conveniently derived from a TV receiver tuned to a local channel. With this video signal applied to the modulator, and an oscillator tuned to the desired carrier, a TV picture can be placed on any desired channel merely by tuning the carrier oscillator.

The modulator is small, compact, and inexpensive ($35.00). It is equipped with Type 874 coaxial connectors for r-f input, output, and for modulation input. Adaptors are available for connection to other types of terminals. Impedance is 50 ohms for r-f circuits, and coaxial 50-ohm attenuators and other accessories are available.—General Radio Company, *275 Massachusetts Avenue, Cambridge 39, Massachusetts.*

Ultra-Sensitive D.C. Current Measuring Device

The new PR6-NL 1000 to 1 capacitive d.c. divider is an ultra-sensitive current measuring device to be used with Millivac's d.c. millivoltmeter, Model MV-17b. The minute currents, to be measured, are fed into a 500-mmf condenser for a definite period

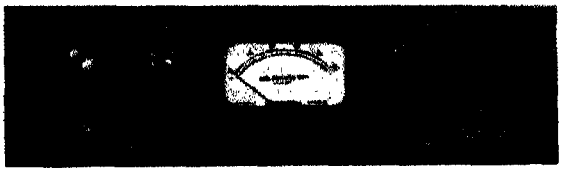


of time. A switch then transfers the charge of the 500-mmf condenser into an 0.5-mf condenser supplying d.c. power to the high impedance MV-17b millivoltmeter. Current measurements down to 5×10^{-13}A can actually be made with a charging time of 50 sec. The PR6-NL can also be used for *infinite impedance* voltage measurements between 1 v and 30 kv. It then replaces sensitive electrostatic voltmeters.—MILLIVAC INSTRUMENTS, *P. O. Box 3027, New Haven, Connecticut.*

Micro-Manometer

The Type 179 micro-manometer is a commercial version of an instrument developed at the National Bureau of Standards by Messrs. Dibeler and Greenough for the purpose of measuring pressures in the micron region in connection with mass spectrometers. It consists of a sensing unit and a separate sensitive and stable electronic indicator which can be mounted at some distance from the sensing unit. The indication of the pressure is independent of condensable vapor in the system and is read directly from the scale of a 4-in. meter calibrated in 1μ steps and having a full-scale value of 50μ.

The sensing unit consists of an exceedingly thin diaphragm contained in an outer chamber which is evacuated to a pressure approximately 1/100 of that to be measured. Pressure from the system to be measured is introduced on the other side of the sealed diaphragm and moves it closer to a radiofrequency transformer. Movement of the diaphragm varies the degree of coupling between the primary and secondary of this r-f transformer, and this effect, in conjunction with the electronic equipment described below, creates the desired indication.



The radiofrequency oscillator, which is automatically controlled in amplitude, supplies radiofrequency current to the primaries of two transformers. These primaries are connected in series, and the same current flows in each. The coupling in one of the transformers is fixed, and a portion of the secondary voltage of this transformer is used as the reference voltage for zero adjustment of the instrument. The second of these transformers is located in the sensing unit in such a way that its coupling is varied by the position of the diaphragm. When the diaphragm moves, the voltage induced in the secondary of this transformer will vary, while the reference voltage from the first transformer remains constant. These voltages are both fed to a 60-cycle chopper or vibrator acting as a single-pole double-throw switch to feed, alternately, one or the other of the two voltages to a diode detector. As long as these two voltages are equal, no audio signal is developed by the detector. However, when they differ, a 60-cycle square wave is developed, the amplitude and phase polarity of which depends upon the magnitude and direction of the inequality of the r-f voltages. This square wave is amplified and rectified by means of the same chopper contacts as are used in the r-f circuit. The rectified output is used to energize the d.c. indicating meter, which is calibrated in terms of pressure on the high pressure side of the diaphragm.

The above arrangement results in a system, having extraordinary stability, which indicates true pressure differentials and is independent of the type of gas being measured. There is no possibility of contamination of the vacuum system by mercury, decomposition or polymerization of vapors by heated filaments, etc. For most applications, calibration curves are not required due to the wide range of linearity.—CLARK INSTRUMENT CORPORATION, *910 King Street, Silver Spring, Maryland.*

Manufacturers' Literature

Cathode Press—Vol. 7, No. 2, 32-page quarterly publication of Machlett, includes articles on a new vacuum bearing system for rotating anode x-ray tubes, a ceramic planar power tetrode, Dynamax motor controls, radiofrequency heating, tubes for 10- to 20-kw induction heaters, the x-ray tube for the 24-Mev betatron, Machlett-Graybar Exhibit at I.R.E. Convention. Price 75¢.—MACHLETT LABORATORIES, *Springdale, Connecticut.*

Box 13058, Houston 19, Texas.*

Radioactivity Measurement—Folder describes and illustrates two recently developed instruments, the RCL alpha-beta-gamma-survey meter and the RCL bismuth wall gamma-counter, and other radiation equipments.—RADIATION COUNTER LABORATORIES, INC., *1844–50 West 21st Street, Chicago 8, Illinois.*

Announcer—No. 50 3 38, 15-page house organ, contains articles on torsion laboratory balance, Coleman photonephelometer, Dyna-Cath magnetic mercury cathode, micropette, Babcock meniscus reader, methyl-purple indicator, water aerator, Neoprene-coated draining rack, Brewer-Petri metal tops, Parafilm, Barnstead laboratory sterilizers, and Temco hot plate. Also included is a brief sketch on John Tyndall and an article on Modern Nephelometry (employing the principle of "Tyndall light").—GREENE BROTHERS, INC., *1812 Griffin, Dallas 2, Texas.*

Electronics Dictionary—64-page illustrated dictionary of electronic terms, including concise definitions of words used in radio, television, and electronics, is available at a cost of 25¢.—ALLIED RADIO CORPORATION, *Chicago 7, Illinois.*

Amplifier—Catalog sheet describes a new wide-band d.c. amplifier (Model 120), designed to serve as a preamplifier in connection with a.c. and d.c. oscilloscopes, vacuum-tube voltmeters and similar instruments to extend their ranges to smaller signals.—FURST ELECTRONICS, *12 South Jefferson Street, Chicago 6, Illinois.*

Nuclear Measurements—40-page Catalog K (1950) presents the company's line of instruments for nuclear measurements.—NUCLEAR INSTRUMENT AND CHEMICAL CORPORATION, *223 West Erie Street, Chicago 10, Illinois.*

Tracerlab Catalog—Catalog B contains 90 pages of detailed information on all Tracerlab products, which are designed for every application of radioisotopes to research, industry, medicine, agriculture, etc. Included is descriptive material on instruments, Geiger-Müller tubes, tagged organic and inorganic chemicals, and industrial beta-ray thickness gauges. Also included is an extensive list of radiochemicals.—TRACERLAB, INC., *130 High Street, Boston 10, Massachusetts.*

Electrical Measuring Instruments—45-page catalog presents the company's line of portable panel and switchboard meters. Prices included.—W. M. WELCH SCIENTIFIC COMPANY, *1515 Sedgwick Street, Chicago, Illinois.*

New Materials

Forest K. Harris: Associate Editor
in Charge of this Section
National Bureau of Standards, Washington, D. C.

Porous Bearing

The *Oil-Well* bearing, of sintered powdered metal, is molded with an annular well or cavity in the form of a ring around the bearing bore. Alternatively the cavity may be filled with sponge iron, or may have a series of small holes. Oil or grease impregnated into the finished bearing will fill the cavity as well as the metal pores to form a reservoir of reserve lubricant. The unit is molded and sintered conventionally, but a special process has been developed to include the cavity which acts as a reservoir. Specific bearing problems should be taken up directly with the company.—MICHIGAN POWDERED METAL PRODUCTS COMPANY, *50 Industrial Street, Northville, Michigan.*

Powdered Stainless Steel

A new stainless-steel powder having excellent compactibility has been developed for use in work involving intricate shapes. Previous stainless-steel powders have been difficult to mold because of their inherent hardness. In contrast parts molded from the new powder have high strength prior to sintering. Analysis resembles chrome and chrome-nickel steels.—AMERICAN ELECTRO METAL CORPORATION, *318 Yonkers Avenue, Yonkers 2, New York.*

Stainless Steel

Armco 17-7 PH is a new precipitation-hardening stainless steel, designed for use in springs, pressure tanks, diaphragms, conveyor parts, and tools in chemical and other plants. This steel is characterized by the fact that its yield strength in compression is equal or higher than yield in tension, that it can be severely formed in the soft-temper state, that it can be wrapped on its own diameter in hard-temper form, and that low temperatures are required in heat treatment. It is available in most gauges and sizes for sheet, strip, and plate in soft-temper form. Wire and certain gauges and widths of sheet material can be obtained in hard-tempered form.—ARMCO STEEL CORPORATION, *701–5 Curtis Street, Middletown, Ohio.*

Knitted Metal

Knitted Wire Mesh, used in certain applications for some time, is now available, because of recently developed processing techniques, for such applications as shields for radio-noise suppression, resilient washers and mountings, high temperature packing, and air or liquid filters. The material is knitted (not woven) into a mesh from wire or ribbon of stainless steel, copper, brass, aluminum, monel, etc. It can be formed into shapes such as disks, strips, and cylindrical tubes that will be resilient and yet possess good mechanical stability. When used for radio-noise shielding, the material is used in the form of cylindrical mesh strip which may be fastened down along joints like weather stripping. Where a flange is provided, the mesh is pressed into resilient conducting gaskets that contain the noise, provide a breather action, and can operate safely at high or low temperature. Anticorrosion properties are determined by the type of material used. Pressure-tight shielding gaskets can be made by combining the mesh with rubber. Formed disks can be used as supporting washers for porcelain insulators.—METAL TEXTILE CORPORATION, *Roselle, New Jersey.*

Heat Treating Material

Hard-N-Deep is the trade name of a powder (containing chromium, carbon, and a catalyst) designed for case-hardening soft steel parts. The process consists in heating parts to a cherry red, dipping them in the powder, reheating, and quenching. The action taking place includes carbonizing, nitriding, and chromizing.—MIRACALOY CORPORATION, *50 Broadway, Room 1907, New York 4, New York.*

Heat Insulation

Alfol Asbestos is a combination of aluminum foil bonded to ¼-in. corrugated asbestos sheet. The corrugations permit fitting the material around edges in ducts and tanks, as well as wrapping it on runs of pipe. The outer surface is smooth aluminum to reflect heat, the ¼-in. thickness is equivalent in insulating value to 1¾ in. of plain air-cell asbestos.—REFLECTAL CORPORATION, *Room 2007, 155 East 44th Street, New York 17, New York.*

Mercury Battery

The *RM-1 Mercury "A" Battery*, latest of a line of hearing-aid batteries, is now available for general applications such as biasing cells in electronic equipment and as a source of constant potential. The unit is compact, having a diameter of 0.625 in. and a height of 0.644 in. It weighs 0.39 oz. and has a capacity of 1000 ma-hr. It is stated to have a very long shelf life, uniform discharge voltage, and a high ratio of energy to volume and weight. The unit operates under extreme pressure and temperature ranges, is leak-proof and dimensionally stable, and has high resistance to humidity and corrosion.—P. R. MALLORY AND COMPANY, *3029 East Washington Street, Indianapolis 6, Indiana.*

Fluorocarbon Plastic

Kel-F, a polymer of trifluorochloroethylene, differs from other fluorocarbon plastics in that inclusion of the chlorine atom in the formula makes the product readily moldable by all standard methods. It is resistant to virtually all corrosives and will withstand operating temperatures up to 390°F. Water absorption is nil and, in addition, the material has high dielectric strength, high insulation resistance, and other properties which are desirable in electronic and electrical equipment. One application is for multi-electrode hermetically sealed terminals in airborne communications equipment where good sealing, resistance to heat and cold, and freedom from "tracking" are important.

A series of dispersions of Kel-F are also available for application to materials and equipment which are not amenable to processing by conventional plastic molding. The general procedure for applying the dispersions is to build up a layer on the surface to be coated, dry out the solvent, and fuse to a continuous film. Coatings of from 10 to 15 mils can be built up in this way.—THE M. W. KELLOGG COMPANY, *P. O. Box 469, Jersey City 3, New Jersey.*

Molding Compound

Plaskon Alkyd 411 is unique among plastics in that it is supplied in the form of a putty rather than the conventional powder or granular form. It can be molded at pressures far lower than any other plastic-pressures as low as 50 p.s.i. being used commercially. For demonstration purposes the material can be molded by hand and cured to a hard, heat-resistant solid by brief heating. Because of the extremely low pressure requirements this material is particularly suited to applications in which a plastic shell must be molded around delicate electrical assemblies that would be crushed by the high pressures necessary to mold other plastics. The molder may preassemble the unit just before molding and produce an integral piece with all components, including wire leads, sealed into a stable moisture- and heat-resistant unit.—PLASKON DIVISION, LIBBEY-OWENS-FORD GLASS COMPANY, *2112 Sylvan Avenue, Toledo 6, Ohio.*

Protective Tape

"Polyken" Industrial Tape is a calendar-oriented polyethylene film with a synthetic adhesive applied to one side. It is designed for corrosion-protective operations, and does not require heat or solvents for application. The tape maintains a permanent pressure around the coated metal equal to the tension with which it was applied, and keeps moisture from reaching the protected metal. The tape is 0.009 in. thick and comes in various widths on 100-ft. rolls. Its insulation resistance is 100 megohms, dielectric strength 1400 volts per mil, moisture absorption 0.1 percent, and operating range −40 to 100°C.—BAUER AND BLACK, *222 West Adams Street, Chicago 6, Illinois.*

Oil-Proof Flexible Conduit

Flexible tubing of galvanized steel covered with *Geon* plastic is designed particularly to carry machine wiring in either stationary or movable positions. In addition to flexibility the conduit has the abrasion resistance, insulating properties and ability to withstand attack by coolants, greases, oils, and moisture associated with the plastic coating. Liquid-tight steel fittings are used in the assembly with standard or water-tight conduit boxes Sizes from ⅜ to 2 in. I.D. are available. —CHICAGO METAL HOSE CORPORATION, *1313 South 3rd Street, Maywood, Illinois.*

Vibration Isolator

Cohrlastic vibration-isolating equipment and instrument mounts employ silicone rubber to provide a unit which will function satisfactorily at temperatures between −100 and +500°F. Units can be designed and supplied for specified service, equipment weight, and vibration frequency.—CONNECTICUT HARD RUBBER COMPANY, *405–9 East Street, New Haven 9, Connecticut.*

Silicone-Treated Paper

A silicone-treated kraft paper has been developed which is non-adhesive to rubber, asphalt, pressure-sensitive tapes (even Scotch Tape), and most other adhesive materials. The non-adhesive qualities are attained by treatment with Dow-Corning's *DC 1107* silicone resin. Appearance, color, and feel of the paper are the same as an untreated paper. Tensile strength, tear resistance, and moisture-vapor transmission are unaltered. However, the new paper is water repellent. The release characteristics of this paper indicate applications such as interleaving sheets for uncured rubber stock, camel-back, tube repair patches, pressure-sensitive rubber tape, and other adhesive tapes. It may also be used to make shipping containers for such materials as asphalt.—CENTRAL PAPER COMPANY, *Muskegon, Michigan.*

A Transfer Device for Low Boiling Liquids

Aaron Wexler and William S. Corak
Westinghouse Research Laboratories, East Pittsburgh, Pennsylvania

(Received February 27, 1950)

The principles involved in the transfer of low boiling liquids under their own vapor pressures are indicated and calculations are presented for the specific case of the transfer of liquid nitrogen. A convenient device for transferring liquid nitrogen by this procedure is described and its operating characteristics are compared with the calculations.

I. INTRODUCTION

SINCE liquid air, oxygen, and nitrogen are so extensively used in research laboratories, the improvement of the transferring technique should be of general interest. It is the purpose of this note to describe a procedure, now generally employed at the Westinghouse Research Laboratories, which permits the convenient transfer of liquid nitrogen from large metal Dewar containers to vessels and apparatus in which immediate use is to be made of the refrigerant.

The standard technique for transferring liquid nitrogen from containers of capacity larger than 15 liters, from which for mechanical reasons it is not wise to pour directly, is to apply pressure above the liquid. The pressurizing gas is usually nitrogen or air. The rate of transfer is controlled by adjusting the pressure above the liquid, and the flow of liquid is stopped by depressurizing to atmospheric pressure. The disadvantages of this procedure are evident from the foregoing description. Thus it is not always convenient to have available a source of pressurizing gas. Moreover, unless pure nitrogen is used, the liquid becomes contaminated. If the pressurizing gas is wet, for example, it is not uncommon for the gas inlet tube to freeze up. In any case, the condensation of the pressurizing gas is reflected in an appreciable loss of liquid in the subsequent depressurization, as will be shown in the following discussion. Finally, this procedure does not permit good regulation of the transfer rate.

The method to be described involves a simple arrangement, which may be fitted easily to standard liquid containers, permitting the controlled transfer of the low boiling liquid under its own vapor pressure. While the principles involved are undoubtedly appreciated by those working primarily with liquefied gases, they seem to have eluded workers using these liquids as refrigerants. The essential point is that the liquid in equilibrium with its vapor at a pressure greater than atmospheric represents a large ballast of gas which tends to maintain the space above it at a relatively constant pressure as the vapor space increases during the transfer operation.

II. PRINCIPLES OF THE METHOD

Given a container full of liquid nitrogen in equilibrium with its vapor at a pressure P_0 atmospheres, one wishes to calculate what the pressure above the liquid will be, under equilibrium conditions, as a function of the fraction of liquid remaining when the liquid is transferred rapidly out of the container. It is assumed that the transfer time is sufficiently small to make the total heat leak negligible compared with the thermal changes accompanying the evaporation process. Let the volume of the container be V_0 liters and let V be the volume of the liquid when the equilibrium pressure has changed to P. The entire system is assumed to be isothermal at a temperature T°K, which is a condition that is met in practice in the case of commercial Dewar-type containers in which the inner vessels are made of copper.

If a small volume dV of liquid is transferred out, the temperature of the liquid will drop to $T=T_0-dT$, as a result of the evaporation of dn moles of the liquid, such that the pressure P above the liquid is just the vapor pressure at the temperature T. Let ΔH_V cal./mole be the latent heat of vaporization of the liquid and C_p cal./mole·degree be its heat capacity. Then, if k is the

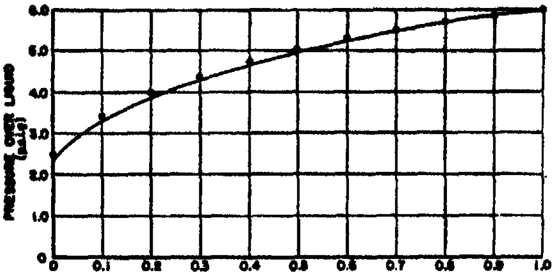

FIG. 1. Pressure over liquid on transferring from a pressurized liquid nitrogen container.

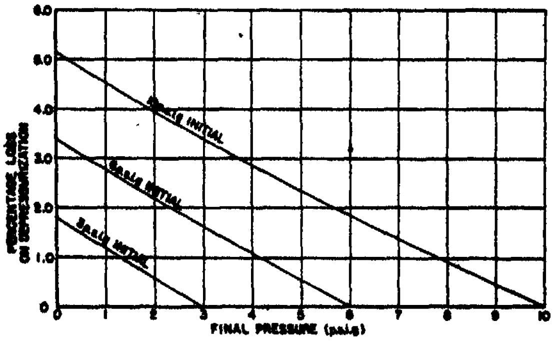

FIG. 2. Theoretical loss of liquid nitrogen when depressurizing liquid from various pressures.

number of moles per liter of liquid,

$$dn = -kVCpdT/\Delta H_V. \tag{1}$$

The changes in the thermodynamic variables of the vapor are obtained from the equation of state

$$Pv = \gamma mRT \tag{2}$$

where $v = V_0 - V$ is the volume of the vapor, R is the gas constant, m is the number of moles of vapor, and γ is the compressibility factor which corrects the ideal gas equation for departure from ideality. Thus,

$$dm = \frac{1}{\gamma RT}\left[(V_0 - V)dP - PdV - P\frac{(V_0 - V)}{T}dT\right]. \tag{3}$$

The equating of (1) and (3) and the substitution of $\alpha = V/V_0$ results in

$$\frac{d\alpha}{dT} + \left(\frac{1}{P}\frac{dP}{dT} - \frac{1}{T} - \frac{k\gamma RTCp}{P\Delta H_v}\right)\alpha = \left(\frac{1}{P}\frac{dP}{dT} - \frac{1}{T}\right). \tag{4}$$

The expressions in the parentheses of Eq. (4) may be expressed as functions of T, so that it takes on the form

$$(d\alpha/dT) + f_1(T)\alpha = f_2(T), \tag{5}$$

whose solution is

$$\alpha = \exp\left[-\int f_1(T)dT\right] \times\left\{\int f_2(T)\exp\left[\int f_1(T)dT\right]dT + C\right\}. \tag{6}$$

The solution of Eq. (6) involves a numerical integration which was performed with the aid of Gauss' mechanical quadrature formula.[1] In this calculation, the following approximations were used for the range of variables considered. The vapor pressure[2] was assumed to be represented adequately by $P = 0.139T - 9.74$. Mean values were selected for the rest of the data: $\Delta H_V = 1320$ cal./mole,[3] $Cp = 15.0$ cal./mole degree,[3] $k = 28.5$ moles/liter,[4] and $\gamma = 0.96$.[5] Figure 1 gives the results of the calculation for an initial pressure of 6 g p.s.i. The vapor pressure relation was used to transform the results obtained from Eq. (6) to give α as a function of the equilibrium pressure above the liquid. It is clear, therefore, that even for the least favorable case of rapid and complete transfer of the contents of a full pressurized liquid nitrogen container, the vapor pressure should be adequate to supply the transfer pressure head.

The losses which result in the depressurizing of a liquid nitrogen container may be estimated from Eq. (1). If β is the fraction of liquid which evaporates when the pressure above it is decreased from P_i to P_f, corresponding to T_i and T_f, then

$$\ln(1-\beta) = -\int_{T_i}^{T_f}\frac{Cp}{\Delta H_V}dT. \tag{7}$$

The percentage loss accompanying depressurization as calculated from Eq. (7) is shown in Fig. 2 for several initial pressures. Thus, when a liquid nitrogen container is pressurized with nitrogen gas to 6 g p.s.i. for the purpose of transferring liquid and is then depressurized to atmospheric pressure at the termination of transfer, the upper limit to the loss by depressurization is 3.4 percent of the contents of the container. This is an upper limit for the loss for the reason that in most transfer operations, thermal equilibrium is not established throughout the bulk of the stored liquid.

III. DESCRIPTION OF THE DEVICE

A transfer device suitable for permitting the transfer of liquefied gases under their own vapor pressures is indicated schematically in Fig. 3. The details of construction are indicated in the legend associated with the figure. The valve *G*, shown in detail in Fig. 4, is adjustable and has a differential between the opening and closing pressures of less than 1 g p.s.i. It is set so as to open at approximately the desired operating pressure. Valves of this type have been found to be very useful as safety valves for systems containing condensed gases. They are helium leak detector[6]-tight when operated at pressures less than atmospheric. Normally, the container is filled by connecting a suitable tube to fitting *D* and opening valve *H* for venting purposes. The rubber tube *J* is selected to give a gas-tight closure under operating conditions while acting as a vent at higher pressures. At the termination of the filling operation, the container is left with a pressure of 2 to 3 g p.s.i., which is suitable for most transfer operations. Due to the normal heat leak, the pressure builds up until the relief and regulating valve opens to maintain the container at the pre-set pressure. The transfer of liquid is effected by simply opening valve *C*, the rate of transfer being determined by the amount by which the valve is opened. A Crane No. 88 needle-point globe valve is used for this purpose because, among inexpensive commercial valves it appears to have the smallest heat capacity. The transfer device is shown mounted on a standard 50-liter storage container in Fig. 5.

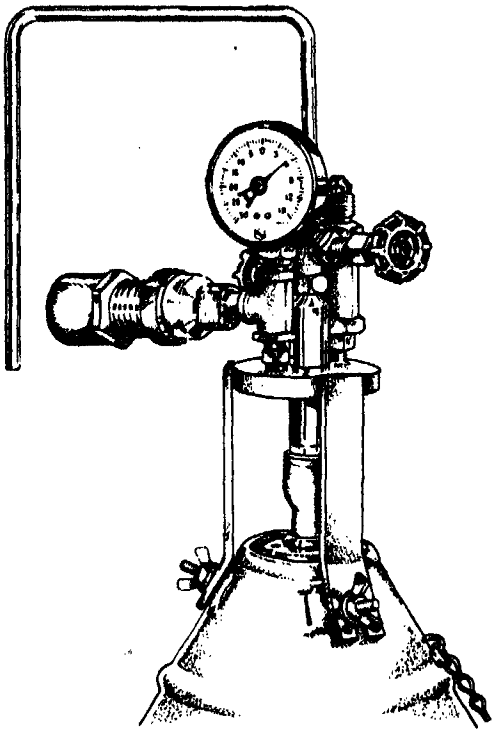

FIG. 5. Transfer device mounted on 50-liter storage container.

The maximum rate of flow permitted by the device is about $2\frac{1}{2}$ liters/min. For the purpose of checking the calculations made according to Eq. (6), a 50-liter container fitted with the device was filled with liquid nitrogen at a vapor pressure of 6 g p.s.i. The liquid was then transferred out at the maximum transfer rate, and the pressure was noted as a function of the fraction of liquid remaining. The experimental points in Fig. 1 indicate excellent agreement with the calculated curve. It was found that under most laboratory conditions, the pressure above the liquid remained very close to the equilibrium vapor pressure as the volume of the vapor space increased during the transfer operation.

IV. ACKNOWLEDGMENTS

The authors' thanks are due Dr. E. V. Somers for pointing out the very convenient method used in integrating Eq. (6). They are also indebted to Mr. G. T. Cunningham for his contributions to the design and construction of the device.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 7 JULY, 1950

A Sector-Type Double-Focusing Magnetic Spectrometer

EARL S. ROSENBLUM
Case Institute of Technology, Cleveland, Ohio

(Received May 26, 1949)

An analysis is made of the focusing characteristics of a magnetic spectrometer having an annular magnetic field which varies approximately with $1/r^{\frac{1}{2}}$, thus permitting axial as well as radial focusing of particles of a given energy. By considering the field angle and source location as independently variable, the analysis provides for an instrument more flexible in use than similar existing types.

An optical analogy is developed from which a first approximation to the field shape is made, and from which the source and image location, magnification, dispersion and resolution can be readily obtained. Information thus obtained, combined with the results of an investigation into the image shape based on a series expansion, through second order, of expressions for the field strength and particle coordinates, yields more detailed information on the field shape which gives optimum focusing conditions and resolution for any chosen set of initial conditions.

Comparisons are made with the homogeneous field spectrometer and with the spectrometer of Svartholm and Siegbahn.

INTRODUCTION

A MAGNETIC spectrometer which achieves axial as well as radial focusing of charged particles by means of a magnetic field which varies radially as $1/r^{\frac{1}{2}}$, with both source and image within the field, has been developed by Siegbahn[1] and Svartholm.[1, 2] They showed that simultaneous radial and axial focusing is achieved after the particles have passed through a field angle of $2^{\frac{1}{2}}\pi$ (254.5°). Shull and Dennison[3] developed the path equations by standard perturbation methods, giving results through the second order of approximation, extending the theory to provide for any field whose axial component is expressible as a series representing arbitrary corrections to the field existing at a reference radius, which corrections are functions of powers of the radial displacement from the reference radius.

Snyder, Lauritson, Fowler, and Rubin[4] have built a spectrometer of this general type, but with the field having an angular extent of 180° and with source and image outside the field boundaries, approximately equidistant from the edges of the field.

This paper proposes to develop the path equations for a similar spectrometer, considering both the field angle and source location as independently variable. A set of equations are developed representing the first-order focusing characteristics in terms of an analogous thick lens system in geometric optics.

From these equations, a first-order determination of the field shape is made, information as to the location of source and image, limits on field angle, magnification and dispersion are obtained, and a preliminary estimate made of the resolution. From the second-order equations, choices of a second-order field shape parameter are made, which will cause the instrument to have a high resolution and good focusing characteristics, as computed through second order, for a chosen set of initial conditions.

Comparisons are made, throughout the development, with the spectrometer of Svartholm and Siegbahn, and with the homogeneous field spectrometer.

THEORY

Most of the symbols used in this paper are indicated on Fig. 1. It will be noted that the coordinates r, φ, and z are used within the field, region III, while two sets of x, y, and z axes are used, single primes indicating coordinates in the object space, region I, and double primes indicating coordinates in the image space, region II.

Throughout the paper, all distances will be given in units of the reference radius, which thus does not appear explicitly in any of the equations. Using this convention, Shull and Dennison's equations[3, 5] for the axial and radial components of the field become:

$$H_z=H_0[1-(r-1)\alpha+(r-1)^2\beta+z^2(\alpha/2-\beta)]$$
$$H_r=zH_0[-\alpha+2\beta(r-1)],$$

where α and β are arbitrary constants representing corrections to the field H_0, which is the axial field at the intersection of the reference radius and the plane $z=0$, henceforth called the equilibrium orbit.

The path equations were shown by Shull and Dennison to have the following zeroth-order solutions:

$$r=1;\quad z=0;\quad r\dot{\varphi}=v_0=\omega=-eH_0/m;\quad \varphi=\omega t.$$

To solve the path equations through second order, the mass, velocity, and coordinates of any particle in the field are expressed as their zeroth-order values plus first- and second-order correction terms.

$$\begin{aligned} r&=1+\lambda\rho_1+\lambda^2\rho_2\\ z&=\lambda\zeta_1+\lambda^2\zeta_2\\ \dot{\varphi}&=\omega+\lambda\theta_1+\lambda^2\theta_2\\ m&=m_0(1+\lambda\gamma)\\ v&=v_0(1+\lambda\eta), \end{aligned}\tag{1}$$

[4] Snyder, Lauritsen, Fowler, and Rubin, Phys. Rev. 74, 1564 (A) (1948).

[5] F. Shull and D. Dennison, Phys. Rev. 72, 256 (1947).

where λ is a parameter of smallness, ρ_1, ρ_2, ζ_1, ζ_2, θ_1, and θ_2 are functions of the time, and γ and η represent small variations in mass and velocity from reference values. There are no second-order corrections to m and v, as the mass and velocity of a particle remain constant within the field.

When the above values of the variables and the field components are substituted into the path equations, the solution proceeds in a manner similar to that described by Shull and Dennison, with the addition of terms in η and γ. It is convenient at this point to eliminate the time from the equations of motion, so that the particle coordinates r and z are given in terms of the angle φ.

Then, to extend the solutions so as to describe the motion in the image space in terms of the initial conditions at the source, it is noted from Fig. 1 that, if ϵ', κ', ϵ'', and κ'' are considered to be small angles,

$$\begin{aligned} y_1 &= b' - \kappa' t' \\ z_1 &= d' - \epsilon' t' \end{aligned} \qquad (2)$$

$$\begin{aligned} y'' &= y_2 + \kappa'' x'' = (r^* - 1) + \kappa'' x'' \\ z'' &= z_2 + \epsilon'' x'' = z^* + \epsilon'' x''. \end{aligned} \qquad (3)$$

The asterisk is used to indicate the values of r, φ, and z and their functions at the III–II boundary. Also,

$$\kappa'' = (1/r^*)(\partial r/\partial\varphi)^*, \quad \epsilon'' = (1/r^*)(\partial z/\partial\varphi)^*. \qquad (4)$$

Substituting Eqs. (4) and the general relationships, Eqs. (1) into Eqs. (3) give

$$\begin{aligned} y'' = \lambda[\rho_1{}^* + x''(\partial\rho_1/\partial\varphi)^*] \\ + \lambda^2[\rho_2{}^* - x''\rho_1{}^*(\partial\rho_1/\partial\varphi)^* + x''(\partial\rho_2/\partial\varphi)^*] \end{aligned} \qquad (5)$$

$$\begin{aligned} z'' = \lambda[\zeta_1{}^* + x''(\partial\zeta_1/\partial\varphi)^* \\ + \lambda^2[\zeta_2{}^* - x''\rho_1{}^*(\partial\zeta_1/\partial\varphi)^* + x''(\partial\zeta_2/\partial\varphi)^*]. \end{aligned} \qquad (6)$$

The solutions of these equations, after substitution of the path equations within the field and their first derivatives with respect to φ, and Eqs. (2), and letting $\varphi = \Phi$ at the III–II boundary, are

$$\begin{aligned} y'' = \kappa'\Big[& -t' \cos(1-\alpha)^{\frac{1}{2}}\Phi - \frac{1}{(1-\alpha)^{\frac{1}{2}}} \sin(1-\alpha)^{\frac{1}{2}}\Phi \\ & + x''\{(1-\alpha)^{\frac{1}{2}} t' \sin(1-\alpha)^{\frac{1}{2}}\Phi - \cos(1-\alpha)^{\frac{1}{2}}\Phi\Big] \\ & + \frac{\eta+\gamma}{1-\alpha}[-\cos(1-\alpha)^{\frac{1}{2}}\Phi \\ & + (1-\alpha)^{\frac{1}{2}} x'' \sin(1-\alpha)^{\frac{1}{2}}\Phi + 1] \\ & - b'[-\cos(1-\alpha)^{\frac{1}{2}}\Phi + (1-\alpha)^{\frac{1}{2}} x'' \sin(1-\alpha)^{\frac{1}{2}}\Phi] \\ & + \text{higher order terms.} \end{aligned} \qquad (7)$$

$$\begin{aligned} z'' = \epsilon'\Big[& -t' \cos\alpha^{\frac{1}{2}}\Phi - \frac{1}{\alpha^{\frac{1}{2}}} \sin\alpha^{\frac{1}{2}}\Phi \\ & + x''(\alpha^{\frac{1}{2}} t' \sin\alpha^{\frac{1}{2}}\Phi - \cos\alpha^{\frac{1}{2}}\Phi)\Big] \\ & - d'[-\cos\alpha^{\frac{1}{2}}\Phi + x''\alpha^{\frac{1}{2}} \sin\alpha^{\frac{1}{2}}\Phi] \\ & + \text{higher order terms.} \end{aligned} \qquad (8)$$

In order to obtain a perfect first-order focus, all rays from a given point on the source must come to a common focus at the image, whose coordinates are $x'' = t''$, $y'' = b''$, and $z'' = d''$. So, for simultaneous focusing in both the y and z directions, the coefficients of the initial angles κ' and ϵ' and Eqs. (7) and (8) must be zero at the image. Equating these coefficients to zero, and solving for t'' in both cases,

$$\begin{aligned} t'' &= \frac{[t'/(1-\alpha)^{\frac{1}{2}}] \cot(1-\alpha)^{\frac{1}{2}}\Phi + (1/\{1-\alpha\})}{t' - [1/(1-\alpha)^{\frac{1}{2}}] \cot(1-\alpha)^{\frac{1}{2}}\Phi} \\ &= \frac{(t'/\alpha^{\frac{1}{2}}) \cot\alpha^{\frac{1}{2}}\Phi + (1/\alpha)}{t' - (1/\alpha^{\frac{1}{2}}) \cot\alpha^{\frac{1}{2}}\Phi}. \end{aligned} \qquad (9)$$

If α is given the value of $\frac{1}{2}$, this equation is satisfied for any combination of t' and Φ, representing a field shape which permits flexibility in the choice of initial conditions.

Certain other values of α, within the allowable limits of $0 < \alpha < 1$, will satisfy this equation. However, for any such $\alpha \neq \frac{1}{2}$, there is at most one value of $\Phi < 2\pi$ for each $t' \geqslant 0$; an instrument so designed would have an inconveniently arranged geometry, would be inflexible, and its radial focusing characteristics would be different from the axial ones. Such cases will not be considered here.

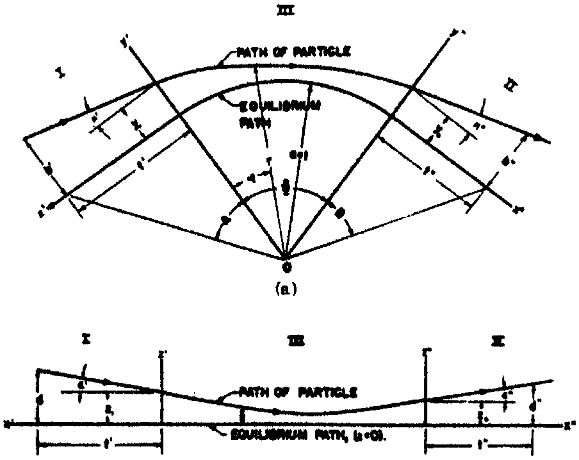

FIG. 1. Path of particle between source and image. (a) Section perpendicular to axis. (b) Axial section taken along a constant radius.

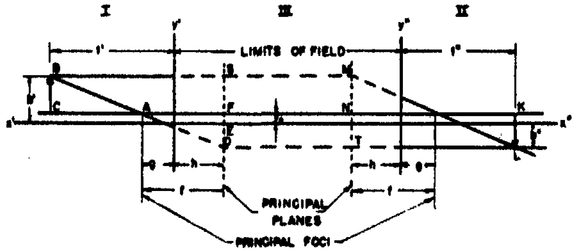

FIG. 2. Radial trajectories, based on optical analogy.

OPTICAL ANALOGY

Letting $\alpha=\frac{1}{2}$ in Eq. (9), either part of the equation, when rearranged, gives

$$2^{\frac{1}{2}}\cot\Phi/2^{\frac{1}{2}}=(t't''-2)/(t'+t'')=g, \tag{10}$$

where g is merely a symbol, for the moment, used to identify this equality. However, if $t'=\infty$ in Eq. (10), $t''=g$; similarly, if $t''=\infty$, $t'=g$. Therefore, g is the location, expressed as a distance from the field edges, where rays from infinity are focused, thus locating the principal foci of an analogous optical system. This parameter, and others derived below, are shown in Fig. 2, in which the equilibrium orbit is considered to be a straight line, for convenience.

The principal planes of the system can be located from the equations for the image coordinates, which are obtained from Eqs. (7) and (8), letting $\alpha=\frac{1}{2}$, using the coordinates of the image, and recalling that the coefficients of κ' and ϵ' vanish at the image.

$$b''=b'M+2(\eta+\gamma)(1-M) \tag{11}$$

$$d''=d'M, \tag{12}$$

where $M=\cos\Phi/2^{\frac{1}{2}}-t''/2^{\frac{1}{2}}\sin\Phi/2^{\frac{1}{2}}$. M, then, is the magnification, and is the same in the radial and axial directions.

For unit magnification, either Eq. (11) or (12), with Eq. (10), show that there is a distance h, given by

$$h=-2^{\frac{1}{2}}\tan\Phi(2^{\frac{1}{2}}2), \tag{13}$$

such that $h=t'=t''$. Therefore, h is the distance from either field edge to the principal planes of the system. Because of symmetry considerations, the nodal points lie on the principal planes.

An incidental result with $t''=h$ is that the coefficient of $\eta+\gamma$ in Eq. (11) becomes identically zero indicating that the dispersion of the instrument is zero at the principal planes. However, the significance of this fact is limited, as explained below.

The focal length f can be determined directly from the values of g and h as, by definition,

$$f=g-h, \tag{14}$$

from which

$$f=2^{\frac{1}{2}}\csc(\Phi/2^{\frac{1}{2}}). \tag{15}$$

The optical analogy is completed by combining Eqs. (10), (14), and (15), resulting in the familiar relations

$$f^2=(t'-g)(t''-g) \tag{16}$$

$$1/f=1/(t'-h)+1/(t''-h). \tag{17}$$

Results Obtained from Optical Analogy

Several items of useful information can be obtained from examination of the equations derived above.

Although the total focusing angle is always an integral multiple of 180°, for a homogeneous field,[6] a comparable relationship does not exist for the present case, and the total focusing angle $A+B+\Phi$ (Fig. 1) is *not* the same for all values of t' and Φ.

Source and image move relative to one another in the same manner as for a thick optical lens; as the object moves toward the field edge, the image moves away, and vice versa.

From Eqs. (11) and (12), information on the magnification can be obtained. At $t''=g$, $M=0$, indicating that a point image is formed at the focus, as expected. As the source moves in from infinity, the image moves out from $t''=g$; from the above equations M is always negative for $\Phi<\pi2^{\frac{1}{2}}$, so that the image is inverted, increasing in size directly with t''. (For $\pi2^{\frac{1}{2}}<\Phi<2\pi2^{\frac{1}{2}}$, the image is erect.)

From Eq. (10), it is seen that object and image distances are equal when

$$t'=t''=t=g\pm f.$$

When $t=g-f$, $t=h$ from Eq. (14), representing unit magnification at the principal planes. When $t=g+f$, $b''=-b'$ and $d''=-d'$, representing an inverted image of unit magnification. The spectrometer of Svartholm and Siegbahn[1] represents a special example of this case, with $t=0$.

Using standard conventions of geometrical optics, a typical path is plotted in Fig. 2 for a particle having momentum slightly greater than that necessary to follow the equilibrium orbit. Referring to Fig. 2,

$$b''=y_f+f(y_f-b')/(t'-g),$$

while, from Eqs. (11), (16), and (17),

$$b''=2(\eta+\gamma)+f[\{2(\eta+\gamma)-b'\}/(t'-g)].$$

Comparing the last two equations,

$$y_f=2(\eta+\gamma).$$

A similar substitution into Eq. (12) shows that for the same particle, $z_f=0$.

This indicates that particles of a given $(\eta+\gamma)$ have an equilibrium orbit in the median plane, displaced from the equilibrium radius by $y_f=2(\eta+\gamma)$.

Herzog[6] has shown that for the homogeneous field spectrometer, $y_f=\eta+\gamma$, representing only half as great a displacement as above. For further discussion of this factor, see the section on Dispersion and Resolution.

---

[6] R. Herzog, Zeits. f. Physik 89, 447 (1934).

Limits of Optical Analogy

The analogy does not describe the motion within the field boundaries, and so is valid only for t', $t'' \geq 0$. Thus, the statement above that unit magnification is obtained at the principal planes is true only if they are outside the field, which is the case only for $\Phi > \pi 2^{\frac{1}{2}}$. Also, the analogy will not account for an image obtained within the field. However, such an image can be located directly from the path equations or by considering that the field is cut off at that point, and letting $t''=0$.

Then, from Eq. (10), additional limits can be set to the location of source and image. That equation shows that source and image distances are negative when, respectively, the image and source distances are less than g. Furthermore, for $g<0$, the maximum values of t' and t'' are obtained for $t''=0$ and $t'=0$, respectively. From Eq. (10), either maximum distance is $-2/g$. For $g \geq 0$, the maxima are infinite.

Within these limits on object and image distances, the location of object and image and the magnification can be determined either graphically by the methods of geometrical optics, or by the use of the optical equations.

Dispersion and Resolution

The momentum of a particle which follows the equilibrium orbit is $p_0 = m_0 v_0$, and the momentum of a particle having slightly different energy is, through first order,

$$p = mv = p_0(1+\eta+\gamma)$$

and, letting $\delta p = p - p_0$, $\delta p/p_0 = \eta+\gamma$. Let $\delta b''$ be the radial change in image coordinates, for a given change in momentum. From Eq. (11),

$$\delta b'' = 2(\eta+\gamma)(1-M),$$

or, letting

$$D = 2(1-M), \quad \delta b'' = D(\eta+\gamma). \tag{18}$$

Then $\delta b''/(\delta p/p) = D(\eta+\gamma)/(\eta+\gamma) = D$, which defines the dispersion of the instrument From Eqs. (18) it is seen that D varies in absolute value directly with t'', so that for best dispersion $t'=0$, or $t'=g$, whichever is greater. The dispersion is zero with the image at a principal plane; $D=4$ for the case where $t'=t''=t=g+h$. This last figure is twice the value determined by Herzog[6] for the homogeneous field spectrometer with equal object and image distances, and checks Shull and Dennison's[3] statement comparing the dispersion of the double-focusing type with the 180° homogeneous field type.

TABLE I. Typical parameters for first-order focusing.[a]

t''	t'	y_0''	D	D_0
g	∞	0	2	∞
∞	g	∞	∞	$2/y_0'$
$g+f$	$g+f$	$-y_0'$	4	$4/y_0'$
h	h	y_0'	0	0
$-2/g$	0	$y_0' \sec\Phi/2^{\frac{1}{2}}$	$2(1-\sec\Phi/2^{\frac{1}{2}})$	$\frac{2}{y_0'}(1-\cos\Phi/2^{\frac{1}{2}})$
0	$-2/g$	$y_0' \cos\Phi/2^{\frac{1}{2}}$	$2(1-\cos\Phi/2^{\frac{1}{2}})$	$\frac{2}{y_0'}(1-\sec\Phi/2^{\frac{1}{2}})$

[a] *Note:* Not all of the quantities tabulated represent real images for all values of the field angle Φ.

The ratio of the dispersion D to the image width y_0'' is the reciprocal of the smallest resolvable percent change in momentum. Defining this ratio as the resolution, D_0, and expressing y_0'' in terms of the object width y_0' by means of Eq. (11),

$$D_0 = (2/y_0')[(1/M)-1]. \tag{19}$$

From this equation it can be shown that D_0 is infinite for $t''=g$ and decreases asymptotically to a magnitude of $2/y_0'$ for $t''=\infty$. At $t''=h$, $D_0=0$. For the particular case where $t'=t''=t=g+f$, $|D_0|=4/y_0'$, compared to the value of $2/y_0'$ determined by Herzog for a comparable geometry with a homogeneous field.

A computation of the resolution based on first-order image coordinates is somewhat deceptive, due to second- and higher-order defocusing; however, these values of D_0 are useful in obtaining a preliminary determination of optimum operating conditions.

Since it may be desirable in certain applications to design an instrument with a predetermined object distance, it will be of interest to select the field angle Φ which will give the best dispersion and resolution at fixed object distance. Expressing D and D_0 in terms of

FIG. 3. Graphical summary of focusing properties. *Note:* t', y_0'', D_0, and D are all plotted as ordinates, to arbitrary scales.

t', and then finding the values of $\partial D/\partial\Phi$ and $\partial D_0/\partial\Phi$ and equating them to zero, the following field angle and object distances are obtained:

$$\Phi=2^{\frac{1}{2}}\tan^{-1}(-t'/2^{\frac{1}{2}})\,;\quad t''=0,$$

which may be an awkward arrangement, physically. Furthermore, the second partials indicate that, while the first-order resolution is a maximum, the dispersion is a minimum. Therefore, nothing can be concluded as to the best field angle at fixed object distance, on the basis of first-order solutions only.

Summary of Parameters for First-Order Focusing

In Fig. 3, values of t', y_0'', D, and D_0 are plotted as functions of t'' for several ranges of Φ. Table I gives numerical values of these quantities at certain values of t'', from which the magnitude of the various ordinates plotted in Fig. 3 can be estimated.

As a special case, $\Phi=\pi 2^{\frac{1}{2}}$. Here, $g=\infty$, so $t''=-t'$, from Eq. (10). The only real solution, then, is for $t'=t''=0$. This is the instrument described by Siegbahn and Svartholm.[1] Note that the first-order magnification, dispersion, and resolution are the same for this instrument and for the sector-type spectrometer with equal object and image distance, $g+f$.

As another special case, $\Phi=\pi/2^{\frac{1}{2}}$. For this case, $g=0$, and the curves are the same as the first illustration of Fig. 3, with the origin of t'' coinciding with g. For this angle, $f=+2^{\frac{1}{2}}$, $h=-2^{\frac{1}{2}}$, and $t't''=2$.

Effect of Non-Radial Field Edges

An attempt has been made to determine whether or not the performance of the instrument could be improved by shaping the field edges so that they are straight lines making arbitrary angles with the y' and y'' axes, respectively (Fig. 1). However, such a modification destroys the flexibility of the instrument, in that there is no value of the field-shape parameter which will allow radial and axial focusing with various object distances. If these angles are considered as small angles, this objection disappears, but the accompanying second-order effects consist of a slight broadening or simply a shift of image position.

Furthermore, although the effects of fringing fields are not discussed quantitatively in this paper, it is probable that their defocusing effects would be as great in magnitude, or greater, than the effects due to this type of field-shape correction.

SECOND-ORDER SOLUTIONS AND CHOICE OF PARAMETER β

If the operations indicated by Eqs. (5) and (6) are performed with $\alpha=\frac{1}{2}$ and if terms in η and γ are neglected, the image coordinates become, in terms of the initial conditions at the source,

$$\begin{aligned}
b''={}&b'\left[\cos\frac{\Phi}{2^{\frac{1}{2}}}-\frac{t''}{2^{\frac{1}{2}}}\sin\frac{\Phi}{2^{\frac{1}{2}}}\right]+\left[(b'-\kappa't')^2\frac{2\beta-1}{3}+\kappa'^2\frac{8\beta-1}{3}+(d'-\epsilon't')^2\frac{3-4\beta}{6}+\epsilon'^2\frac{3-8\beta}{3}\right]\\
&\times\left[\cos\frac{\Phi}{2^{\frac{1}{2}}}-\frac{t''}{2^{\frac{1}{2}}}\sin\frac{\Phi}{2^{\frac{1}{2}}}\right]+\left[\kappa'(b'-\kappa't')\frac{4\beta-2}{3}-\epsilon'(d'-\epsilon't')\frac{4\beta}{3}\right]\left[t''\cos\frac{\Phi}{2^{\frac{1}{2}}}+2^{\frac{1}{2}}\sin\frac{\Phi}{2^{\frac{1}{2}}}\right]\\
&+\left[\{(b'-\kappa't')^2-2\kappa'^2\}\frac{4\beta+1}{12}-\{(d'-\epsilon't')^2-2\epsilon'^2\}\frac{\beta}{3}\right][\cos 2^{\frac{1}{2}}\Phi-t''2^{\frac{1}{2}}\sin 2^{\frac{1}{2}}\Phi]+\left[-\kappa'(b'-\kappa't')\frac{4\beta+1}{3}\right.\\
&\left.+\epsilon'(d'-\epsilon't')\frac{4\beta}{3}\right]\left[\frac{1}{2^{\frac{1}{2}}}\sin 2^{\frac{1}{2}}\Phi+t''\cos 2^{\frac{1}{2}}\Phi\right]+[(b'-\kappa't')^2+2\kappa'^2]\frac{1-4\beta}{4}\\
&+[(d'-\epsilon't')^2+2\epsilon'^2]\frac{2\beta-1}{2}+\frac{t''}{2^{\frac{1}{2}}2}[(b'-\kappa't')^2-2\kappa'^2]\sin 2^{\frac{1}{2}}\Phi+\kappa'(b'-\kappa't')t''\cos 2^{\frac{1}{2}}\Phi. \qquad (20)
\end{aligned}$$

$$\begin{aligned}
d''={}&d'\left[\cos\frac{\Phi}{2^{\frac{1}{2}}}-\frac{t''}{2^{\frac{1}{2}}}\sin\frac{\Phi}{2^{\frac{1}{2}}}\right]+\left[-(b'-\kappa't')(d'-\epsilon't')\frac{4\beta}{3}+\kappa'\epsilon'\frac{6-16\beta}{3}\right]\left[\cos\frac{\Phi}{2^{\frac{1}{2}}}-\frac{t''}{2^{\frac{1}{2}}}\sin\frac{\Phi}{2^{\frac{1}{2}}}\right]\\
&+2^{\frac{1}{2}}\left[-\epsilon'(b'-\kappa't')\frac{4\beta}{3}+\kappa'(d'-\epsilon't')\frac{3-4\beta}{3}\right]\left[2^{\frac{1}{2}}\sin\frac{\Phi}{2^{\frac{1}{2}}}+t''\cos\frac{\Phi}{2^{\frac{1}{2}}}\right]+\left[\{(b'-\kappa't')(d'-\epsilon't')\right.\\
&\left.-2\kappa'\epsilon'\}\frac{3-4\beta}{6}\right][\cos 2^{\frac{1}{2}}\Phi-2^{\frac{1}{2}}t''\sin 2^{\frac{1}{2}}\Phi]+2^{\frac{1}{2}}\left[\epsilon'(b'-\kappa't')\frac{4\beta-3}{6}+\kappa'(d'-\epsilon't')\frac{4\beta-3}{6}\right]\\
&\times[2^{\frac{1}{2}}\sin 2^{\frac{1}{2}}\Phi+2t''\cos 2^{\frac{1}{2}}\Phi]+[(b'-\kappa't')(d'-\epsilon't')+2\kappa'\epsilon']\frac{4\beta-1}{2}\\
&+\frac{t''}{2^{\frac{1}{2}}2}[(b'-\kappa't')(d'-\epsilon't')-2\kappa'\epsilon']\sin 2^{\frac{1}{2}}\Phi+\frac{t''}{2}[\epsilon'(b'-\kappa't')+\kappa'(d'-\epsilon't')]\cos 2^{\frac{1}{2}}\Phi+\frac{t''}{2}(b'\epsilon'-d'\kappa'). \qquad (21)
\end{aligned}$$

The most satisfactory solutions to these equations depend on the uses to which a given instrument is to be put, the space and equipment available, and the economics of the project. The initial conditions and field angles selected below for investigation were based on a desire for the following characteristics, which are enumerated together with their respective somewhat contradictory effects on the instrument design.

1. Source and image should be accessible for use with auxiliary equipment and for easy removal during an experiment. If they can be located in regions where the magnetic field is relatively weak, some difficulties in the use of certain types of sources and detectors are lessened. These requirements are best satisfied by maximum separation of source and image from the field edges. However, design on this basis, besides conflicting with items listed below, may cause undue increase in the volume and complication of the vacuum system.

2. If the instrument is to be used with particles of energies so high as to make collimation of the image within the instrument difficult, it is desirable to work with an image large enough so that the detector itself can act as the exit slit. In this case, the object distance should be a minimum and the image distance a maximum, so that the dispersion will be as large as possible for the limiting image width.

3. The instrument should transmit a maximum amount of the radiation from the source. With a given pole shape and separation, this requires that the source be at the edge of, or within the field. Pole separation is limited by the problem of maintaining the field shape over a large cross section, particularly due to excessive fringing near the inner and outer radii. With a large gap, power consumption will be quite high.

4. The resolution should be as large as possible. The narrowest possible image, together with maximum dispersion make for highest resolution. First-order focusing characteristics are not very helpful here, as second-order defocusing terms may be large enough to cause extremely large changes in the resolution. It has been found that (for a given object size and fixed limitations on radial and axial angles transmitted), when the field shape parameter β is chosen for minimum image width at each object distance, the resolution does not vary greatly with object distance.

The resolution can be increased by decreasing the object width and radial and axial angles, but with a corresponding decrease in intensity. The optimum ratio of these quantities and object length depends somewhat on the actual size of the instrument; a radius in the 10- to 20-cm range is assumed here.

Naturally, all these considerations could not be satisfied simultaneously; one immediate result has been that the object size and other initial conditions have been limited to smaller values than those allowed by Shull and Dennison.[3] In the analysis below, somewhat arbitrary limitations on the design parameters have been chosen; as one compromise combination:

TABLE II. Performance data with selected design parameters.

Φ	t'	t''	g	h	f	D	D_0	$\frac{\delta p}{p_0}=\frac{1}{D_0}$
$\pi/2^{\frac{1}{2}}$	1	2	0	$-2^{\frac{1}{2}}$	$2^{\frac{1}{2}}$	4.83	154	0.0065
π	0.7	0.7	-1.08	-2.86	1.78	4.00	174	0.0057

$$|b'|\leqslant 0.01;\quad |d'|\leqslant 0.05;\quad |\kappa'|\leqslant 0.1;\quad |\epsilon'|\leqslant 0.05;$$
$$0.7\leqslant (t',t'')\leqslant 2.$$

The limitation on angle can be obtained by a suitably shaped baffle placed at $\varphi=\pi/2^{\frac{1}{2}}$; a rectangular-shaped baffle is assumed here. The restriction on object and image distances imposes limits on the field angle which are given roughly by

$$\pi/2^{\frac{1}{2}}\leqslant\Phi\leqslant\pi.$$

Equations (20) and (21) have been solved at these two limits of field angle, and a value of β has been chosen to result in the narrowest possible image, for ($\Phi=\pi/2^{\frac{1}{2}}$, $t'=1$, $t''=2$; $\beta=0.35$) and for ($\Phi=\pi$, $t'=t''=0.701$, $\beta=0.25$).

On Fig. 4 is plotted the image of half of a rectangular source for the two cases, along with a rectangle representing the object size, and sections showing the image of a point object at two positions on the source. The image width is obtained from these plots, and using that width and the optical equations, the information tabulated in Table II is obtained.

With these combinations of initial conditions, about one-fifth to one-fourth percent of the total radiation from an isotropic source is transmitted. This represents a lower intensity than that obtainable with the same gap for the case where $t'=t''=0$, but with other accompanying advantages in flexibility, accessibility, etc.

COMPARABLE PATH EQUATIONS FOR THE HOMOGENEOUS FIELD SPECTROMETER

With a homogeneous field, $\alpha=\beta=0$, the path equations within the field are those given by Shull and Dennison. These path equations can be extended to describe the image coordinates with an arbitrary set of initial conditions and field angle, but this is not done

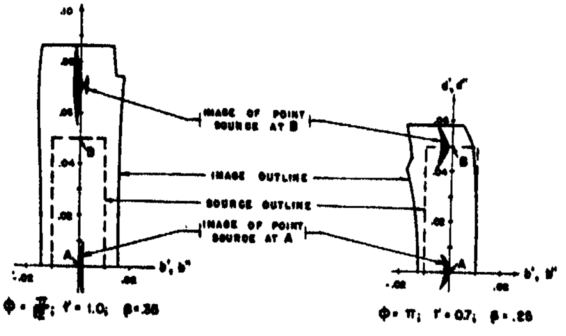

FIG. 4. Image size with selected field shapes and initial conditions.

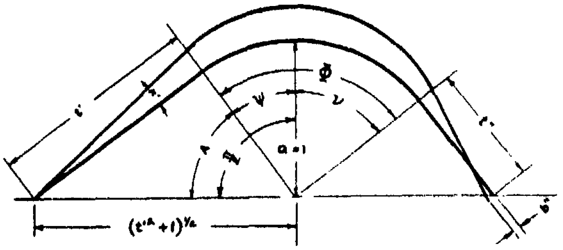

FIG. 5. Path of particle in homogeneous field spectrometer.

in the present paper. However, Stephens[7] has developed an equation for the case represented by Fig. 5. where $b'=d'=\epsilon'=0$. That equation is

$$b''=-\left(\frac{\kappa'^2}{2}\right)(t'^2+1)^{\frac{1}{2}}\left(\frac{\sin^2\psi}{\sin\nu}+\frac{\sin^2\nu}{\sin\psi}\right). \tag{22}$$

Now, substituting the same initial conditions into the path equation gives, at the image,

$$b''=\left(\frac{\kappa'^2}{2}\right)\left[-\frac{1}{t'\sin\Phi-\cos\Phi}+t'\sin 2\Phi\right.$$
$$\left.+\frac{t'^2-1}{2}\cos 2\Phi-\frac{t'^2+1}{2}\right]. \tag{23}$$

When the angles ψ and ν in Eq. (22) are expressed in terms of angles A and Φ, using Fig. 5, that equation becomes identical with Eq. (23), thus affording a check on the two approaches to the problem.

CONCLUSIONS

With suitable choices of initial conditions and field-shape parameters, the instrument described in this paper is one of high intensity and resolution, although the intensity suffers when the source is not at the field edge. However, advantages are gained in flexibility and convenience which allow the instrument to be a useful one.

It has the same advantages over spectrometers of other types as does the Siegbahn spectrometer, the latter being a limiting case of the spectrometer described above, with object and image distance set equal to zero, resulting in a focusing angle of $\pi 2^{\frac{1}{2}}$. This combination transmits a higher intensity than all other combinations, except for those with zero object distance, and does not suffer from possible defocusing effects caused by fringing fields (see below), so probably has as high a resolution as any other combination. However, the source and image are located in a strong field between the poles of the magnet, thus decreasing the flexibility and accessibility of the instrument. The sector-type spectrometer is also more suitable for determining the energy of particles which must originate in other equipment, and which should cross the fringing fields as nearly as possible normal to them, to minimize defocusing.

The effects of fringing fields have not been discussed in detail, but by analogy to Coggeshall's[8] analysis of the edge effects of a homogeneous field, it is probable that these effects will not cause considerable defocusing, if source and image are located either completely within the field or in regions of low field strength, and if the particles enter and leave the field nearly normal to the fringing field.

Although the resolution as computed through second order neglects the defocusing due to higher order terms, the fact that the intensity is not uniform over the image indicates that the computed values of resolution probably can be closely realized. Shull,[9] and Kurie, Osaba, and Slack[10] have shown that the resolution of the instrument does not vary widely with variations of β in the range $\frac{1}{8}\leqslant\beta\leqslant\frac{3}{8}$ for the $\pi 2^{\frac{1}{2}}$ instrument; it is considered likely that the behavior will be similar for an instrument with a different field angle.

The author wishes to express his appreciation of the help of Dr. E. F. Shrader, who supervised the work of this paper, and of Dr. E. C. Crittenden, whose suggestions led to the investigation of the double-focusing spectrometer and some of its more significant properties.

A Linear Preamplifier for Driving a Long Coaxial Cable*

LLOYD G. LEWIS, JAMES G. ROBINSON, AND JOHN TOLL
Palmer Physical Laboratory, Princeton University, Princeton, New Jersey

(Received January 23, 1950)

A circuit for driving a long coaxial cable is described. Its response characteristics permit impedance matching of the coaxial line without sacrificing linearity of response, and make possible a relatively long line between the particle detector and the recording apparatus. The circuit was found to be reasonably stable for long periods of time, even under severe outdoor operating conditions.

INTRODUCTION

FAST wide-band amplifiers, such as the Los Alamos Model 100 and Model 500 amplifiers,[1] have found considerable use in nuclear physics and cosmic rays. These amplifiers have stabilized gains of about 10^6, rise times as short as 0.15 μsec. excellent monatonic transient response to step signal, and good linearity of response. Their characteristics have made these amplifiers extremely useful for studying the size and the shape of the pulses produced by particle detectors excited by heterogeneous radiations.

The arrangement of the apparatus is usually such that the particle detector and the preamplifier are located very near each other in order to make the signal lead from the detector as short as possible. The amplified signal is transmitted to the main amplifier and recording circuits by a short piece of coaxial cable. For a cable no longer than about six feet, impedance matching at each end is usually not necessary, and the cable can be considered to be a capacity shunting the output of the preamplifier. Under these conditions the cathode follower that drives the coaxial line can work into a fairly high impedance, and the linearity of the cathode follower can be made to approach that of the rest of the amplifier.

For some experiments it is essential that the preamplifier be located at a considerable distance from the main amplifier. Figure 1 shows an example of such a situation encountered in an experimental arrangement for recording the height and shape of each pulse produced by cosmic-ray events in each of four electron collection ionization chambers. The chambers were located so that they measured the particle density in a cosmic-ray air shower at four points separated by as much as 25 meters. The four cathode-ray tubes were located side by side so that they could be photographed by the same camera. This arrangement was made possible by the 100 ft. long coaxial signal cables between the preamplifiers and the main amplifiers.

A coaxial line 100 ft. long should be terminated in its characteristic impedance to avoid distortion of fast signals by the reflections from the ends of the line.

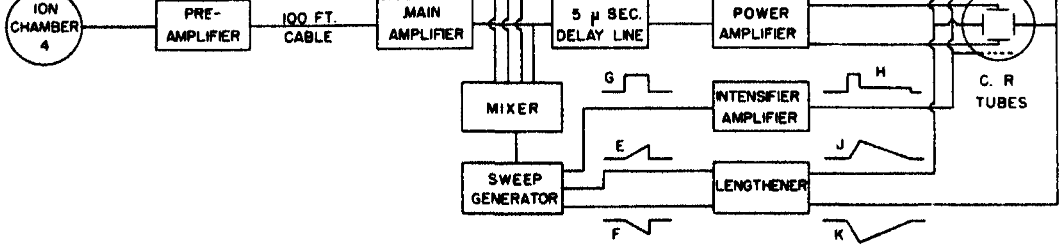

FIG. 1. This figure gives the schematic layout of the several components in a four channel pulse amplifier and recorder. A step signal A and the several amplified signals B, C, D are shown together with the sweep voltage E, F, J, K and cathode-ray intensifier pulses G and H produced by the triggered single-sweep generator. The cathode-ray tube beam is turned on for the fast sweep from left to right and remains on for the much longer return sweep from right to left. In this way coincidences between channels could be studied for resolving times as long as 0.1 sec.

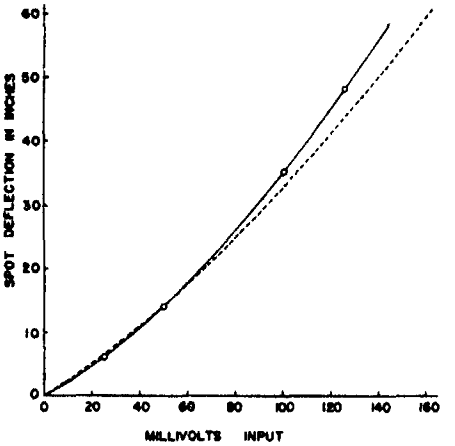

FIG. 2. The solid curve gives the deflections of the cathode-ray tube spot as a function of the signal voltage fed to a preamplifier that contained a simple cathode follower for driving the signal cable. The large deflections plotted were obtained by measuring the deflections on the screen of the cathode-ray tube and multiplying them by factors obtained from attenuators in the main amplifiers. The dotted curve is the response computed assuming all amplifier components linear except for the cathode follower that drives the long 98-ohm coaxial cable.

The 98 ohm characteristic impedance of an *RG7U* cable is so low that the 6*J*6 cathode follower in the Model 500 preamplifier output stage has a noticeably nonlinear response over the range of signals produced by the ionization chambers. This nonlinearlity is illustrated in Fig. 2. The solid curve gives the deflection of the cathode-ray tube spot as a function of the signal placed on the input of the preamplifier. The large deflections plotted were obtained by measuring smaller deflections and multiplying by a factor obtained from an attenuator in the main amplifier. The dotted curve in Fig. 2 is the computed response of the amplifier under the assumptions that all components except the 6*J*6 are linear and have the gains measured for each stage; that the 6*J*6 is biased at $-4V$, works into a 100 ohm load and has the published average characteristics. The similarity between the two curves indicates that almost all of the nonlinear response can be attributed to the characteristics of the 6*J*6.

Considerable gain in linearity can be obtained by replacing the simple cathode follower with a circuit whose gain is stabilized by inverse feedback. The circuit to be described here makes use of well-known principles and may possibly have been worked out independently by others;[2] however, it is presented here to call attention to the obtainable improvement in linearity and to the possible added convenience of a longer cable be-

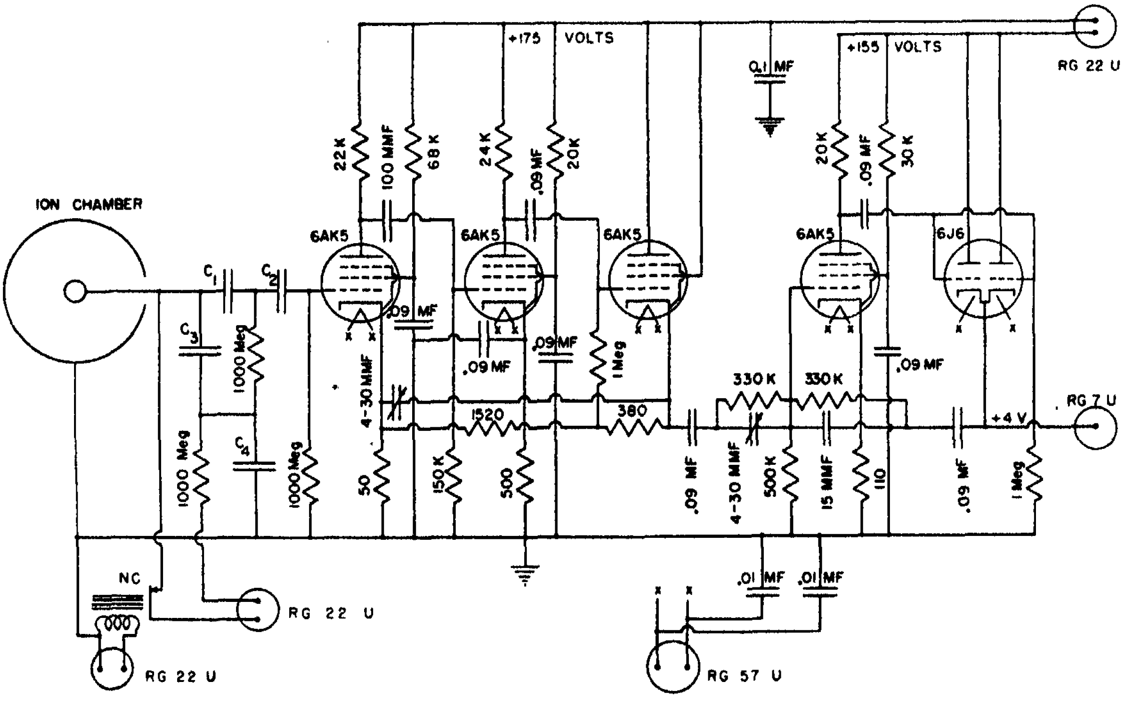

FIG. 3. This figure gives the wiring diagram of the complete pre-amplifier used to drive the long coaxial cable shown in Fig. 1. The three tubes next to the ion-chamber are operated similarly to those in the Los Alamos Model 500 amplifier. The last two tubes are connected so that their gain is stabilized by inverse feedback. The connection shown is for a gain of -1. The cathode of the 6*J*6 is maintained at $+4$ volts with respect to ground by a resistor condenser network across the $B+$ of the main amplifier. C_1 is a 30-$\mu\mu$f air condenser, C_2 is a 50-$\mu\mu$f double cup ceramic condenser, C_3+C_4 are the guard ring stray capacities.

---

[2] A single tube gain of -1 circuit is described by E. W. Titterton and V. L. Fitch, Rev. Sci. Inst. **18**, 639 (1947), for inverting trigger pulses, and V. L. Fitch and E. W. Titterton, Rev. Sci. Inst. **18**, 821 (1947), for inverting a sawtooth to get push-pull cathode-ray tube sweep signals.

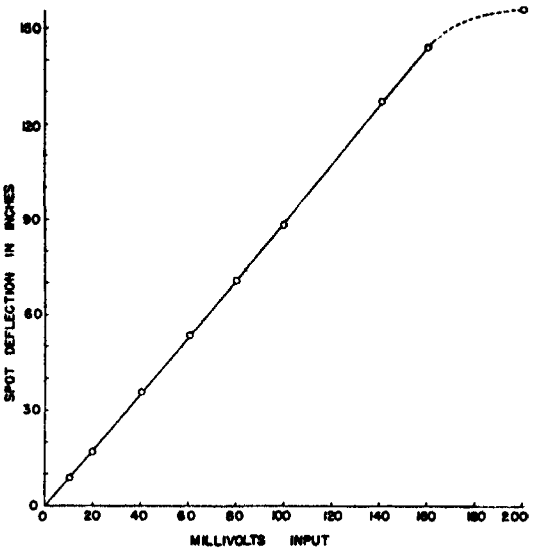

FIG. 4. This figure gives the cathode-ray tube spot deflection as a function of the signal supplied to a preamplifier wired as indicated in Fig. 3. The large deflections plotted were obtained by multiplying the observed deflection by a factor obtained from an attenuator in the main amplifier. The dotted portion of the curve indicates the region of overloading.

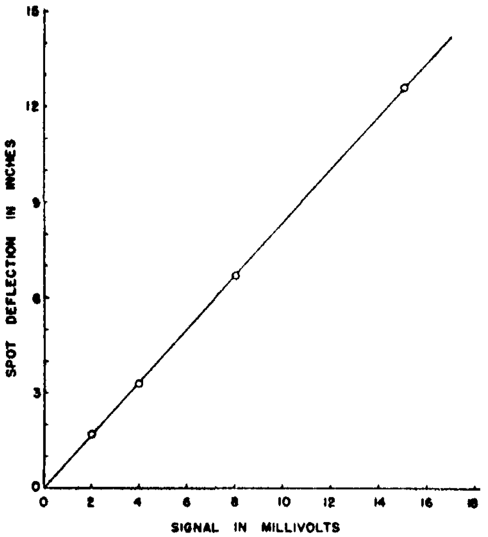

FIG. 5. This graph gives the first part of the curve Fig. 4 in more detail. A comparison of the slope of this curve with the slope of the upper part of Fig. 4 indicates that the non-linearity has been reduced to a few percent.

tween preamplifier and main amplifier. It should be emphasized that the attenuation of a coaxial cable increases with frequency so that the maximum length of the cable will be set by the rise time of the pulses or of the amplifier, whichever is longer, and by the permissible distortion. For our case a 100-ft. *RG7U* cable gave only slight rounding of the corners on a step signal. The amplifier rise time was measured to be about 0.3 μsec.

AMPLIFIER CHARACTERISTICS

The complete preamplifier circuit is shown in Fig. 3. The first three tubes are operated essentially as in the Model 500[1] preamplifier inverse feedback loop except that the rise time has been lengthened by using the larger plate load resistors shown The second inverse feedback loop consisting of the fourth 6*AK*5 and the 6*J*6 is shown connected to give a gain of -1. This inversion of signal is convenient since the ion chamber pulses are negative and it is convenient to have positive pulses at the input to the 6*J*6. Gains different from unity are obtained by choosing other values for the components of the voltage divider network in the grid circuit of the fourth 6*AK*5. The grid bias voltage for this fourth 6*AK*5 can be obtained in a number of ways. The circuit diagram of Fig. 3 shows it obtained by using the 110 ohm cathode resistor. This necessitates the 0.09-μf blocking condensers shown. If the blocking condensers are omitted, the grid bias voltage can still be obtained from a cathode resistor of about 1200 ohms, but this resistor must be suitably by-passed.

Two variable condensers are shown in Fig. 3, one in each of the feedback loops. The adjustment of the condenser in the first feedback loop was found to have very little, if any, effect on the shape of the pulse on the coaxial cable when a step pulse was put into the preamplifier. There was no oscillation of the first preamplifier loop for any possible setting of this condenser, so it was set at minimum capacity and left there. The shape of the pulse on the cable was found to depend on the adjustment of the second variable condenser. The amplifier response to a step signal could be made anything from an oscillatory overshoot to a very slow monatonic rise. The adjustment of this condenser also changed the shape of the response curve, Fig. 4. This response curve was nearest to a straight line when the response to a step signal was a non-oscillatory overshoot that was just visible on careful inspection. The magnitude of this overshoot was less than three percent of the pulse height. Figure 5 gives the spot deflections for small signals. The difference between the slope of the straight line, Fig. 5, and the slope of the curve, Fig. 4, for large signals, shows that there is still a small non-linearity in one or more of the amplifiers between the ion chamber and the cathode-ray tube. Most of this remaining non-linearity may be caused by the cathode follower that drives the delay line.

LONG TERM PERFORMANCE

Each of four preamplifiers, made according to the circuit diagram, Fig. 3, was used for nearly 3000 hours of observation during the period July 1948 to May 1949. The amplifiers were mounted in small tents on the mountainside near Mt. Evans, Colorado. They were exposed to wide variations in temperature and to occasional covering by snowdrifts. The cables were frequently buried in a layer of ice and had to be chopped out when the experimental arrangement was changed.

The apparatus performed satisfactorily under these conditions except when the ends of the high voltage cables were wet from melting snow.

Calibration curves similar to those of Fig. 4 and Fig. 5 were run several times in each 24-hour period. The slope of the curve in Fig. 4 drifted about eight percent during the first few hours after the equipment was turned on. Thereafter, the change in slope of the curve in Fig. 4, between the coldest part of the day (just after sunrise) and the warmest part of the afternoon, was about two percent. The initial adjustment of each of the several condensers in the feedback loops of the preamplifiers was made in July 1948 and did not have to be changed during the whole of the summer's and following winter's work, even though the tubes were changed several times.

In general, we feel that the linear response of the recording apparatus resulted in a great simplification of the analysis of the cosmic-ray data. The effort required to install and adjust the second feedback loop in the preamplifier was so small that the change was very much worth while.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 7 JULY, 1950

A New Vacuum Gauge

R. HAVENS, R. KOLL, AND H. LAGOW
Naval Research Laboratory, Washington, D. C.

(Received January 23, 1950)

A new vacuum gauge has been developed that is capable of measuring pressures from one atmosphere down to less than 10^{-5} mm Hg. The principle and construction of the gauge and experimental results are given.

A NEW vacuum gauge has been developed that is capable of measuring pressures from one atmosphere down to less than 10^{-5} mm Hg. Although there are many vacuum gauges now available which measure these pressures, usually three different types are required to cover this range completely. In addition, most of these gauges must be checked carefully for proper performance. The new gauge not only covers the complete range of pressures, but is rugged, has a small volume, and requires little attention for high accuracy of measurement.

The new gauge works on the principle that an a.c. signal can be obtained from a normally d.c. pressure gauge by cyclically changing the pressure at a given frequency. Many pressure-sensitive devices develop a d.c. signal as a function of pressure, temperature, applied voltage, and other physical quantities. In the new gauge the pressure changes, while the other physical quantities contributing to the d.c. voltage remain constant during a cycle. Thus, an a.c. signal is developed which is primarily a function of pressure alone, as long as the electrical signal from the gauge is appreciably above thermal and microphonic noise.

A model of the gauge has been constructed in which resistance wires are used as detecting elements and bellows are employed to change the pressure. A schematic drawing of the gauge is shown in Fig. 1, while Fig. 2 is a photograph showing the bellows arrangement. The detecting elements in the gauge are each placed inside a sylphon brass bellows, 6 cc in volume. The eccentric shaft of a small motor drives both bellows, changing their volumes by about 20 percent. With this double bellows arrangement, the shaft is working against the same pressure in each of the bellows independently of the pressure surrounding the gauge. The pressure is communicated to the element inside the bellows through small holes—one of 1-mm diameter and the other of ½-mm diameter—which restrict the flow of the gas. At any pressure the gas cannot escape at a speed greater than one-third of the speed of sound, i.e., about 100 meters per second. For the ½-mm hole, 20 percent of the volume of the gauge cannot escape in

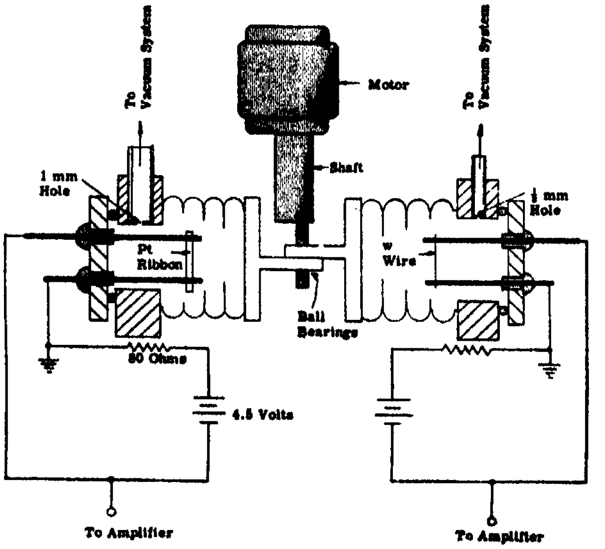

FIG. 1. Schematic drawing of the new gauge showing the arrangement of bellows and motor and the tungsten and platinum elements in their circuits.

less than 0.06 sec. Since the pressure inside the bellows is changed almost every 0.02 second, the greater part of the percent change in volume is realized as a percent pressure change. At low pressures a larger hole is satisfactory, due to restrictions in the tubing to the vacuum system.

One of the detecting elements used in the gauge model is a 1000-ohm tungsten wire, 7μ in diameter, wound around a mandrel with 4-mm spacings between mechanical supports. The signal from such an element can be understood by first considering its calibration curve when it is used simply as a Pirani gauge (Fig. 3A). At a pressure of 0.6 mm Hg, a 20 percent change in the pressure changes the voltage across the wire 0.27 volt. At other pressures this change is different, as Fig. 3B shows. When the pressure surrounding this element is actually changed by the motion of the bellows, an a.c. signal is developed whose magnitude corresponds to the average pressure surrounding the element. A curve of the peak-to-peak a.c. voltage, or d.c. voltage change, across the 7μ-wire as a function of pressure when the bellows is expanded 20 times a second is shown in Fig. 4A. The theoretical values derived from Fig. 3A and partly shown in Fig. 3B are plotted on the semilogarithmic scale of Fig. 4 as a dashed curve. The discrepancy between curves 4A and 4B is due to the time lag of the tungsten wire at low pressures.

At pressures higher than 50 mm Hg the tungsten wire is acting as a simple thermal element and is no longer effective as a Pirani gauge, as Fig. 3A shows. At these pressures the temperature, and correspondingly the resistance, of the wire increases when the gas in the bellows gives up heat under compression, and decreases when the gas expands. The temperature change of the wire is a function of the mass of gas in the bellows and hence of the pressure.

A brief summary of this somewhat involved explanation may perhaps serve to clarify it: There is a large signal across the wire at one atmosphere which decreases as the pressure decreases. When the wire starts acting as a Pirani gauge the signal begins increasing, reaches a peak value, and then decreases, becoming linear at 200μ and indicating extrapolation to 0 signal at 0 pressure. The curve in Fig. 3B shows that the response of the tungsten wire is directly proportional to the pressure at pressures below 200μ. Although the actual signal is less than this theoretical one because of the time lag of the wire, its curve is also linear at pressures below 200μ.

FIG. 2. Photograph of the new gauge in its present form showing the arrangement of bellows and motor and the tungsten element wound on its mandrel.

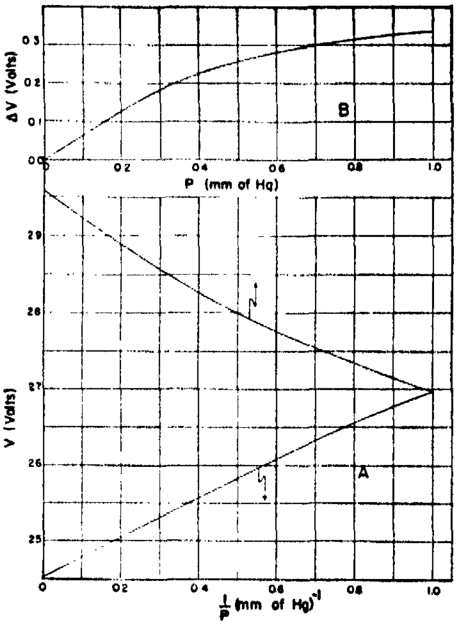

FIG. 3. Curve A is the calibration of the tungsten element used as a Pirani gauge. Curve B shows the change in d.c. voltage for a 20 percent change in pressure as a function of the mean pressure. This curve is derived from curve A.

Another element used in the gauge is a platinum ribbon 0.2μ thick, 0.5 mm wide, and 8 mm long.[1] Data obtained from this element at pressures below 1μ of Hg are shown in Fig. 5. Calibrations were made at two different values of current through the element, one at 27 ma and the other at 13 ma. It should be noted that the curves deviate from linearity below 0.1μ, the signal actually increasing in the case of the higher current. This increase is apparently due to a vibration of the ribbon with respect to the walls, which affects the heat transfer by radiation. This effect may or may not be in phase with the volume change. In designing the gauge no attempt was made to decrease this effect, but it can be greatly reduced by changing the position of the ribbon.

With the gauge just discussed, pressures below 10^{-4} mm Hg could not be measured accurately because of the motion of the ribbon. While this effect can be reduced, there are two other factors that will limit the sensitivity of the gauge—the sensitivity of an a.c. amplifier and the gas coming from the walls of the bellows.

Roess[2] has detected signals as low as 5×10^{-10} volt with an amplifier intended to measure the alternating output of a rapid-response thermocouple in an infra-red

---

[1] This ribbon was obtained from Baird Associates, Cambridge, Massachusetts. It was originally developed for use in sensitive bolometers. Its low heat capacity per unit surface area also makes it a sensitive pressure element.

[2] L. C. Roess, Rev. Sci. Inst. 16, 172 (1945).

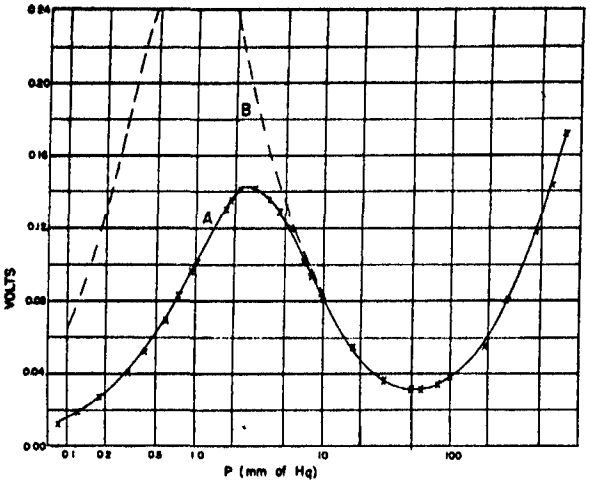

FIG. 4. Curve A is the calibration of the new gauge employing the tungsten element. The peak to peak magnitude of the a.c. voltage is given. Curve B is curve B of Fig. 3, which represents the theoretical calibration of the gauge below 50 mm Hg ignoring the time lag of the tungsten wire.

spectrograph. The only essential difference between Roess' instrument and the vacuum gauge is that in his, radiation is interrupted at 1 to 5 c.p.s. while in the vacuum gauge the pressure change interrupts the energy lost by heat conduction at 20 c.p.s. The inherent noise level of the amplifier described by Roess is less than the thermal noise of either resistance element used in the new vacuum gauge. Roess calculates the thermal noise voltage of a 1000-ohm thermocouple to be 2.5 $\times 10^{-9}$ r.m.s. volts.* A pressure of 10^{-7} mm Hg will give a signal of 10^{-8} volt, which should be above the noise level. Gas from the walls of the bellows will probably maintain the pressure above 10^{-7} mm Hg, so that this will be the main factor in limiting the range of the gauge. If a bellows can be evacuated below the pressure corresponding to the minimum detectable signal from the gauge in its present form, still lower pressures can be measured by creating larger signals in the detecting element. This can be done by increasing the pressure change inside the bellows and by using an element with a larger surface area. For example, the 10-ohm platinum ribbon has an area of 0.05 sq. cm. If the ribbon were ten times as long and ten times as wide, the thermal noise would be the same, but the voltage output would be ten times as large.

If a thermocouple were used in the new gauge in place of the tungsten wire or platinum ribbon, the a.c. voltage developed would be directly proportional to the average pressure, as long as the ratio of the heat capacity of the gas to the heat conduction of the gas was small compared to the period of the gauge or as long as the temperature change did not approach an adiabatic temperature change. By switching from the thermocouple to the resistance element at 200μ the gauge could be made to be linear with pressure from 400 mm Hg or more, down to as low a pressure as can be measured.

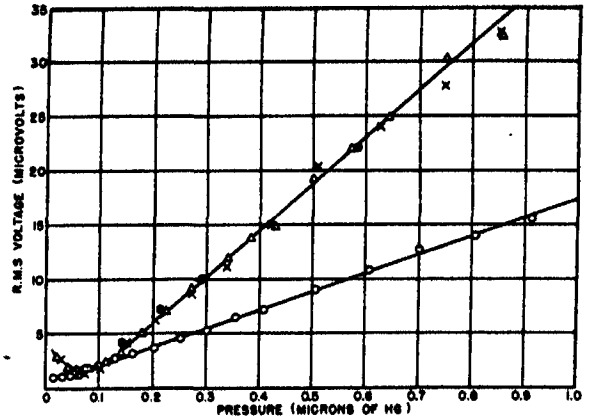

FIG. 5. Calibration curve of the new gauge employing the platinum ribbon. Data represented by the symbol ○ were obtained while operating the element at 13 ma. Data represented by symbols △ and × were obtained at 27 ma through the ribbon.

Another pressure-sensitive device adaptable to the principle of the new vacuum gauge is the ionization gauge. The range of pressures measured by the ionization gauge is limited by a current of photo-electrons from the collector, produced by soft x-rays generated in the tube. For standard ionization gauges the photoelectric current corresponds to 10^{-8} mm Hg. This current, remaining constant during a cycle, will be eliminated from the a.c. signal of the new gauge. With an ionization gauge as the pressure-sensitive element in the new gauge, the factors limiting the lowest detectable pressure, assuming such a pressure could be obtained, are the maximum pressure change that can be made surrounding an enclosed ionization gauge and the minimum measurable current at ten to 20 c.p.s. J. W. Townsend[3] states that with an amplifier with a 100-c.p.s. band pass, a 1000-c.p.s. current of 4×10^{-14} amp. can be measured. A 10- to 20-cycle current can be measured to as low a value. The current in a standard ionization gauge is 10^{-5} amp. at a pressure of 10^{-4} mm of Hg, so that with a one percent pressure change a current of 4×10^{-14} amp. would correspond to 4×10^{-11} mm of Hg.

It has been shown how a resistance element, a thermocouple, and an ionization gauge can be used in the new gauge. It is possible, however, to use any pressure-sensitive device that develops an electrical signal. The gauge can also operate by any means of changing the pressure other than a volume change.

The model of the new gauge, with the tungsten wire, was used to measure pressures at the nose of a Viking rocket fired September 6, 1949. The gauge performed successfully, measuring pressures from 660 mm Hg at ground level to 570μ of Hg at the peak of the flight at 53 km.

---

* This calculation was made for a band width of 0.4 cycles and a temperature of 300°K with the 1000∼ filament at 600°K and a 5-cycle band width. The thermal noise would be 1.2×10^{-8} volt.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 7 JULY, 1950

A 4π-Radiometer

T. BENZINGER AND C. KITZINGER
Naval Medical Research Institute, Bethesda, Maryland

(Received January 25, 1950)

Total radiated heat loss and average surface temperature of living bodies have heretofore required laborious computation from numerous local measurements. The present study introduces the blackbody principle for this objective. Shieldless surface receivers have been designed, and built from identical and symmetrical sets of thermoelectric foil junctions, which were then made different only in their power to absorb or reflect radiation. By means of thermal shunting, they have been rendered stable against air motion up to 8 m/sec. A cavity, when uniformly lined with such receivers, will integrate the measurements of radiated output into every direction of space, permitting a direct recording of the total. The receivers have been developed specifically for application to the human gradient calorimeter now under construction. However, since the laws of radiation apply to cavities of any size or shape, the proper function of blackbody radiometry could be experimentally verified with a smaller number of receivers in a body of $8\times8\times16$ cu. in. The 4π-measurement is practically independent of location, size, or shape of the emittent source. The sensitivity is 76 μv/cal./sec. Full response is attained within 2.4 sec.

BACKGROUND AND OBJECTIVES

RADIANT energy is dissipated by human or animal bodies at different rates from different sites. The shape of the radiant surface of the body is irregular and changeable. The temperature of the radiant body surface is by no means uniform. It is, therefore, difficult to measure the total flux of radiated energy. It is also difficult to determine by integration of single measurements the average temperature of the human or animal skin. It seems even more difficult to follow the temporal variations of human skin temperature or radiant heat loss through continuous recordings, for instance, under various kinds of sudden and transitory stress or stimulation. There is, however, considerable interest in such measurements because in a normal environment the radiant fraction of heat amounts to more than one-half of the thermal output of a living body. Furthermore, skin temperature is essential for the measurement of "conductance," an important factor in blood circulation and in the over-all control of body temperature and heat exchange. Measurements of skin temperature have therefore been attempted by many investigators, with various principles of instrumentation.

Although existing methods have their individual merits, they have certain limitations. The *contact measurement* with mercury, thermoelectric, or resistance thermometers at single points or in special suits is based on the assumption that the thermometers assume the temperature of the skin, which is difficult to verify. Movements of the body under muscular exercise may add to this difficulty. Moreover, contact thermometers, when continuously applied, will unavoidably influence the temperature of the skin. Therefore, our method is based on the direct measurement of *thermal radiation*. Existing radiometers, however, show variations in zero reading because the receiver takes up radiation not only from the source of radiation but also from other parts of the instrument or from the surroundings, or from both. While single measurements are readily corrected for such variations, stability of zero is required for the purpose of continuous recording.

Air movement is a source of error in conventional radiometers, unless they are completely shielded either by contact with the skin or by windows. Contact with the skin tends to influence skin temperature, and windows tend to increase the response time of the instrument and make it susceptible to heat conveyed to the windows by conduction or convection. Furthermore, no method is known to us for a simultaneous integration of radiometric measurements into a total of radiant heat loss or an average of surface temperature. Existing instruments and the methods of evaluation give only approximate average temperatures. The procedures, moreover, are cumbersome. They do not lend themselves to continuous recording.

It has, therefore, been the objective of the present study to develop a radiometer for continuous recording of radiant flux, automatically integrating total radiated heat loss or average surface temperature over a solid angle of 4 π-radians in a manner which does not interfere with the radiant environment of the object. It was essential to avoid contact of any part of the instrument with the object. Moreover, it was necessary to insure that neither movements accompanying exhausting muscular exercise nor air motion would appreciably affect the measurement of thermal radiation. High accuracy and a rapidity of response sufficient to permit study of sudden reflex changes in cutaneous circulation were considered desirable characteristics. With reference to the gradient calorimeter now under construction[1] the simultaneous measurement of the totals and fractions of heat loss including the radiant part, as well as the simultaneous recording of skin and rectal temperatures, was desired. "Conductance" could then be continuously determined.

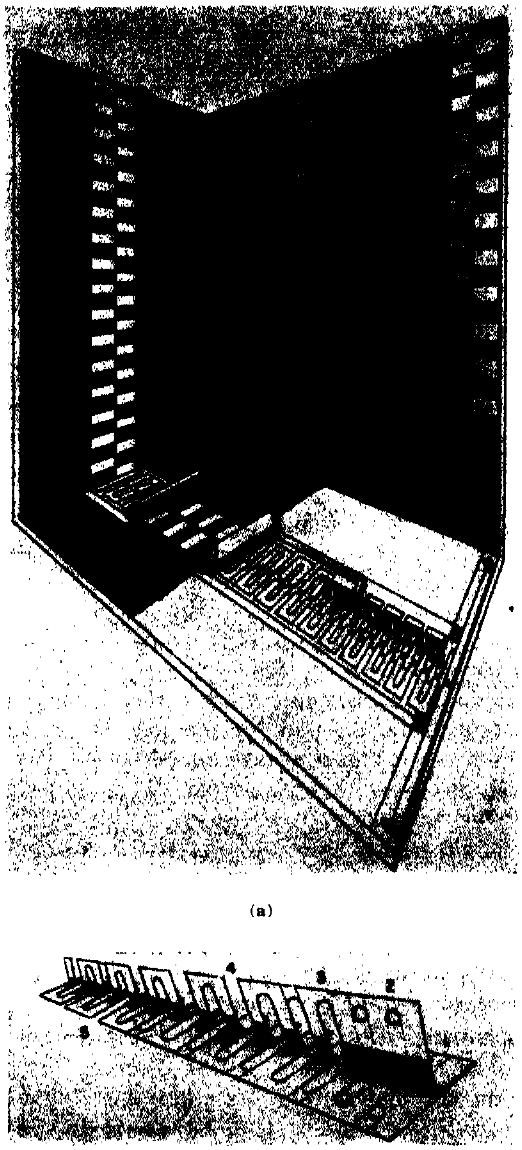
THEORETICAL PREMISES

Rigorous requirements as outlined above called for a deviation from current concepts of dermal radiometry. Instead of the usual receivers of small size and undefined shape, a blackbody surface receiver entirely enclosing the emitter was introduced.



(a)

(b)

Fig. 1. Upper part: Design of thermoelectric receivers. The perpendicular walls at a corner of the blackbody radiometer show the external appearance of the receivers. The receiver at the bottom is partially uncovered and unfolded. Note the symmetrical arrangement in a twin chain which compensates the effect of heat flows in the three directions of space. Note the junctions along the center line of the twin chain, the U-shaped bridges of copper or constantan, the insulating foils, the copper leads (right), the copper bridge between the mates (left), and the covering foil of anodized aluminum with alternate black and shining surfaces. Lower part: Process of making thermoelectric chains. The procedure is shown in subsequent steps: soldered double foil strips of copper and constantan are first marked (1, dotted line), then circular holes are punched (2), then common slits are cut into the copper and constantan foil (3), and last, alternatingly either a copper (4) or constantan (5) bridge is removed.

Let it be assumed that a non-selective thermoelectric surface receiver of uniform temperature and emissivity can be so constructed that every small element of its area will develop a certain potential in response to a unit net rate of incident radiant energy. If the individual potentials from the small elements could be made additive by serial wiring, their sum would represent the net rate of radiant energy falling upon the entire surface of the instrument. When such a receiver is extended to form a boundless surface enclosing the emitter, the limiting edges disappear, and the solid angle of 4π-radians is intersected. The following characteristics of this type of radiometer can be predicted: (a) Disturbing influences from any external sources of radiation will be excluded, (b) the instrument will intercept and measure the total, not a selected fraction, of the rate of energy emitted from a source of radiation. The following factors do not enter into this measurement: *The size of the radiometer*, because the density of radiant flux at the surface will increase or decrease in reversed proportion with the size (or number of sensitive elements) of the surface; *the shape of the radiometer* (defined by the angular inclination of different parts of the surface), because the product of the surface area and the density of the radiant flux received on the same area remains constant, when the surface is turned from the perpendicular to an oblique position with respect to the direction of radiation (Lambert's cosine law); *the geometric size of the source of energy*, because the receiving area intersects a solid angle of 4π-radians at any mean distance from the emitting surface; *the shape of the source of radiation*, because Lambert's cosine law applies to the source as well as to the receiver; *the distribution of temperature and emissivity at the surface of the radiant source*, because the closed surface of the blackbody will correctly integrate the radiation coming from all angles; *the location of the emitter* within the radiometer, because it has no influence upon the average density or mean angle of incidence of radiant flux exchanged between the emitter and the receiver.

For the enumerated reasons, a blackbody radiometer is distinguished from all former radiometers inasmuch as its measurements are practically independent of the relative location of emitter and receiver as well as of their angular positions in space.

Thermal radiation received and measured by the instrument can be written:

$$\Phi = A\cdot\sigma\cdot\epsilon\cdot(T^4 - T_e^4),$$

according to the Stefan Boltzmann law, where Φ = radiant flux [cal./sec.]; A = radiant surface of the source of radiation [cm^2]; ϵ = mean emissivity of the source of radiation [percent of blackbody emissivity]; T_e = temperature of receiving surface [° Abs.]; σ = Stefan Boltzmann constant, 1.373×10^{-12}[cal./(sec. cm^2 deg.^{4})]; = average surface temperature of the source of r

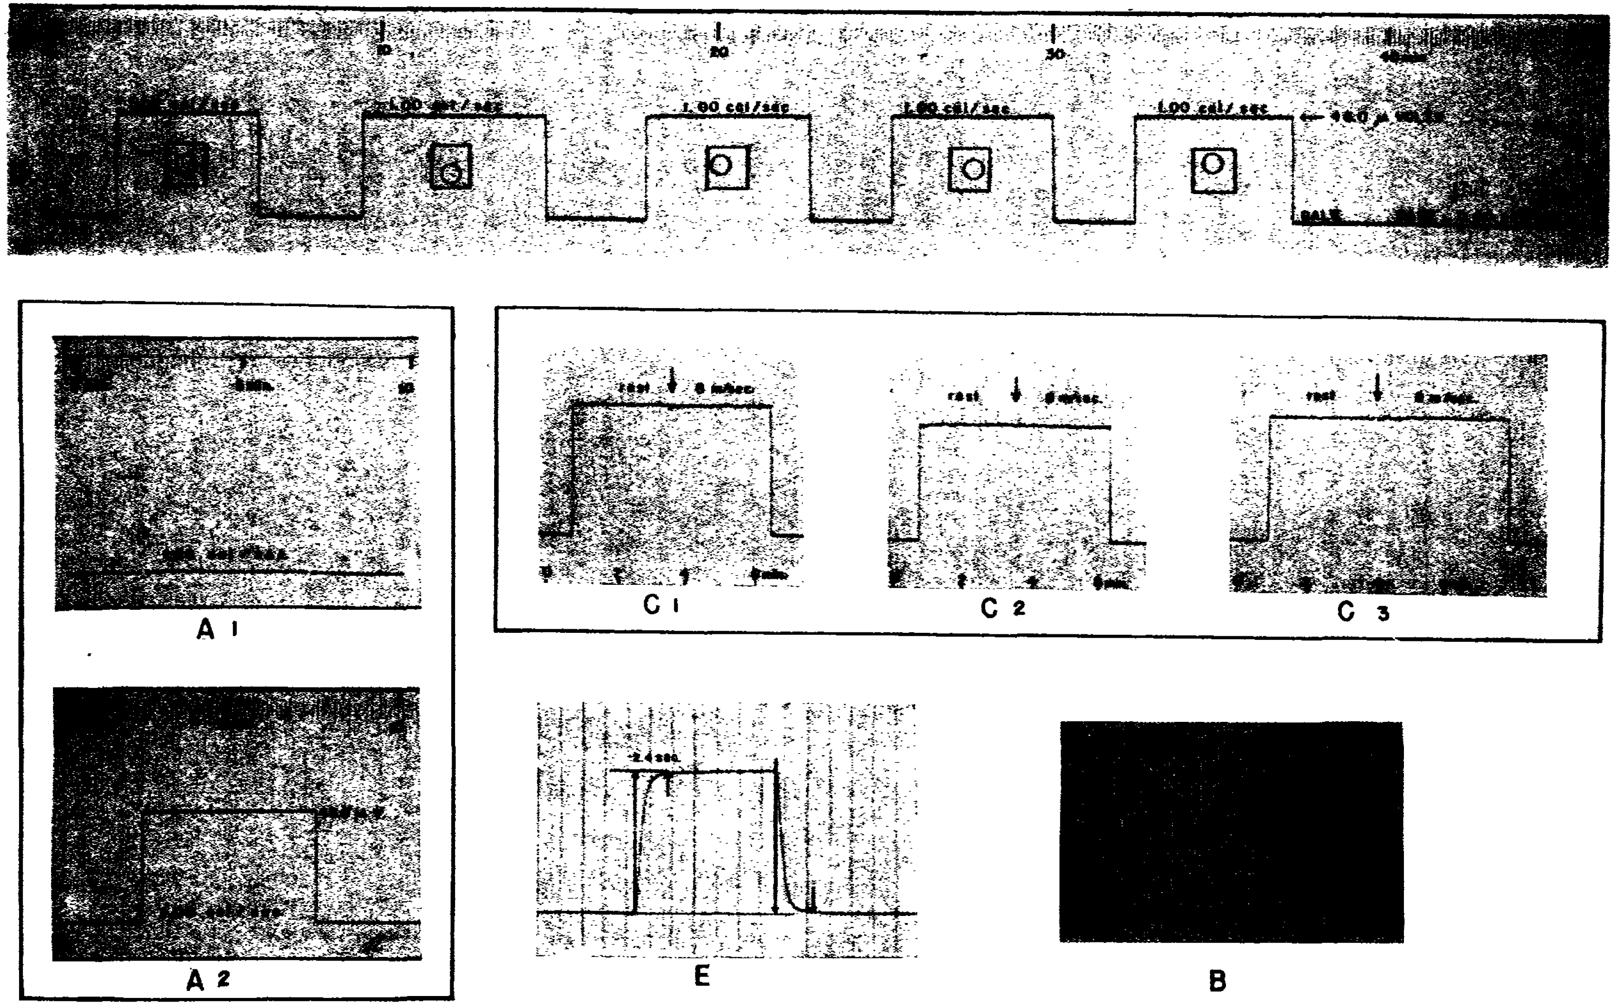


FIG. 2. A. Response specific to radiant heat. Potentials from the surface receivers of the 4π-radiometer have been recorded over time with a mirror galvanometer and slit camera, A.1 before, and A.2 after making every other junction reflective for thermal radiation. The recordings show responses in potential induced by 4.18 watts (1 cal./sec.) of heat loss from an electrically heated resistance coil in the interior of the instrument. The completed receiver responded with 46 μv to the radiant fraction (0.60 cal./sec.) of heat lost from the coil (A.1). The incomplete receiver with its uniformly absorptive surface was relatively unaffected as shown in A.2. B. Characteristics of zero. The galvanometer beam has been recorded over time with a slit camera; the radiometer was switched into or out of the galvanometer circuit. Full scale corresponds to human basal heat output. C. Measurement of thermal radiation in the presence of air motion. Potentials induced by thermal radiation (approximate intensity 1.4 cal./sec. m^2) to a receiving chain have been recorded over time, with a mirror galvanometer and slit camera, in the presence or absence of air movement in the three directions, longitudinally (left), transversely (center), and vertically (right) with respect to the chain. D. Location of heat source in the blackbody, and radiometer response. Potentials induced by the radiant fraction of a constant loss of 4.18 watts (1 cal./sec.) from a heated resistance coil were recorded with the coil moved into five different locations within the blackbody. The locations of the coil relative to the walls are schematically indicated. Shortest distance from the walls: ¼ in. E. Response time of surface receivers. Potentials were recorded over time with mirror galvanometer and slit camera, when a shield was placed between, or removed from between, a source of heat and the radiometer. One side of the radiometer was open.

tion [° Abs.].* Hence, when Φ is measured, and A, ϵ, and T_e are kept constant, changes of T can be observed and recorded in correct proportion. They can be measured in absolute terms, when A, ϵ, and T_e are known. On the other hand, changes of the radiant surface (with changes of bodily posture) can be observed in correct proportion as long as T is constant, or measured, when T is known. The blackbody radiometer may, therefore, be applied to observations of (a) rate of radiant heat loss; (b) average surface temperature of bodies of determined surface area and emissivity; (c) radiant surface area of bodies of known surface temperature and (d) emissivity of bodies when area and temperature of the surface are known.

Problems of a similar nature may arise in physics (emissivity of coatings, determination of radiation constants), or in technology (evaluation of sources of heat, light, or other kinds of radiated energy). In meteorology or astronomy, where the enclosure of radiant sources is out of consideration, there may, however, be applications for a simplified surface receiver. Heavenly or solar radiations can be intercepted on plane surfaces. The measurement of total radiant surrounding would require an inversion of the blackbody, i.e., the closed surface of a body of uniform temperature, uniformly covered with a surface receiver.

CONSTRUCTION OF SURFACE RECEIVERS

The source of thermal radiation to be measured is accommodated in a closed container of high thermal capacity and conductivity, the temperature of which is precisely set and carefully maintained. The inner walls of this "blackbody" are absorptive for thermal radiation. There are, however, numerous small reflecting spots distributed uniformly on the wall in equidistant longitudinal rows (Fig. 1). Beneath these rows, continuous chains of thermoelectric junctions are installed. The chains consist of alternating strips of copper and constantan foil. All copper constantan junctions (sequence in one direction of the electric circuit) are located beneath shining spots. All constantan copper junctions, on the other hand, are located beneath absorptive sites of the radiometer wall. Hence, with a source of radiant energy inside, all the constantan copper links will become slightly warmer than the corresponding copper constantan links, from which thermal radiation is reflected. Every couple of thermojunctions will, therefore, develop a small thermoelectric potential. Serial wiring of the junctions in continuous chains makes these potentials additive. Their sum will, after proper calibration, represent the total of thermal radiation which the wall received from the subject or heat source. 1280 junctions were installed. The details of their serial construction are shown in Fig. 1. The internal resistance of the whole instrument amounts of 35 ohms.

CHARACTERISTICS OF PERFORMANCE

In the design and construction of the radiometer, efforts had been made to obtain reproducible responses (in potential) to radiant energy (in calories per second) regardless of disturbing influences such as air movement or heat flows of other than radiant origin. Linear characteristics of response were desired. Stable zero reading was considered essential for continuous recording. The sensitivity was expected to be adequate to operate commercially available recording potentiometers without preliminary amplification. The response time, on the other hand, should be in the order of seconds only. The following tests have been carried out to evaluate these characteristics of the instrument.

Response specific to radiation.—Absence of response to heat transfer except thermal radiation must be ascertained before the instrument is made sensitive to radiation. For this purpose, a blackened coil of Nichrome tape, $\frac{1}{8}$ in. wide, 3Ω per ft., with a total resistance of 49.0Ω and a surface area of 600.0 cm², was placed within the radiometer before the installation of the reflectors, and heated with an input of 4.185 watts (1 cal./sec.). After a few minutes, the coil reached a final temperature and acted as a constant source of thermal radiation as well as heat for transfer by conduction and convection. It is observed that the total heat flow of one calorie per second does not induce an appreciable potential in the instrument as long as the mates in every pair of thermojunctions are both black (Fig. 2A.1). When, however, one mate in each pair was covered by reflecting aluminum foil, a response toward radiation was obtained as shown in Fig. 2A.2.

Stability of response.—The specific response to thermal radiation is stable as shown by the straight appearance of the line drawn by the mirror galvanometer (Fig. 2A.2). Repeated tests (compare Fig. 3) showed that the responses were identical on any experimental day.

Stability of base.—The base line of the radiometer prior to or following a given heat input was found to be stable and the same as the base line of the galvanometer, the sensitivity of which had been adapted to the range of measurements (Fig. 2B). It can, therefore, be concluded that disturbing galvanic potentials were absent and that thermal potentials were properly compensated in the pile of 1280 junctions.

Negligible influence of air movement.—As a source of thermal radiation, an electrically heated metal rod was placed above a radiometric chain at a distance of 10 in. which resulted in a stable potential of 42 μv from the chain. This potential was recorded over time with a mirror galvanometer and slit camera. In the first part of the recording (Fig. 2C), the air was still. At the point indicated by the arrow, a powerful convection current was established. The air movement came from the open end of a copper tubing of 0.16 cm² diameter which was supplied with compressed air at room temperature. The air left the tubing at an average velocity of 8 m/sec. as computed from diameter of the opening and air volume per unit time. The distance between the chain and the opening of the wind pipe was 1 cm in every instance. Tests were performed with wind blowing in three directions, i.e., longitudinally, C.1, transversely, C.2, or vertically, C.3, with respect to the chain. The wind influence on the measurement shows to be negligible.

---

* The statement of the formula $\Phi = A \cdot \sigma \cdot \epsilon(T^4 - T_e^4)$ presupposes that the temperature and the emissivity are mean values. A more detailed statement would be $\Phi = \sigma \int_s \epsilon_{(dA)}(T^4_{(dA)} - T_e^4)dA$, where $\epsilon_{(dA)}$ is the emissivity of the surface element dA, and $T_{(dA)}$ is the temperature of the surface element.

Linearity of response.—A sphere $3\frac{3}{4}$ in. in diameter was made of solid aluminum. The surface was "anodized" in order to make it sufficiently emissive in a reproducible manner. A soft soldered thermojunction of 36-gauge copper and constantan wires was hammered into a shallow notch chiseled into the surface. The "cold" junction was soldered to a disk of copper sheet 1 in. in diameter and 5/1000 in. thick, which was cemented to the wall of the radiometer. The potential of this pair of thermoelectric junctions was read from a precision null balance potentiometer to determine the difference between the temperature of the receiving surface, T_e, and the temperature of the radiating surface, T. The sphere was heated and suspended on light threads in the interior of the radiometer where it lost its added heat in an exponential manner. Therefore, the readings of both radiometer potential and surface temperature of the sphere needed to be taken quickly. The same potentiometer was used for both measurements. A double-pole double-throw switch was turned to change from one reading to the other. Readings were taken every minute of either radiometer potential or temperature difference, T_1-T_2. Potentials and temperatures were then plotted against the time of the reading, and simultaneous readings of radiometer potential and surface temperature were obtained by graphic intrapolation. Responses in potential were then plotted against values $(T^4-T_e^4)A\sigma$, which represents calories per second of thermal radiation, when A is the surface [cm^2] and σ the Stefan Boltzmann constant, 1.373×10^{-12}[cal./sec. cm^2 deg.^{4}], assuming that the emissivity of the sphere was 100 percent of blackbody emissivity. Actually, it was less than 100 percent, as will be shown later. However, within a narrow range of temperatures, emissivity is a constant. Figure 3 shows that the radiometer responds in a linear manner to radiant heat output. For the measurement of surface temperature, the characteristics deviate from linearity in the degree required to satisfy the Stefan Boltzmann equation.

Sensitivity.—Since the instrument responds in a linear manner to radiant heat loss, its sensitivity can be expressed in microvolts per watt, or calories per second, of radiant energy, after proper calibration. For this purpose, however, the emissivity of the radiant

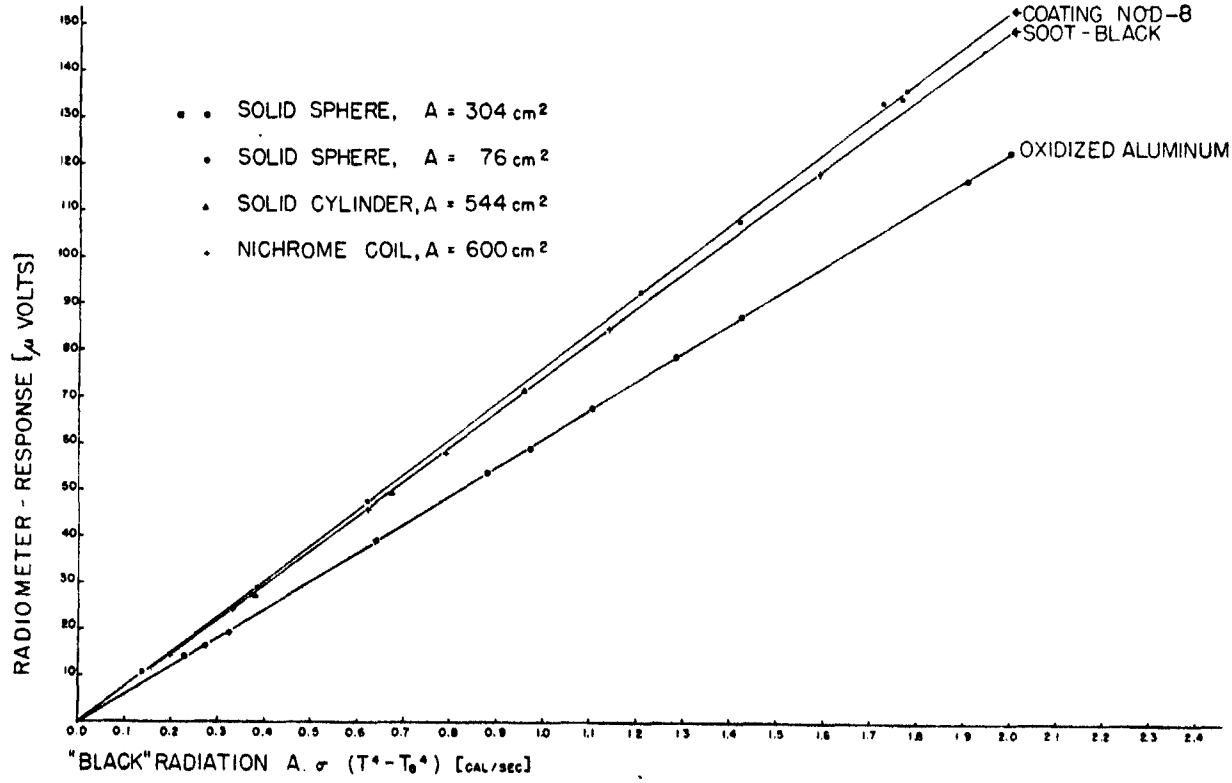

FIG. 3. Calibration of blackbody radiometer. Bodies of various sizes, shapes, and emissivities of surface have been used as source of radiation. Radiometer responses [μV] have been plotted against the radiant flux [cal./sec.], which the source of radiation would emit, when perfectly black, from its surface, A [cm^2] at its temperature T [° Abs.] toward the walls at a temperature, T_e[° Abs.]. σ was assumed to be 5.75×10^{-8}[watt/m^2 deg.^{4}]. The graph shows that size, shape, and material of the source have no appreciable influence on the values observed. The relative emissivities of the surfaces appear from the radiometer responses. Blackbody radiation for a determination of the absolute sensitivity was unavailable. The absolute sensitivity must, therefore, be slightly higher than 76.2 v/cal./sec. as observed with the special coating "air interface absorber N.O.D.—8".

surface must be known, or close to unity. Figure 3 shows calibrations performed on bodies with different coatings. "Air interface absorber N.O.D.—8"† appeared to be 2½ percent better than soot black. It shows the highest emission and can be considered almost completely absorptive, according to recommendations by the National Bureau of Standards. Hence, the sensitivity of the radiometer (Fig. 3) should only slightly exceed 76.2 μv/cal./sec. Ideal blackbody radiation is not directly applicable in the present instance.

Uniformity of response of all receivers in the radiometer.—If the geometrical considerations are correct and if the measuring units of the receiving surface are sufficiently numerous and evenly distributed, the same response to radiated energy will be obtained from large or small sources of radiation, as shown in Fig. 3.‡ The response of the radiometer also is not altered, when a source of radiation is moved from one position to another, up to a distance of ½ in. from the wall (Fig. 2D).

Rapidity of response.—A test was carried out with an electrically heated metal rod mounted above the open radiometer. A shield was placed between the radiometer and the source of radiation. When the shield was removed or replaced, the instrument responded in an approximately exponential manner (Fig. 2E). Half-response was attained within a quarter of a second, approximate equilibrium within 2½ sec. The time of half-response of the galvanometer was 0.1 sec. under the conditions of these experiments.

DISCUSSION

The tests have shown a satisfactory stability of the present receivers against thermal flows of other than radiant origin as well as against air motion. It may be of interest to discuss how these characteristics have been obtained without the use of shields or windows:

Whereas in known thermopiles the "warm" junctions differ from the "cold" junctions by separate location (Moll,[2] Coblentz[3]) or selective shielding (Coblentz,[3] Hardy[4]) or selective thermal insulation in a vacuum (Bohnenkamp[5]), or selective shunt with the instrument body (Moll,[2] Johansen,[6] Harris[7]) the junctions in the present radiometer are identically constructed and symmetrically arranged. They differ only with respect to their absorption of radiated energy. Heat flows of other than radiant origin, coming either from the object, or striking the instrument wall at the outside, will therefore affect the two mates in any couple of adjacent junctions almost simultaneously and with similar intensity, yet with opposite direction of the potentials developed. This compensation applies, for example, to heat conveyed to the receiver by warm air currents.

Convection, however, has a further effect upon a radiation thermopile: even if the moving air does not carry any exchangeable heat, the thermal resistance between the "warm" and "cold" junctions will decrease during air motion, since moving air is more conductive than resting air. This must result in a decrease of the response to radiated energy during air motion. We have attempted to eliminate this source of error on several ways: Translucent windows failed, as they absorb and store heat from various sources and radiate it subsequently towards the radiometer. Establishing a constant maximum convection appeared to be cumbersome and would put limitations on the variability of experimental conditions. Cooling of the warm junctions by the Peltier effect of an attached chain supplied with a measurable current, was insufficient, as the Joule effect interfered. Heating of the cold junctions would disturb simultaneous calorimetric measurements.

While these attempts were generally unsuccessful, the following approach effectively eliminated the convection error: Within certain limitations, the sensitivity of a radiation thermopile is inversely proportional to the thermal conduction between the "warm" and "cold" junctions. The conduction, C, can be considered as the sum of two parts, C_s and C_a, C_s taking place through the solid connections, and C_a taking place through the surrounding air. If C_s is made very large in comparison with C_a, variations in C_a induced by air motion, will have little influence upon the total conduction (C_s+C_a), which determines the sensitivity. In the present radiometer, C_s has been made very large, by close contact between the junctions and the base. An additional thermal shunt was introduced by the covering aluminum foil. By this means, sensitivity is decreased, and stability against air motion is obtained. The loss of sensitivity can be accepted, as the large number of junctions provides more voltage than necessary to operate the recording instruments.

Since the characteristics observed correspond to the requirements already outlined under objectives of the present study, further discussion of the performance does not seem necessary.

---

‡ For computations of radiant flux Φ in Fig. 3, the receiving surface has been considered "black," because of the blackbody condition. In this assumption, however, the finite surface area of the emitter has been neglected. For an emitter the surface area of which equals the surface area of the blackbody receiver, Φ would be smaller by a factor ϵ', namely, the mean emissivity of the wall coating. For small emitters this correction becomes negligible. In the examples of Fig. 3, it would be less than one percent of observed values. The sensitivity of the radiometer to radiant flux, however, does not change when the surface of the emitter increases or decreases.

A Recording Torque Magnetometer

D. S. Miller
Research Laboratory, United States Steel Corporation of Delaware, Kearny, New Jersey

(Received February 6, 1950)

This instrument produces, automatically, a curve of torque *versus* angle of orientation for a thin iron or steel disk in a strong magnetic field. A resistance strain gauge converts the torque acting on the disk specimen to a small d.c. voltage, which is recorded on a "strip-chart" recording potentiometer. The specimen is rotated in synchronism with the translation of the chart paper, both being driven by synchronous motors. A torque curve is completed in six minutes.

TORQUE magnetometers of various types have been used for many years in laboratory studies of the magnetic anisotropy of single crystals. For instance, such instruments were used by Weiss[1] in the study of pyrrhotine and by Webster[2] in the study of iron crystals. More recently, others[3-6] have used them for the study of both single crystal and polycrystalline iron alloys. N. P. Goss[7] used the same type of device in developing a treatment to produce a high degree of preferred orientation in an iron-silicon alloy.

The torque magnetometers used by these workers were manually operated, readings being made point by point. It has recently been found that the instrument is useful in both development and production where rather large numbers of specimens are to be tested. It was considered, therefore, worth while to devise a modification of the instrument which would record the data automatically and more rapidly than could be done with the manual type of instrument. Ingerson and Beck[8] devised a scheme for generating the torque curve on the screen of a cathode-ray tube, which would provide the speed we wished, but was not exactly suited to our needs since we preferred a directly produced permanent record such as is provided by a pen-driving type of potentiometer-recorder.

In the instrument which we have designed to fulfill these requirements the torque exerted on a disk specimen is converted, by a resistance strain gauge, to a small direct-current voltage. This voltage is applied to the measuring circuit of a "strip-chart" voltage recorder of the proper sensitivity. The disk is rotated about an axis perpendicular to its plane by means of a synchronous motor and reduction gearing. The chart paper in the recorder is also driven by a synchronous motor, so that there is a definite relation between the angular rotation of the disk and the movement of the chart paper. As the disk rotates the torque varies and the pen in the recorder moves in accordance with this variation. By use of the proper conversion factor, the voltage record on the chart paper becomes a plot of torque *versus* angle of orientation of the disk in the magnetic field.

The construction of the torque transducer is shown in Fig. 1. The specimen, a disk one inch in diameter, is held between spring jaws on the holder (*B*), which fits on two taper pins on the cross-head (*J*) of the transducer. The torque on the specimen is transmitted through the cross-head and the shaft (*I*), producing a displacement of the shaft of the strain gauge (*K*) by means of a bronze strip (0.002×0.020 in.) wrapped once around the shaft (*I*) and attached to the two collars (*H*) on the strain gauge shaft. Figure 2 shows the manner in which the strain gauge is coupled to the shaft (*I*). Pivots at the ends of shaft (*I*) ride in *V*-jewels mounted in the supporting rectangular frame.

The strain gauge (*K*), which is a product of the Statham Laboratories of Beverly Hills, California,

consists of four resistance strain elements connected as a Wheatstone bridge to which a direct current of not more than 30 ma is supplied. The gauge used here has a range of 4 oz. applied force, producing an output of approximately 20 mv maximum. The torque limit of the transducer is 50,000 dyne-centimeters, which is adequate for practically all of the steels which we have tested, in thicknesses from 0.015 to 0.080 in. To produce curves of usable amplitude from thinner specimens, having thicknesses from 0.010 to 0.015 in., we have made holders to take specimens of 1.5 in. diameter. The graduated scale on the base plate (*D*) provides a measure of the angle between the direction of the applied magnetic field and the orientation of the transducer. It is an approximate measure of the angle between the magnetization in the specimen and a chosen reference direction in the specimen. The errors involved in this reading will be discussed later. The small hand lever (*Q*) controls one stop which operates the limit switch (*Z*). With this stop in the operating position the allowed rotation is 100 degrees. A fixed stop limits rotation to 200 degrees when the lever (*Q*) is in the open position.

The position of the torque transducer between the poles of the electromagnet is shown in Fig. 3. It is attached, by means of three screws through the base plate (*D*), to a drive plate on the base of the magnet yoke. This drive plate connects, through a gear train in the base of the magnet, to a small synchronous motor mounted below and in back of the yoke. The drive rotates the gauge at a rate of 30 degrees per minute. A thumb lever (*E*) disengages the drive so that the gauge may be rotated by hand to set the starting position. Two switches (*F* and *G*) on the right foot of the magnet pedestal control the motors for rotating the torsion gauge and driving the chart paper in the recorder. A limit switch (*Z*) under the right hand magnet coil shuts off both of these motors at the completion of a run. A plug and four wire cable (*U*) connects the strain gauge to its supply battery and to the recorder.

The output terminals of the gauge are connected to the input of the recorder. We have used a Brown strip-chart recorder with a range, −4 to +4 mv. By making the range of the recorder a fraction of that of the gauge we have enhanced the useful range of the instrument. A specimen whose maximum torque is 50×10^3 dyne-cm is kept on scale by setting the gauge input current to 6 ma; a specimen whose maximum torque is 10×10^3 dyne-cm is made to record full scale by setting the gauge current at its maximum, 30 ma. Furthermore, by selection of the gauge current, a convenient factor for the torque scale on the chart can be chosen. The current required for a preselected scale factor can be determined by a simple calculation, using the volume of the specimen to be tested and the constant of the gauge.

The electromagnet is of conventional design. Each coil has approximately 4500 turns of No. 16 wire. With a current of 2.3 amp. the field at the center of the 1.75 in. gap is about 4000 oersted. The heat dissipation at this current is not sufficient for continuous operation but is adequate for short runs. At 2.0 amp. continuous operation is possible. With this current the field is about 3700 oersted.

The recorder and controls for the electromagnet and the recording circuit are mounted in a cabinet 22 in. wide, and 68 in. high. A field-discharge switch, a 50-ohm 200-watt rheostat, and a 3-amp. ammeter provide control of the magnet current. A milliameter (30 ma) and two rheostats (1000 ohm for coarse, and 100 ohm for fine adjustment) for control of the input current to the strain gauge are mounted on a panel above the recorder. On the same panel a 50-ohm potentiometer wired into the recorder measuring circuit provides fine control of the zero point of the recorder. This adjustment is necessary because the strain gauges cannot be so precisely adjusted in manufacture that the output voltage is zero for zero strain.

Within the limits of the useful range the output of the transducer is linearly proportional, to within ½ percent, to the applied torque and to the input current. The transducers were calibrated by using a torsion fiber of known constant, attached, at its upper end, to a graduated circle (a converted optical goniometer), and at its lower end, to the specimen holder (*B*).

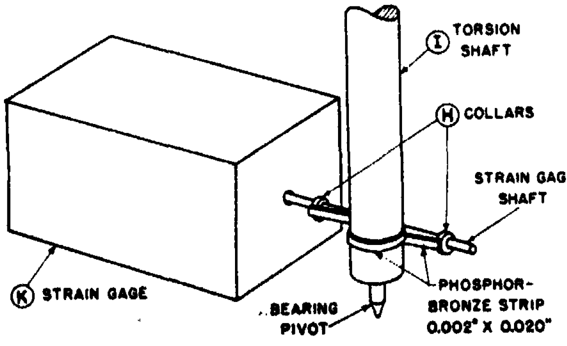

FIG. 2. Method of coupling strain gauge to torsion shaft.

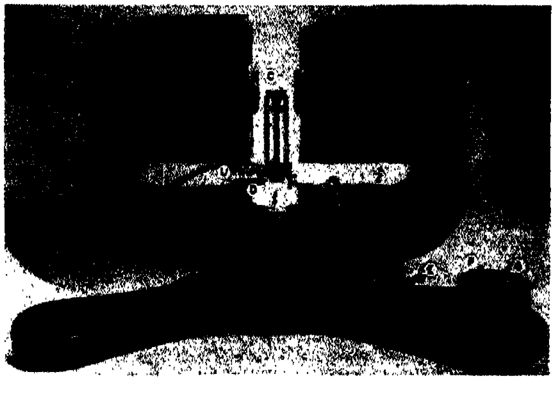

FIG. 3. Torque transducer mounted on electromagnet.

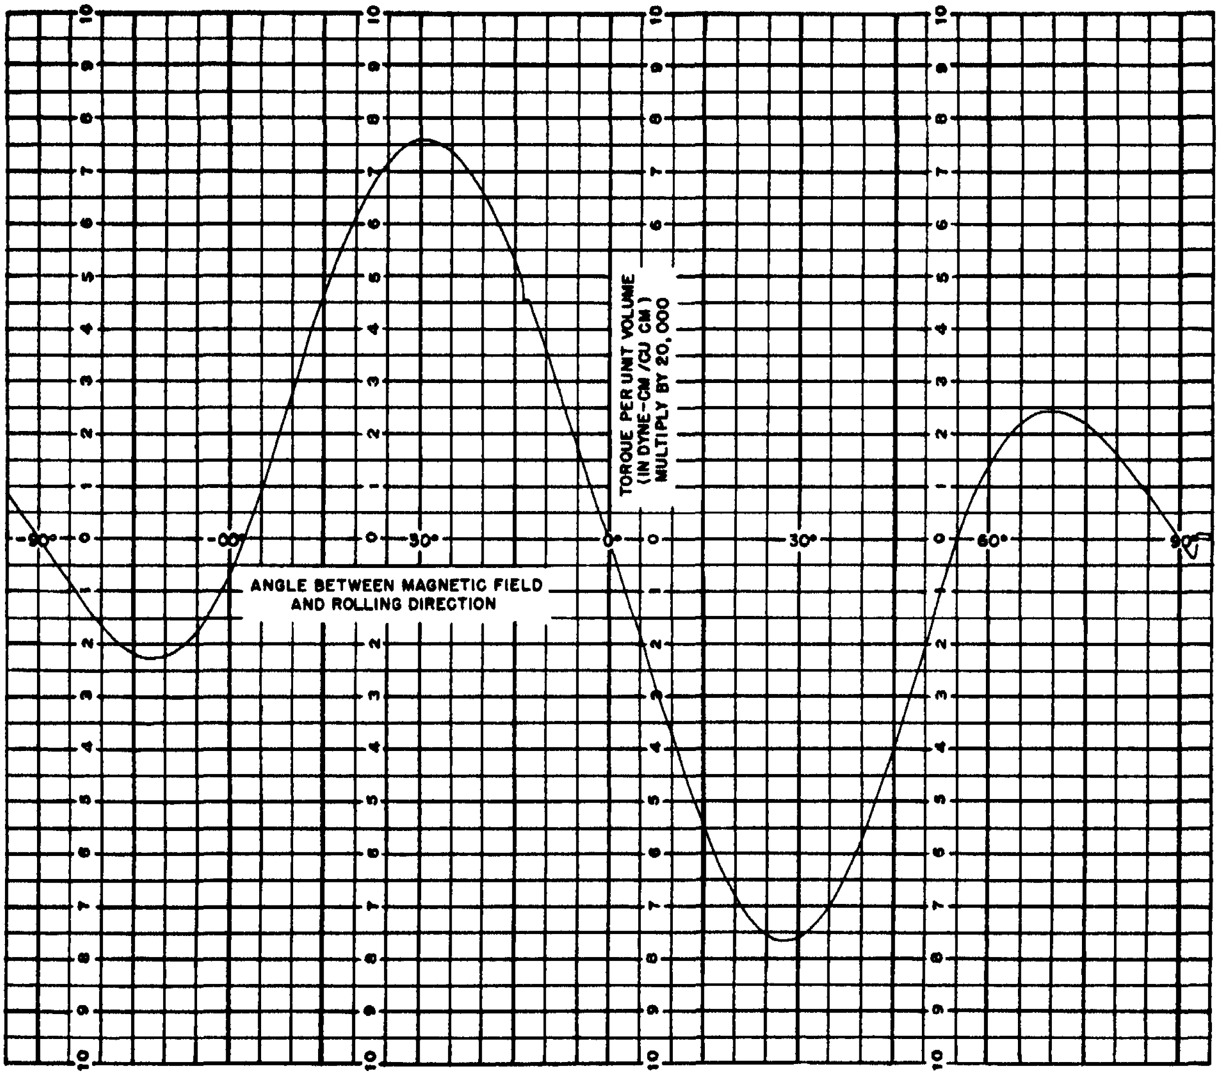

FIG. 4. Typical magnetic torque curve obtained on a specimen of silicon steel having a high degree of preferred orientation.

As stated previously, the plot obtained is an approximation to the true torque as a function of the angle between the direction of magnetization and the reference direction in the specimen. The principal error, which is in the angular measurement, arises from two sources. For any torque other than zero, the specimen must be deflected from its rest position with respect to the torsion gauge. The maximum value of this deflection is 0.7 degrees; for the torque radius of the gauge is 0.125 in. and the limit of displacement of the strain gauge shaft is 0.0015 in. The second source is the deviation of the magnetization in the specimen from the direction of the magnetizing force. Bozorth[9] has calculated this effect and shown that it becomes small at high fields. An error in the torque arises from the fact that in punched disks the edges are not saturated. This could be eliminated by making the specimen ellipsoidal. A more complete discussion of these errors is given in reference 6. In the applications for which we have used the instruments up to the present the errors are not large enough to be significant.

A typical curve obtained on an iron-silicon alloy specimen is shown in Fig. 4. This material was processed in a manner somewhat similar to that developed by Goss.[7] The curve approximates that of a single crystal having a (110) plane in the plane of the specimen and a (100) direction parallel to the reference direction (zero degrees). The step in the curve at about −13 degrees was caused by the operation of the automatic standardizing mechanism in the potentiometer-recorder.

Molecular Diffraction Attachment for RCA Microscope

B. O. HESTON AND P. R. CUTTER
University of Oklahoma, Norman, Oklahoma

(Received February 17, 1950)

A new device for the distribution of vapors across an electron beam for molecular diffraction studies is described. The efficiency of the new method has made it possible to obtain molecular diffraction patterns with an electron microscope without need of alterations.

The vapors are ejected from a circular crest of a diffusion box immediately surrounding the beam to give a heavy concentration of vapors in contact with the beam while releasing a small amount of vapor. The method has been standardized with well known patterns of CCl_4 and CBr_4.

INTRODUCTION

THIS paper describes a molecular diffraction attachment designed to fit an RCA microscope. The attachment consists of a radial diffusion box and needle valve assembly, which is shown unassembled in Fig. 1, and assembled on an RCA diffraction adapter in Fig. 2. Figure 3 gives a cross-sectional drawing of the diffusion box as prepared and used for this study.

The radial diffusion box, Fig. 1, part *A*, and Fig. 3, was used for both distribution of vapors and as a sample box in the study of crystalline organic compounds with vapor pressures of less than 1.0 mm. With organic liquids of higher vapor pressures the diffusion box was used for the distribution of vapors and the needle valve was used as a sample box to give better control on the amount of vapors released.

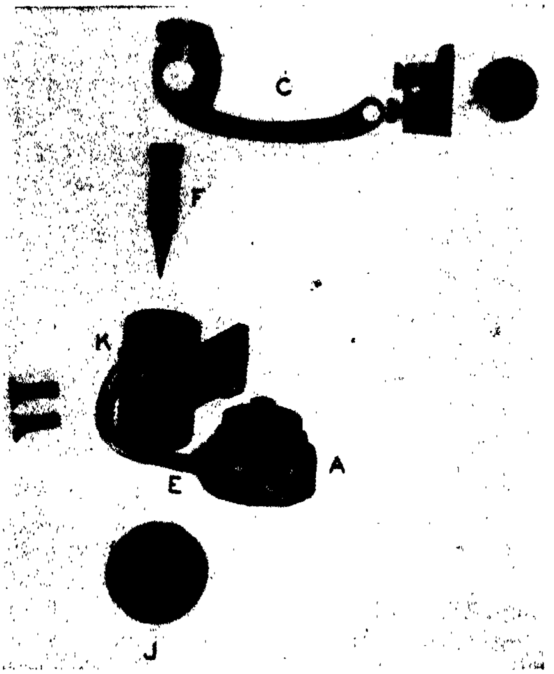

FIG. 1. Unassembled radial diffusion box and needle valve used for molecular diffraction studies with the electron microscope. A. Radial diffusion box. C. Control lever for opening and closing needle valve. E. Tube for transporting vapors from needle valve to box. F. Needle valve. J. Needle valve sample box cover. K. Needle valve body.

The radial diffusion box was so made that when it was placed in a vacuum and opened a fraction of a turn, any vapors present in the box would converge as a thin circular front of increasing density toward a central point in the open cylindrical channel traversing the center of the box. By passing the electron beam of the microscope through this point of greatest density, it was possible to obtain excellent molecular diffraction patterns without overloading the instrument with vapors. The amount of vapors released with the new method was so small that the use of a cold finger[1-5] or rapid auxiliary pump[6] was unnecessary. By using the diffusion box as the sample holder for low vapor pressure compounds, the need of an electrically heated sample box was partially eliminated. The operational technique of the microscope was not altered in any way, and the small amount of vapor going through the vacuum pumps did not hamper their operation. The development of the new device thus introduces a new use for the electron microscope.

APPARATUS

The Radial Diffusion Box

The radial diffusion box, Fig. 1, part *A*, and Fig. 3, was machined from brass and had an O.D. of 9/16 in. and a height of 3/16 in. which was as large as the space in the microscope permitted. The lid, Fig. 3, part *M*, screwed inside the box *Z* and had an O.D. of 7/16 in. with an outer depth of 2/16 in. and an inner depth of 1/16 in. A channel was drilled through the center of both the lid and box 1/16 in. in diameter giving a cylinder 3/32 in. in depth for the concentration of vapors. The box and lid were threaded with 40 threads per inch. When the concave lid was completely closed, then opened 1/5 revolution, a circular crevice 0.005 in. wide and 0.2 in. in circumference admitted vapors toward the centrally located electron beam, Fig. 3, part *e*. The under side of the lid was machined out

1/16 in. to allow space for organic crystals, Fig. 3, part *E*, when the box was to be used as a sample holder. The box was then soldered on the back side of the RCA orifice designed to hold penetration specimens. When the new assembly was placed on the under side of the RCA diffraction adapter as shown in Fig. 1, part *A*, and Fig. 2, and the entire assembly placed in the instrument, the point of greatest density of vapors or the distance from the circular crevice to the photographic plate was found to be 25.9 cm. To open the box, one end of a small steel chain was soldered on the edge of the lid. By attaching the other end of this chain to a tiny hook which has been soldered to the lower RCA rotating rod, Fig. 2, the box could be opened after being placed within the instrument. The diffusion box alone was sufficient for the study of crystalline compounds with vapor pressures ranging between 0.01 to 1 mm, but with organic liquids the loss of vapor through the threads of the box was too great. For this type of work it was found necessary to design a needle valve assembly as a side attachment to the diffusion box for better control of the amount of vapors released.

Valve Assembly

The needle valve assembly as shown in Fig. 1 was machined from brass with the exception of the needle which was made of Tobin bronze for greater wear resistance. The over-all length of the assembly was made slightly less than one inch in order to fit the limited cylindrical space present in the instrument. The needle used, Fig. 1, part *F*, was 0.81 in. long with a diameter of 0.167 in. The needle valve body Fig. 1, part *K* was 0.625 in. long and cut from a 0.375 in. O.D. brass rod. The needle valve body was brazed to a 0.064 in.×0.20 in.×0.75 in. brass strip for attachment to the RCA adapter by means of two steel screws. The lower end of the needle valve body was machined out for a sample compartment. This compartment could then be sealed by screwing on the cap, Fig. 1, part *J* and closing the needle valve. Lead turnings were melted in the bottom of the cap to give a lead gasket 1/16 in. in depth for proper sealing. The vapors released from the needle valve compartment were transported to the diffusion box through a tiny copper tube Fig. 1, part *E*, soldered into port holes in the side of the needle valve body and diffusion box respectively. The diffusion box was then opened and closed, after placing it in the instrument, by means of attachments, Fig. 1, part *C*. By rotating the upper thumb knob, Fig. 2, the upper rod could be moved in or out thus making it possible to open and close the needle valve within a few seconds.

EXPERIMENTAL

Sample with Low Vapor Pressure

Diffraction patterns of vapors derived from organic crystals were obtained using the diffusion box alone. To place the sample in the box, the bottom side of the lid was turned up and a small number of purified crystals were placed in the machined out chamber. The lid was then screwed in place while holding it in the same position. After completely closing the lid, the loose end of the attached chain was fastened to the lower rod before placing in the instrument. When the diffraction attachment had been screwed into the instrument, the microscope was prepared for operation in the same manner as for magnification work. All lenses of the machine were left in turned-off position except the condenser lens which was used to focus the electron beam to give the brightest spot on the fluorescent screen. After the beam was properly adjusted, the box was opened by rotating the lower thumb knob, Fig. 2, until a diffraction pattern appeared on the screen. Five exposures were then made in rapid succession allowing slightly different time for each. As soon as the plate was exposed the instrument was shut off and the diffraction adapter removed. It was unnecessary to close the box after each exposure with low vapor

pressure compounds such as CBr_4 as the amount of vapor released was not great enough to disturb the vacuum of the instrument or interfere with the diffraction pattern.

Sample with High Vapor Pressure

The first attempt to run liquid samples such as CCl_4 with the diffusion box alone did not prove successful for when the box was slightly opened, the vapors left through the threads around the outside of the box as well as the circular crevice which resulted in overloading the instrument. To correct this, a needle valve assembly was constructed for a control of these vapors and the threads of the diffusion box sealed with solder after opening 1/4 revolution. When this assembly was placed in operation it was discovered that when the needle was opened slightly in the vacuum of the instrument, instead of a steady stream of vapor coming off the liquid sample, the flow appeared to be intermittent. This was believed to be caused by droplets of liquid coming from the needle valve compartment. To correct this, a small pad of cotton which had been previously freed of any volatile matter by heating to 110°C in an oven was immersed in the liquid sample to be studied. The cotton pad was drained of all surplus liquid by placing it on a dry piece of filter paper. The damp pad was then sealed in the sample box of the needle valve assembly and the instrument made ready for the run. Before turning on the high voltage and electron gun, the needle valve was opened and closed once to be sure that no droplets were present to cause an overload while exposing the plate. With this improved technique, the needle valve could be opened, the diffraction pattern photographed, and the needle valve again closed without any danger of excess vapors. This made it possible to run numerous samples in a single day without operational difficulties. Here again, the time of exposure was varied to bring out different orders of the diffraction pattern.

RESULTS

Although the authors will reserve any detailed discussion of results for another paper, the electron diffraction patterns of CCl_4 and CBr_4 which were used to standardize the method, are shown in Fig. 4, and the corresponding microphotometer tracings are given in Figs. 5 and 6. The pattern of CBr_4 was made using the diffusion box as the sample holder while the pattern of CCl_4 was made using the needle valve compartment to control the amount of vapors released across the electron beam.

Theoretical equations were derived from tetrahedral models for both of the above compounds based on the concept of Debye's[7]

$$I=K\sum_i \sum_j f_i f_j \sin sr_{ij}/sr_{ij},$$

where the symbol I is the intensity of the scattered electrons; r_{ij} is the distance between the ith and the jth atom; s is equal to $(4\pi \sin\theta/2)/y$; $\sin\theta/2$ is equal to one-half the angle between the incident beam and the point of intensity under observation; y is the wavelength in angstroms. For simplification, the symbol f_i and f_j were set equal to the corresponding atomic numbers of the atoms under consideration.

The reduced theoretical scattering equations for CCl_4 and CBr_4, based on tetrahedral models were found to be

$$(CCl_4)\quad I/K=4.25\sin X/X+\sin 0.612X/0.612X,$$
$$(CBr_4)\quad I/K=8.75\sin X/X+\sin 0.612X/0.612X,$$

where X is substituted for sr.

Theoretical values of X found where I/K reached maximum or minimum values, were then divided by corresponding experimental s values derived from corresponding ring diameters to give the desired values of r. For CCl_4 the average value of r, or the Cl—Cl distance, was found to be 2.89±0.02A. By multiplying this value by 0.612, a C—Cl distance of 1.76±0.03A resulted which agrees well with the now accepted value[8] for this

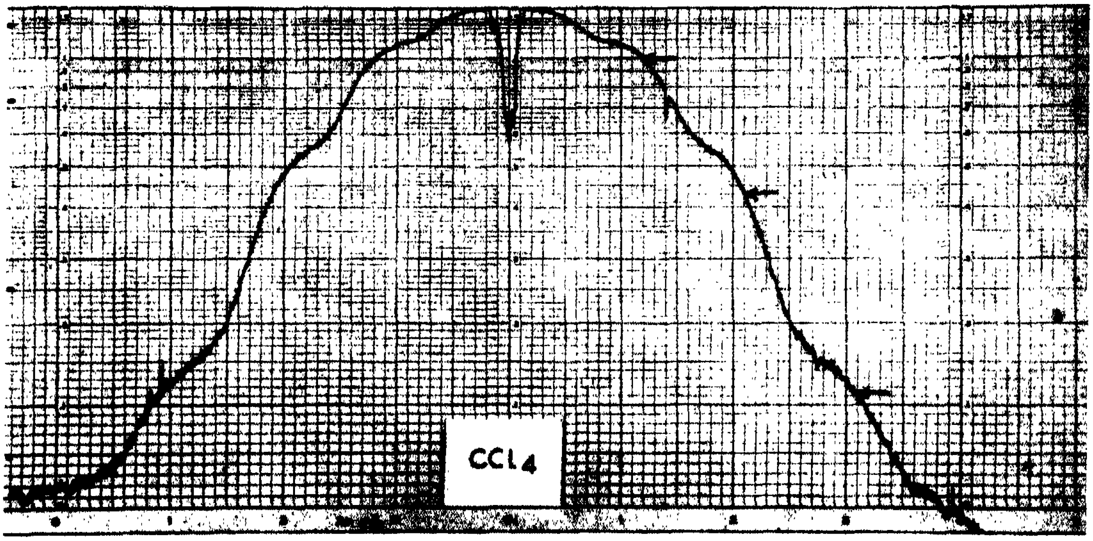

FIG. 5. Microphotometer chart of a CCl_4 diffraction pattern showing the location of the first three maxima.

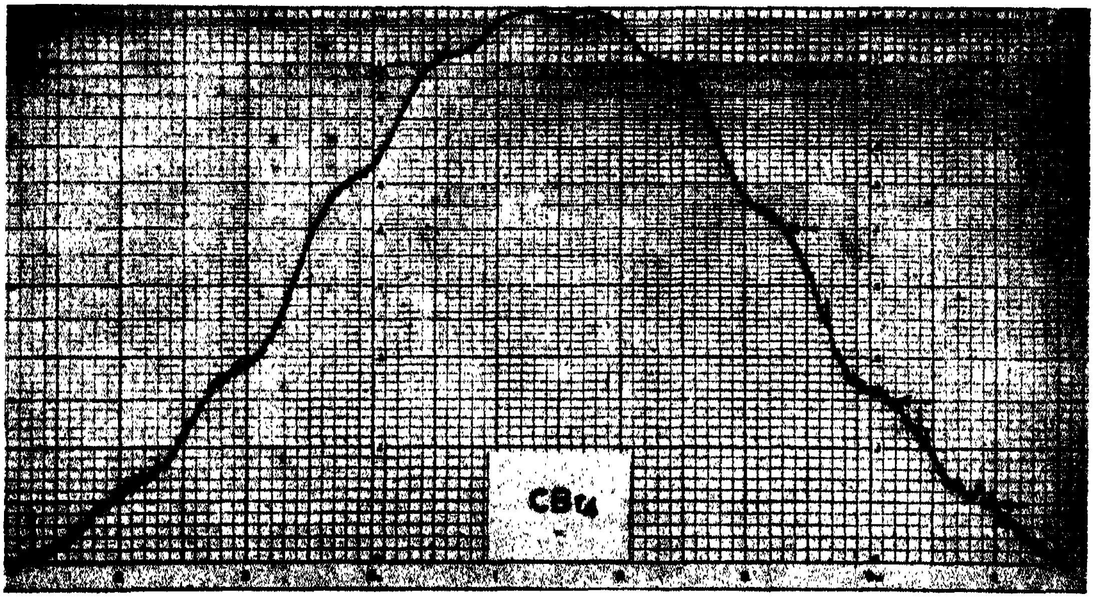

FIG. 6. Microphotometer chart of a CBr_4 diffraction pattern showing the location of the first four maxima.

[8] L. Pauling and L. O. Brockway, J. Chem. Phys. 2, 867 (1934).

atomic distance. Similarly, analysis of CBr_4 gave an average Br—Br distance of 3.15±0.03A which is within the accepted value of 3.12±0.03A.

From the close agreement with the literature with both compounds, the method was considered sufficiently accurate for analysis of compounds of unknown structure.

ACKNOWLEDGMENT

Due credit is given Mr. Carl Starkey, University of Oklahoma, for his excellent assistance in helping the authors prepare the molecular diffraction attachment described in this article.

SUMMARY

The greatest contribution of this paper is believed to lie in the new technique of distributing vapors for electron diffraction work, first by eliminating any possibility of directional effects, and second, that the efficiency of the method opens a new use for the electron microscope with no alterations or changes necessary. The accuracy of the new method has been established by analysis of the diffraction patterns of CCl_4 and CBr_4.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 7 JULY, 1950

Apparatus for Rapid Measurement of Internal Friction

Herbert I. Fusfeld
Pitman-Dunn Laboratory, Frankford Arsenal, Philadelphia, Pennsylvania

(Received April 13, 1950)

This paper describes apparatus for measuring internal friction which satisfies the conditions (a) low induced stress amplitude to preclude any plastic flow of the specimen, (b) ability to install specimen within a few minutes after treatment, (c) rapidity of measurement, at a rate of ten to twenty per minute, (d) accuracy of at least one percent.

Longitudinal vibrations are induced by an eddy-current drive, similar to one previously described in the literature, satisfying (a) and (b). Conditions (c) and (d) are obtained by measuring the decay time of free vibrations using vacuum tube trigger circuits and a counter chronograph. Satisfactory measurements can be made with push-button rapidity and simplicity.

INTRODUCTION

In order to investigate certain aspects of internal friction of metals arising from cold-work, apparatus had to be developed embodying the following characteristics: (a) Induced stress amplitudes must be so low that negligible plastic flow occurs due to the measurement itself. (b) Specimen must be properly installed in the apparatus within a few minutes after metallurgical treatment. (c) It should be possible to obtain ten to twenty measurements per minute. (d) An accuracy of about one percent or better should be obtainable.

The first requirement is admirably fulfilled by electromagnetic coupling of the specimen to the driving and detecting units. This method was used by Wegel and Walther[1] utilizing steel armatures cemented to the ends of the specimen, with electromagnets at the driving and detecting units. The second requirement is met by a similar arrangement, but without the added steel armatures, used by Randall, Rose, and Zener.[2] Eddy currents induced in the specimen interacted with a fixed magnetic field to set the specimen into vibration.

The apparatus to be described utilizes this latter eddy-current method, but modifies the measuring equipment to include trigger circuits and a counter chronograph. Shorter times are thus measurable with satisfactory accuracy to meet the last two requirements. A detailed description of the method with accompanying diagrams is presented. These items, though not inherently difficult to workers in the field, do not appear to have been published previously.

The only other semi-automatic method thus far described in the literature to the writer's knowledge is by Förster and Breitfeld.[3] This also measures the decay time of a freely vibrating specimen by arrangement of thyratrons which fire between specific amplitudes of vibration. In their arrangement, condensers are alter-

nately charged when a thyratron fires, then discharged through a ballistic galvanometer. The total galvanometer deflection is then a measure of the number of cycles of vibration undergone by the specimen during decay, from which the damping is determined. It is believed that the apparatus described in this paper is simpler to operate and more accurate.

METHOD OF MEASUREMENT

A measurement of internal friction or damping capacity is essentially a measure of the energy dissipated internally within the specimen when mechanical energy is applied externally. If a specimen is set into vibration, several possible quantities may be used to evaluate damping: (a) The decrement of the equivalent circuit formed by incorporating the specimen into an electrical circuit through electromechanical coupling. (b) The power input necessary to maintain a constant vibrational amplitude. (c) The relative width of the amplitude *vs.* frequency curve. (d) The time necessary for the specimen to decay a known fraction of some predetermined amplitude while in free vibration at a resonant frequency.

The first method provides the highest accuracy, but requires relatively elaborate installation of the specimen. The last method named has been chosen as allowing the simplest installation of the specimen and, with the use of a counter chronograph, yielding satisfactory accuracy. In principle, all of the last three measurements can be made with the one method of specimen installation and vibrational drive. However, the measurements of power and of frequency width contain somewhat more uncertainties than that of decay time.

The mechanical arrangement of specimen, drive, and detector units is shown in Fig. 1. The specimen is a bar of uniform cross section, supported by two vertical wires. An alternating voltage is applied to the drive coil, which induces eddy currents in the specimen. A bar magnet, placed along the axis of the specimen and adjacent to it, sets up a magnetic field with radial components in the region affected by the eddy currents. These currents flowing circumferentially interact with the radial magnetic field to produce an axial force on the end of the specimen. The resulting motion is transmitted through the specimen with the frequency of the driving voltage and at the velocity of sound in the material. A similar arrangement of coil and magnet is present at the pick-up end. The vibrations of the specimen in the magnetic field now cause eddy currents to be set up in it, which in turn induce a voltage in the coil surrounding the specimen.

The electronic components of the apparatus are shown schematically in Fig. 2. An alternating signal is produced by the variable oscillator and fed to a power amplifier. The drive coil is placed in the plate circuit of the output tube, a 6F6 power pentode. To measure the frequency, the output of a multivibrator is mixed with the oscillator signal to produce beat notes which can be identified with the aid of a speaker.

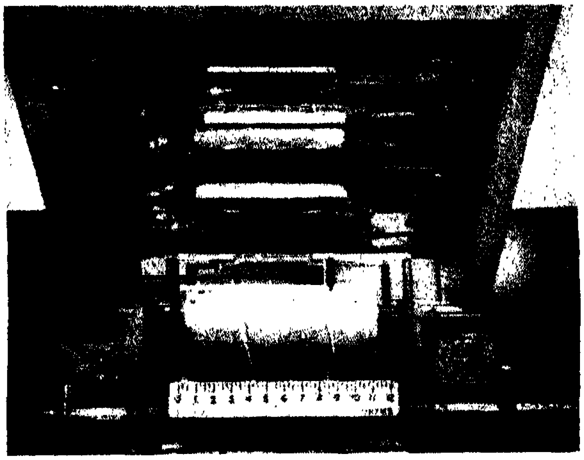

FIG. 3. Photograph of specimen in position; mirror at top gives view looking down on apparatus.

The detector amplifier serves to amplify the pick-up signal and rectify it, giving a d.c. output on the order of 100 to 200 volts. This output is fed to two trigger circuits, each of which is designed to produce a sharp voltage pulse when the d.c. signal from the amplifier drops below some particular value. Both circuits feed into a counter chronograph.

To measure the damping capacity, the driving amplifier is shut off electronically, with a minimum of decay transients, so that the specimen is left in free vibration. As the amplitude of vibration decays, the amplifier output voltage decreases to a value which fires one of the trigger circuits. This "start" circuit feeds into a counter chronograph to initiate the counter. When the vibration decays further, the amplifier output reaches a lower value at which the second trigger circuit has been set to fire. The output of this "stop" circuit operates to stop the counter. The counter thus registers the time interval for the amplifier output to decay between the voltages at which the respective trigger circuits fire. To take into account possible nonlinearities in the amplifier, the values used for computing the damping are obtained by placing known a.c. voltages across the pick-up coil and determining the input voltages which fire the trigger circuits.

The actual operation of the apparatus consists in pressing a button to shut off the driving signal, so that the time interval appears on the counter chronograph. This interval is recorded, a second button pressed to reimpose the driving signal, and a contact on the counter closed to reset that instrument. The cycle of operation can be carried out with manual recording at a rate of about 5 to 10 per minute. Up to 20 readings per minute can be obtained with two operators, or with photographic recording of the time readings and an auxiliary clock.

The damping capacity of the system is related to the measured quantities by the expression:

$$\delta = (\log V_1/V_2)/ft$$

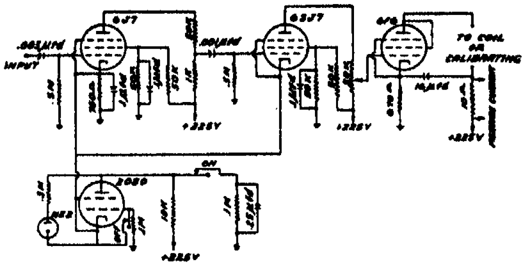

FIG. 4. Circuit of drive amplifier with cut-off.

where δ = damping capacity, V_1 = input voltage to fire "start" circuit, V_2 = input voltage to fire "stop" circuit, f = frequency of vibration, t = time for voltage input to decay from V_1 to V_2.

For most frequencies, the mechanical impedance of the specimen will be so high as to prevent the rod from converting any appreciable fraction of the electrical input energy into mechanical motion. At the natural frequencies of the specimen, however, the mechanical impedance is low and measurable vibrations are induced. Hence, the method described is limited to operate only at a set of discrete frequencies. These frequencies are given by the relation:

$$f_n = nv/l$$

where v = velocity of sound in the specimen, l = length of specimen, $n = 1, 2, 3, \cdots$.

Should measurements be desired at frequencies other than the harmonics corresponding to a particular length of specimen, specimens of different lengths can, of course, be prepared to allow new sets of frequencies.

SPECIMEN ARRANGEMENT AND AUXILIARY COMPONENTS

Figure 3 shows a specimen of 0.220 in. diameter positioned between drive and pick-up units supported in a radiation-type furnace used for tests at elevated temperatures. The mirror allows a top view of the arrangement with the lids removed from the furnace, drive and pick-up units.

The supporting wires are 0.005-in. diameter iron and constantan, respectively. They are utilized as a thermocouple, using the specimen itself as the hot junction. The furnace shown consists of a section of Superex pipe insulation between two aluminum cylinders that were shaped to fit the insulation. About 120° of the cross section was cut out as a lid to be removed for positioning of the specimen. Number 24 (AWG) Nichrome wire wound on lengths of ceramic tubing forms the heating element.

Drive and pick-up coils consist of No. 36 (AWG) wire wound on Lucite forms with $\frac{9}{32}$ in. I.D. Each form is fastened to a bar magnet entering one end of the form. The top view of Fig. 3 shows this connection, but the coils themselves fit into the cylindrical portions of the drive and pick-up boxes in alignment with the specimen and bar magnets. In the pick-up coil, where maximum sensitivity is desired, iron wire is used to increase the radial component of magnetic field in the specimen. Copper wire is used for the drive coil.

The drive and pick-up units, specimen and furnace supports are mounted on brass plate, containing grooves in which the drive unit can slide to allow positioning of the specimen. This plate is mounted on a steel base plate upon which a steel chamber is lowered to permit measurements in a vacuum. All electrical connections are made through spark plugs fitted to the base plate with a close thread. These plugs are covered with specially machined copper shields visible in Fig. 3.

ELECTRONIC COMPONENTS

Oscillator

The driving voltage is supplied by an oscillator with a range of approximately 1 to 100 kc and capable of being tuned to within 0.001 cycle per second. The precision of the setting is limited by a frequency drift of about 0.01 cycle per minute. A method of beat notes is used for frequency determination. The oscillator output is mixed with a standard frequency from a multivibrator, the resulting frequencies then being fed into a speaker. Audible beat notes between the oscillator output and harmonics of the multivibrator can then be identified as kilocycles and fractions of kilocycles.

Drive Amplifier with Cut-Off

The oscillator output of several volts is amplified by the circuit of Fig. 4 to produce about 120 volts across the drive coil, representing a mean power of about six watts. This driving power must be shut off so completely and quickly that no transient decay voltages of the amplifier output can act to drive the specimen while measurements of supposedly free vibrations are under way.

For this purpose, the circuit of Fig. 4 includes an auxiliary 2050 thyratron tube which permits instantaneous cut-off of the output. The "on" and "off" switches shown are merely push buttons, so that both are open in normal use. While the amplifier is in operation, the thyratron is not conducting. The plate is at 225 volts, the grid is at ground potential, and the cathode is tied to the cathodes of the first two tubes (6J7 and 6SJ7) at a few volts above ground, so that the neon lamp in the plate-to-cathode circuit is lit. When the "off" button is momentarily pressed, the grid is shorted to the cathode, and the tube becomes conducting. The plate current thus produced flows through the cathode resistor of 750 ohms in the first two tubes, raising their cathodes by about 16 volts. These tubes are therefore biased well below their cut-off point, and cease to pass any signals. Finally, with the 2050 tube conducting, the small voltage drop between plate and cathode is not enough to keep the neon tube aglow.

The amplifier can be made to function again by pressing the "on" button. This momentarily places the plate of the 2050 tube at ground potential and stops conduction. The current through the cathode resistor is decreased, lowering the cathode potentials on both tubes (6J7 and 6SJ7) and hence elevating the grid bias above the cut-off point. The amplifier is now in normal operation, and the neon lamp in the plate-to-cathode circuit of the 2050 tube is lit due to the rise in plate voltage of that tube.

High Gain Detector Amplifier

The peak signal induced in the pick-up coil is from about fifty to several hundred microvolts. This must be amplified and rectified to a level capable of firing trigger circuits, while keeping the inherent noise level at a negligible fraction of the signal.

The amplifier consists of five stages of amplification, including a tuned plate circuit in the third stage, coupled by an audio transformer to a rectifier-voltage doubler unit. It has a gain of about 7×10^5 d.c. out/a.c. in, and a noise level of about one microvolt. Considerable care in wiring and shielding is necessary to secure a high signal-to-noise ratio. Partitions of copper strip are used to shield the separate stages, while the condensers and coil of the tuned plate circuit are in a separate shielded box. Two power supplies are used, one for the first three stages, a second for the remainder. Both supplies are well regulated, the first having an a.c. ripple of less than 0.001 volt, the second of less than 0.010 volt.

While the tuning is highly effective in reducing the noise level, the quality of the rectified signal is dependent on the choice of *RC* circuit in the cathode circuit of the voltage doubler unit. This rectified signal should provide a smooth envelope through the peaks of the damped sine wave produced by the specimen vibration. If one considers an initial peak voltage V_1 and the succeeding peak voltage V_2, their relation in terms of the damping of the system δ is given by:

$$V_2=V_1e^{-\delta}.$$

Similarly, the voltage on a condenser C discharging through resistance R drops from V_1 to V_2 in time t according to the relation:

$$V_2=V_1e^{-t/RC}.$$

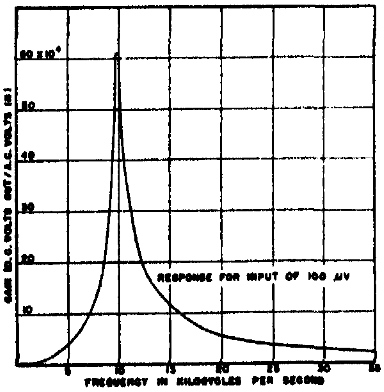

FIG. 5. Frequency response of amplifier for input of 100 μv.

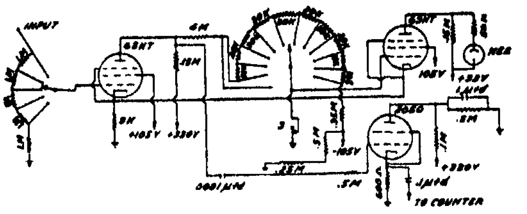

FIG. 6. Trigger circuit used to start and stop counter chronograph.

Hence, the rectified output will reproduce the proper damping characteristics when these two processes are equivalent, or when:

$$\delta=t/RC=1/fRC,$$

where f is the resonant frequency of the specimen. In practice, the condensers of the *RC* circuit are changed when the product $f\delta$ changes by an order of magnitude.

The response of the amplifier when tuned for 9800 cycles per second is shown in Fig. 5. Its gain is reasonably flat from approximately 50 to 350 μv.

Trigger Circuits

When the drive amplifier is shut off, the d.c. output from the detector amplifier decays. It is necessary to obtain a sharp voltage pulse at two values of this decaying voltage to start and stop a counter chronograph. The use of a simple thyratron tube, with grid bias controlled by the d.c. output, was not reproducible to within several percent. A hard vacuum tube trigger circuit, shown in Fig. 6, was therefore designed for this function.

The d.c. voltage from the detector amplifier, or a suitable fraction, is applied to the grid of a 6SH7 pentode. The output of this first tube is coupled through an *RC* circuit to the grid of a 2050 thyratron and, through resistors, to the grid of a second 6SH7 serving as a control tube. Both 6SH7 tubes operate from a common cathode resistor. Before a measurement, the first 6SH7 has a high potential at the grid and is conducting while the 2050 is biased below the firing point. The second 6SH7 has a large negative grid bias and is not passing plate current, hence the neon glow tube in its plate circuit is out.

When the detector amplifier output decays, a value is reached at which the grid of the first 6SH7 drops below the cut-off point. The plate potential suddenly rises to the value of the plate supply, transmitting a positive pulse on the order of 200 volts to the grid of the 2050. This tube now is conducting, its cathode potential rises sharply to several volts, and a pulse of this value is transmitted to the counter chronograph.

The second 6SH7 has its grid raised above the cut-off point by the rise in plate potential of the first tube. It therefore begins to conduct, lighting the neon glow

TABLE I.

Temp.	Av. time ±probable error	Percent probable error
T_1	1.683±0.007	0.4
T_2	1.678±0.020	1.2
T_3	1.204±0.009	0.7
T_4	0.566±0.005	0.9

tube in its plate circuit, raising the cathodes of both 6SH7 tubes above ground. When the signal level on the first 6SH7 grid has been raised by reimposing the driving voltage prior to another measurement, switch *S* is closed. This momentarily grounds the grid of the second 6SH7, stops its conduction, lowers the cathode potentials, and permits the first 6SH7 to conduct. The second grid again becomes negative, and the circuit is set for another operation.

Two trigger circuits are used for starting and stopping the counter chronograph. The output of the detector amplifier is developed across two 100,000-ohm resistors in series, with the "start" trigger circuit actuated by the voltage at the midpoint of this combination and the "stop" trigger circuit operating from the peak voltage across both resistors.

Calibrating Circuit

It is necessary to know the ratio of the input voltages to the detector amplifier corresponding to the decay voltages at which the "start" and "stop" trigger circuits fire. To do this, a calibrating circuit is used which takes the signal from the drive amplifier at the identical frequency used in driving the specimen, and applies a measured voltage in series with the pick-up coil into the detector amplifier.

A switch is used to replace the drive coil in the output plate circuit of the drive amplifier with a resistor. This resistor is coupled through condensers to a microvolter whose output is placed across a 500,000- and 1500-ohm resistor in series. The voltage across the smaller resistor is put in series with the pick-up coil and fed into the detector amplifier. This input voltage is varied by adjusting the microvolter, which can be read to an accuracy of about 0.5 percent.

PERFORMANCE OF EQUIPMENT

Measurements of decay times can be recorded to an accuracy on the order of one percent. A typical series of data that lends itself to statistical analysis can be taken from tests made of the variation of damping with temperature. Ten measurements were recorded at each temperature. The readings of the counter chronograph are summarized in Table I.

As discussed in the section on Method of Measurement, the damping is computed from the log of the ratio of stop and start voltages, the decay time and the resonant frequency. Each stop and start voltage can be read, and is reproducible to, 0.5 percent. Since the logarithm is on the order of unity, the error is less than one percent. The resonant frequency is determined to better than one part in 10^4. The decay times are accurate to about one percent. The total error in the calculated damping is therefore on the order of 1.5 percent.

ACKNOWLEDGMENT

The writer would like to express his sincere appreciation for the initial guidance and suggestions in setting up this work provided by Dr. T. A. Read, School of Mines, Columbia University. Finally, it is desired to thank Mr. Joseph T. Gilbert for his work in wiring and testing the components of the apparatus. His efforts have greatly expedited the program.

Observations on Some Properties of Ultra-High Frequency Gas Discharges*

CHARLES F. ROBINSON†
Norman Bridge Laboratory of Physics, California Institute of Technology, Pasadena, California

(Received March 6, 1950)

A series of experiments designed to yield information on the mechanisms of ultra-high frequency discharges which influence the operation of ion sources employing such discharges is described. The main conclusions are that such discharges exhibit a high negative space charge due principally to secondary emission from the walls of the discharge chamber and that ion production is inhibited by the space-charge trap so formed, that under certain conditions extremely intense electron beams may be obtained from a resonant cavity containing a gas discharge, and that fairly large ion currents may be obtained by the interaction of the emergent gas and the emergent electron beam in the exit orifice of the cavity.

A FREE charged particle having mass m, charge q, placed in an alternating electric field, will exhibit a motion described by

$$z=\frac{qE_0}{m\omega^2}[\sin\theta-\sin(\omega t+\theta)]+\left[\frac{qE_0}{m\omega}\cos\theta+\dot{z}_0\right]t, \quad (1)$$

where the field is given by

$$E=E_0\sin(\omega t+\theta), \quad (2)$$

and $\dot{z}_0$ is the particle's velocity at the instant $t=0$. This is clearly a superposition of two simple motions, the first being a steady drift in the direction parallel to the field, of magnitude

$$V_{\text{drift}}=qE_0\cos\theta/m\omega+\dot{z}_0, \quad (3)$$

and the second being a sinuous motion in synchronism with the field, of amplitude

$$a=qE_0/m\omega^2. \quad (4)$$

In the absence of initial energy ($\dot{z}_0=0$) we have the kinetic energy

$$T=\frac{q^2E_0^2}{2m\omega^2}[\cos\theta-\cos(\omega t+\theta)]^2, \quad (5)$$

which has its maximum value

$$T_{\max}=(q^2E_0^2/2m\omega^2)[1+|\cos\theta|]^2 \quad (6)$$

at the instants given by

$$t=[(n\pi-\theta)/\omega] \quad (n=0, \pm1, \cdots), \quad (7a)$$

$$\cos(\omega t+\theta)\cos\theta>0. \quad (7b)$$

An electron placed in a rarefied gas such that the drift velocity given in (3) vanishes, and exposed to a field such that its amplitude as given in (4) is less than the distance to the nearest wall, may make many oscillations before being collected at one or another surface. In so doing, its probability of ionizing a gas molecule may be much enhanced over that of an electron accelerated by a steady or slowly varying field. Additionally, the presence of m in the denominators of (4) and (6) suggests that ions formed by electrons moving in this way would be relatively very insensitive to such a field so that they might be withdrawn from an enclosure—an ion source—by a comparatively weak steady field. These two facts make it appear that an ion source based on this principle of excitation would operate at lower pressures, and hence at lower gas consumption and pumping load, than conventional sources employing self-sustaining discharges, and that the independence of control over the fields used to form ions and the field used to withdraw them might permit the circumvention of some space-charge effects. It can be anticipated that the superposition of a steady field would inhibit the discharge by imparting appreciable steady velocities to electrons which might otherwise have average velocities of only thermal origin.

The work here to be described was done in an attempt to gain some understanding of the phenomenology of ultra-high frequency discharges in order to permit assessment of the feasibility of constructing practical ion sources based on such discharges.

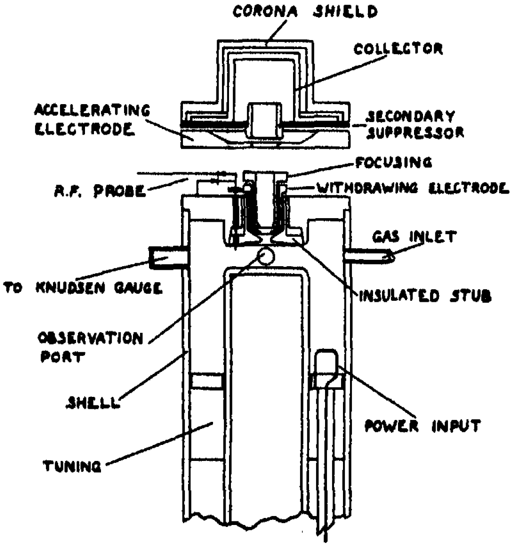

FIG. 1. The basic discharge cavity and ion collector.

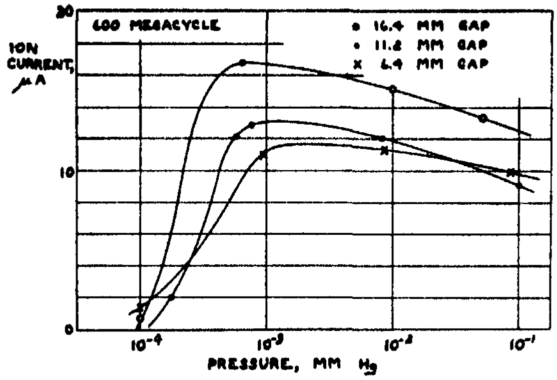

FIG. 2. Ion yields as a function of pressure and gap spacing at 600 Mc.

The theory for such discharges has been developed[1-4] far beyond the derivation given here, but unfortunately under hypotheses on whose validity these results cast grave doubts; these results, far from confirming that secondary emission from the walls of the discharge chamber may be ignored, suggest that secondary electron emission may play a role of governing importance, at least once the discharge has started.

The source of r-f power consisted of a three-stage oscillator-buffer-amplifier system incorporating 2C43, 2C40, and 2C39 high frequency (lighthouse) triode tubes, each one in a conventional double cavity representing the equivalent of a tuned-plate-tuned-grid arrangement. All three stages worked at the same frequency in the range 550 to 900 Mc, coupling was by means of RG8U cables, and impedance matching was obtained by "trombones" of conventional type. Output power delivered to the discharge was estimated at 10 to 20 watts. Although this system worked extremely well it has been rendered obsolete by recently developed CW magnetrons and need not be discussed in detail here.

The basic discharge cavity was of copper-plated steel; it was of the "concentric line" type as shown in Fig. 1, immersed in an evacuated bell jar of essentially conventional construction. Gas was admitted directly to the cavity and pressures were measured by a Knudsen-DuMond gauge connected directly to the cavity. The fixed end stub was insulated from the remainder of the cavity, being pressed into a mica-lined tapered socket. This was done in order to permit the superposition of d.c. and a.c. fields and to permit measurements of d.c. stub currents arising from the discharge.

The central pillar of the cavity could be moved in and out to investigate the effect of changes in gap spacing, and tuning was accomplished from outside the bell jar, without disturbing the vacuum, by means of an O-ring joint. A $\frac{1}{4}$-in. diameter hole, sealed by mica held in place with Scotch Tape, served as an observation port. The bell jar was evacuated by a VMF 100-W oil diffusion pump backed by a Cenco "Megavac" and the pressure in the bell jar was usually in the range $1-5 \times 10^{-5}$ mm Hg. The r-f sensor shown in Fig. 1 was useful principally as an aid to tuning and coupling adjustment in the no-load condition since, with a discharge in the cavity, the probe was shielded by space charge to such an extent as to be essentially useless.

The first stage of the work, done with dry air as the ionized medium, with no magnetic field, and with an all-metal (copper-plated steel) discharge chamber, led to the following conclusions.

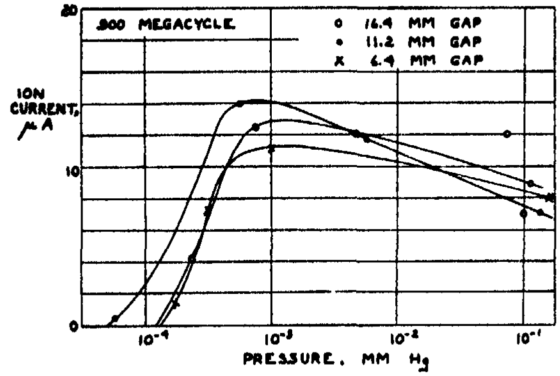

FIG. 3. Ion yields as a function of pressure and gap spacing at 900 Mc.

1. That an ultra-high frequency discharge could be initiated and maintained, in a metal cavity, at pressures ranging from 10^{-4} mm Hg up to several tenths of a millimeter. Only rarely was it possible to initiate the discharge at low pressures; more usually it was necessary to introduce a burst of gas to raise the pressure up to 2 to 3×10^{-3} mm, after which the pressure could be reduced, sometimes as far as 5×10^{-5} mm, and the discharge maintained. It has been mentioned that the electrons which are effective in maintaining the discharge at low pressures are those having very little initial energy; apparently random electrons which have their origin in ionizing events in the laboratory are sufficiently energetic that they are ineffective in initiating a high frequency discharge either directly or through secondary emission at the walls, unless there is sufficient gas in the chamber to provide a mechanism for energy degration. Once the characteristically high frequency (that is to say, low energy) discharge has been started, pressure may be depressed one or two orders of magnitude before the discharge goes out.
2. Neither the ion yields (Figs. 2 and 3) nor the general behavior showed appreciable frequency dependence in the range 600 to 900 Mc, and there was no clear evidence for dependence on gap spacing in the range 6.4 to 16 mm.
3. No ions were ever observed in amounts over 5 μa, and rarely over 1, without an auxiliary withdrawing potential, and the magnitude of the ion currents increased monotonically with withdrawing potential up to some 700 volts (Fig. 4), although electron currents over 100 μa were frequently observed with no steady potentials anywhere, even on the collector.
4. The superposition of a parallel axial steady electric field always depressed the ion yield regardless of polarity, and a steady field strength of 200 to 300 volts per centimeter was sufficient to extinguish the discharge altogether at low pressures.
5. Ion currents to a collecting chamber of conventional type (Fig. 1) tended to be in the range 10 to 20 μa. They showed a

[4] L. M. Hartman, Phys. Rev. 73, 316 (1948).

surprisingly small dependence on the r-f field strength. The excitation of a discharge in the cavity changed the resonant point in a direction corresponding to an inductive load.

6. The initial energies of the ion beam, expressed as volts referred to the source chamber, were as high as 120 volts (Fig. 5). This indicates a high positive space charge in the presence of the withdrawing field and conclusion (3) above indicates an even higher negative space charge in its absence.

7. There is essentially no difference in performance when the working medium is changed from air to hydrogen, which suggests that if space-charge effects are present, they are insensitive to the mass of the ion involved.

At the conclusion of this phase of the work it was felt that the results were being influenced by a space-charge effect whose exact nature was unknown. Accordingly an arrangement was provided to inject electrons into the cavity in order to influence this charge. The result of electron injection, as shown in Fig. 6, was to *reduce* the ion current; this indicates that the net space charge is negative and that ion production is inhibited by the potential "trap" caused by this space charge.

It seemed obvious that such a space-charge trap must have its origin in secondary electron emission at the walls of the cavity; consequently the walls were next coated with Aquadag in an attempt to suppress these secondaries. Two effects were noted as soon as this was done, the first being that there was no important change in ion current[‡] and the second being that the d.c. current to the insulated stub *changed sign* when the tuning plug was moved through the resonant position (Fig. 7), being negative when the cavity was off resonance and positive when the cavity was tuned to resonance, although nothing else in the cavity was affected and no d.c. fields except those due to space charge were present anywhere. A series of observations with various d.c. biasing fields on the insulated stub were next made; these results are also shown in Fig. 7. The fact that this current becomes more positive when the stub bias itself is made more positive, and vice versa, indicates that the "primary" stub current is composed principally of electrons and that the sign of the current is a function largely of the electron energy on impacting the stub, being positive when the impact energy corresponds to a secondary emission coefficient greater than unity and conversely.

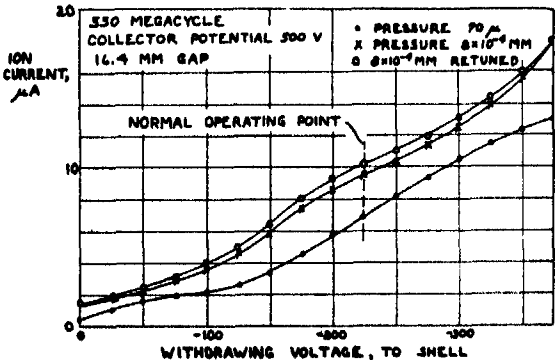

FIG. 4. Collector current as a function of pressure and withdrawing voltage.

The next observations were made with an axial magnetic field in the cavity. These observations showed that at pressures of about 10^{-3} mm and below, a magnetic field of a few tens of gauss would extinguish the discharge altogether; in a few instances such a field would blow the discharge out within the gap but would leave a fringing discharge around the edges of the gap. It was further observed that even magnetic fields not strong enough to extinguish the discharge altogether would impair the ion yield; the degree of impairment depended on pressure and withdrawing voltage, but there was no instance in which the magnetic field increased the ion yield unmistakably and there was always at least one value of the magnetic field whose employment resulted in marked impairment of the ion yield regardless of the withdrawing voltage.

A final measurement in this series was made with an insulated copper sheet on the inner wall of the cavity; the arrangement and the electron current to this sheet, as a function of magnetic field, are shown in Fig. 8.

The explanation of these observations seems to be the following: With no magnetic field in the cavity, secondary electron emission from the walls of the cavity gives rise to an intense negative space charge which traps ions and interferes with their removal. The injection of electrons from below increases the intensity of this space-charge trap and inhibits ion production still further. The stray field from a withdrawing electrode sweeps away some of this space charge and permits the withdrawal of ions in numbers which depend on the magnitude of the withdrawing potential. If the electrons are swept away by a withdrawing field, the positive ions which remain behind by reason of their greater inertia give rise to a positive space charge which may impart anomalous energies to the ions which are removed.

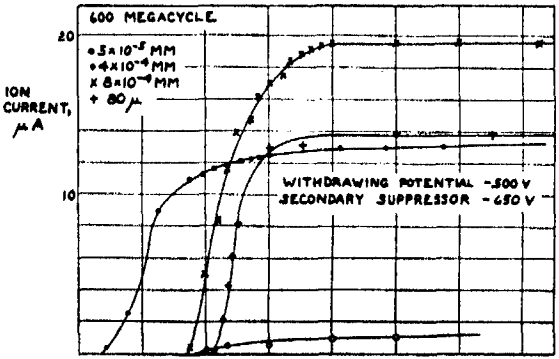

FIG. 5. Collector current as a function of collector potential, showing anomalies in ion energy.

[‡] Data given by Harries (Electronics 17 (2), 100. (1944)) indicate that Aquadag is somewhat overrated as a suppressor of secondary electrons, the secondary emission coefficient being greater than unity through the range of 100 to 500 volts in primary bombarding energy.

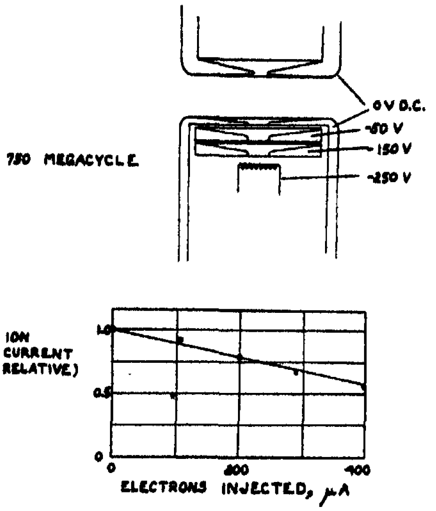

FIG. 6. The depression of ion yield resulting from the injection of electrons into the cavity.

Under a considerable range of conditions the end surfaces of the gap may run at a secondary emission coefficient greater than unity, excess electrons being ejected radially by the space-charge-induced field, collected on the inner radial surfaces of the cavity where the main field is a steady one due to space charge and from where they return to the gap surfaces by conduction through the walls. This phenomenon is at least qualitatively the same whether the gap surfaces are copper, Aquadag, or bare polished steel and there can be little doubt that the emission of secondary electrons is enhanced by the gas present in the cavity.

The imposition of an axial magnetic field inhibits this radial circulation of electrons (Fig. 8) and the resultant space charge increases. At low magnetic fields, the space-charge trap is deepened and ion withdrawal is inhibited, while at higher magnetic fields the space-charge-induced field is strong enough to extinguish the discharge altogether at low pressures, where the discharge is not self-starting. At higher pressures the phenomena are masked by collisions and by the self-starting character of the discharge and the discharge has more of the properties of a low pressure d.c. arc, which is of secondary interest here.

Hall[5] has reported an ultra-high frequency ion source in which ion currents of the order of several hundred microamperes were obtained in a well-focused beam. Inasmuch as such currents are more than an order of magnitude greater than the ones thus far observed here, it was of interest to investigate the behavior of a discharge induced in a Pyrex bottle rather than a metal cavity since this was Hall's arrangement. It was decided to attempt to duplicate Hall's results if possible; several Pyrex bottles of the type described by Hall were obtained[**] and measurements with them begun.

The first measurements indicated that ion current showed the previously observed dependence on withdrawing voltage and that even with a withdrawing voltage of some 700 volts, the ion currents were only about 30 μa. Ion currents showed the previously observed insensitivity to r-f field strength. The intense localized "core" first noted by Hall was observed; the formation of this core *reduced* the ion current by nearly a factor of four. These observations are made with a withdrawing potential of 400 volts (negative, of course, with respect to the body of the cavity). Rapid erosion observed in the Pyrex bottles and occasional sodium color in the discharge made it appear certain that the excitation was as violent as the Pyrex could withstand.

Finally it was observed that in the absence of any steady electrode voltages, electron currents to the collector as high as two or three milliamperes could be obtained; further, by adjusting the obvious parameters to their optimum values, electron currents to the collector as high as 20 to 30 *milliampere* could be obtained; on several occasions, 40 *milliampere* were observed, and on one occasion, 50. This current was enhanced by an axial magnetic field; a plot of current *vs.* magnetic field showed sharp strong maxima, and the current increased monotonically with increasing r-f drive. Under optimum conditions the emergent electron beam formed a well-collimated jet plainly visible in a well-lighted room. It was always necessary to run at high pressure (over 10^{-3} mm Hg) to prevent extinction of the discharge by the magnetic field.

At this time the discharge was being fed gas (hydrogen) produced by an electrolytic generator running at some 200 ma. Visual examination of the Pyrex bottle suggested strongly that electrons were ejected from both ends about equally; taking this into account and making a reasonable allowance for gas leakage within the bell jar, it results that the assumption that the electrons observed came from ionization of the hydrogen requires an over-all conversion efficiency for the process of somewhat more than 100 percent. Consequently it would seem reasonably certain that at least some, and

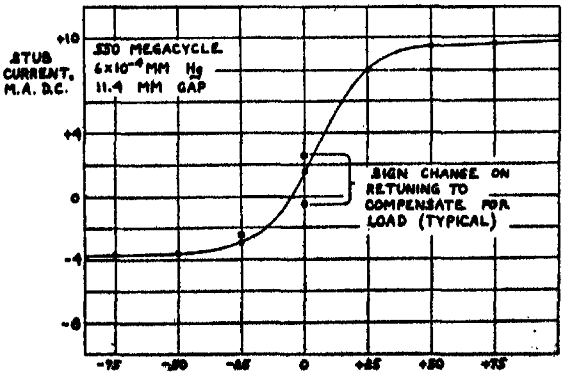

FIG. 7. Stub current as a function of stub voltage, showing stub current to change from negative to positive when the cavity is retuned to match the load introduced by the discharge.

[5] R. N. Hall, Rev. Sci. Inst. 19, 905 (1948).

[**] The first one used, which served as a pattern for the remainder, was furnished by Mr. Holloway of the Kellogg Radiation Laboratory at this Institute.

probably nearly all, of the electron currents observed must have had their origin as secondaries within the cavity.

The exit bore of the Pyrex bottle was approximately 1 mm diameter by 0.8 mm long; using Langmuir's[6] ionization coefficient for 100 volt electrons[††] of 0.038 ion per centimeter per electron and assuming an average pressure in the exit bore of 4×10^{-2} mm (based on pumping speed calculations), one finds ions produced in the exit jet at the rate of some 600 μa per mm of jet length per 40 ma of electron current. This agreement with Hall's work is fully as good as could be expected and these data seem to point inescapably to the conclusion that the ion currents reported by Hall were formed not by high frequency ionization within the cavity but by collisions between the emergent gas and the emergent electron stream in the exit orifice.

High ion currents could not be brought to a satisfactory focus with the voltages and geometry available here; a special collector capable of receiving a considerable portion of a widely divergent ion beam was constructed and ion currents of 350 to 400 μa to it could be obtained provided the withdrawing voltage was made zero or slightly *positive.*

The emergent ion beam was not subjected to mass analysis; however, visual spectroscopic examination showed the Balmer lines to be bright and clear compared to the weak band background, which is in general agreement with Hall's measurement of some 60 percent protons in the beam. The chief function served by the Pyrex bottle would seem to be to ensure that the emergent hydrogen is atomic, having been dissociated in the discharge, rather than molecular in form.

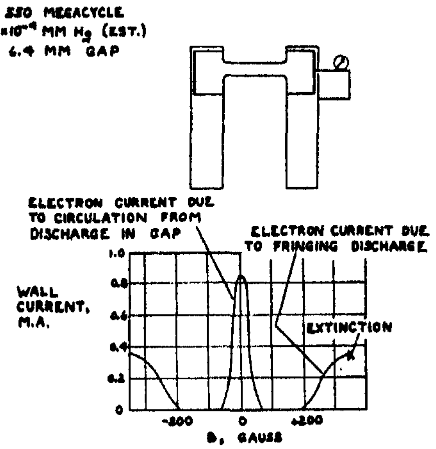

FIG. 8. Showing the circulation of electrons from the discharge to the cavity wall in the absence of an axial magnetic field and the inhibition of circulation by a magnetic field.

CONCLUSION

At frequencies of 500 to 900 Mc and with gap spacings of 7 to 15 mm a self-sustaining discharge can be maintained at pressures well below those where a d.c. or low frequency discharge is no longer possible. Such a discharge is a prolific source of electrons, most of which have their origin as secondary electrons at the faces of the gap. Ions produced in the discharge tend to be trapped by high negative space charge due to these secondary electrons. If a d.c. field sufficient to sweep away these electrons and aid in ion removal is applied, the residual positive space charge may give rise to anomalies in ion energy of several score volts so that such a discharge would appear to have little use as an ion source in applications, such as mass spectrometry, where the ion energy needs to be held to an accurately determinable value. Such a discharge would seem to have interesting possibilities as an ion source in one segment of a sealed-off accelerating column, possibly for work with rare isotopes, since the high frequency discharge would be self-sustaining at pressures below those at which a subsequent series of d.c. accelerating gaps might be expected to break down.

[††] This was approximately the potential to which the electron beam, unaided, would raise the collector and is consequently a rough measure of the electron energy on emergence from the bottle.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 7 JULY, 1950

Microwave Power Stabilizer

IVAN K. MUNSON
National Bureau of Standards, Washington, D. C.

(Received March 20, 1950)

An apparatus for the power stabilization of medium-level microwave power sources, intended for laboratory use, by means of a degenerative feed-back network connected in tandem with the power source is described. An analysis of the operation of the network is presented, based on obtaining optimum stabilizing action and optimum transmission efficiency for the network. Design of an electrically-operated attenuator (which is a servo device), and its effect on the stabilization characteristics of the network are discussed. A transmission efficiency of 70 percent and a stabilization factor of 21 were obtained in an experimental model.

UNMODULATED microwave power in excess of a few milliwatts for laboratory use is usually obtained from reflex klystron oscillators. The power stability of klystrons is adversely affected by ambient temperature variations, electrode voltage changes (such as may be encountered in an automatic frequency control), and mechanical disturbances. In some cases, these variations can be minimized. However, an oscillator sufficiently isolated for stabilization purposes is not a very useful device. The use of a feed-back network, described in this paper, inserted between the power source and the r.f. load is in general a practical solution of the problem. The network described has a transmission efficiency of 70 percent and a stabilization factor of 21.

THE NETWORK

A block diagram of the network is presented in Fig. 1. A small amount of the output power is fed to a crystal rectifier by means of a directional coupler. The output voltage of the crystal rectifier is compared with a reference voltage and the difference is applied to a d.c. amplifier. The output of the amplifier is coupled to an electrically-operated attenuator thereby completing the feed-back loop.

ANALYSIS

The crystal detector is assumed to be a square law device for small input power. The network equations are then,

$$P_2=(\alpha+mV_2)P_1, \tag{1}$$

$$P_3=(1-R)P_2,\quad 0<R<1, \tag{2}$$

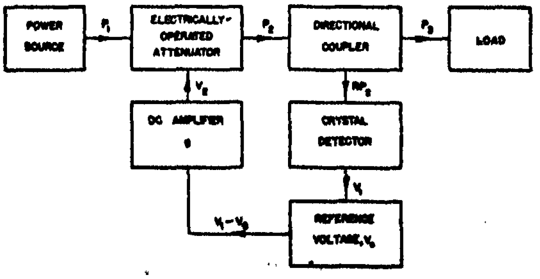

FIG. 1. Block diagram of the stabilization network.

$$V_2=g(V_1-V_0),\qquad g>1, \tag{3}$$

$$V_1=kRP_2,\qquad k>0. \tag{4}$$

The powers P_1, P_2, and P_3 and the voltages V_1 and V_2 are identified in Fig. 1. The coefficients α and m describe the electrically-operated attenuator, α being the attenuation when V_2 is zero and m the derivative of the attenuation with respect to V_2. The sign of m may be reversed by reversing the connections to the attenuator. The amplifier gain is g and the ratio of the power diverted out of the side arm of the directional coupler to the input power P_2 is given by R. The crystal characteristic is k and is defined by Eq. (4).

P_2, the output power of the electrically-operated attenuator may be obtained by the substitution of Eqs. (3) and (4) into Eq. (1) and is found to be,

$$P_2=\frac{(\alpha-mgV_0)P_1}{1-mgkRP_1}. \tag{5}$$

The useful output power, P_3, obtained from Eqs. (2) and (5), may be written,

$$P_3=(1-R)\alpha[(1-(mg/\alpha)V_0)/1-mgkRP_1]P_1. \tag{6}$$

P_3 must, of course, always be positive. R is positive and less than one. Hence, the quantity in the brackets must always be positive.

In practice, the reference voltage, V_0, is adjusted so that V_2 is zero when P_3 has the desired value, $P_3{}^0$. Then $V_0=kRP_2$ and Eq. (6) can be rewritten,

$$P_3{}^0=(1-R)\alpha P_1{}^0. \tag{7}$$

Most laboratory power sources operating in the microwave region provide relatively little power output and it is therefore essential that auxiliary apparatus operate as efficiently as possible. We may express the efficiency of the network as simply:

$$\eta=P_3{}^0/P_1{}^0=(1-R)\alpha. \tag{8}$$

We may also define a stabilization factor as the inverse of the slope of the response curve, evaluated for the selected output power, P_3^0.

$$S=\frac{1}{([dP_3]/[dP_1])_0}=\frac{1-mkgRP_1^0}{(1-R)\alpha}. \tag{9}$$

From Eqs. (8) and (9), we obtain a relation between efficiency and stabilization factor.

$$S/\eta=1-mgkRP_1. \tag{10}$$

It is seen that a value of $(-mgkRP_1)\gg 1$ is necessary for good stability and efficiency. For a given P_1 and a given network, however, it is seen that stability can be increased only at the expense of efficiency. Thus, for a given network and input power, the stability obtainable is dependent upon the output power required.

MODEL DEVELOPED

The design of the apparatus described in this paper was based on a desired transmission efficiency of 70 percent. An *mgkR* product of 50 was estimated for the components used. The calculated stabilization factor was 16 for an input power of 200 mw.

The components comprising the microwave transmission path are shown in Fig. 2.

The electrically operated attenuator is designated *A* in the figure. A directional coupler is shown at *B*, whereby a small amount of the output power is coupled to the crystal rectifier *C*. The amplifier used was a commercial d.c. amplifier[1] having suitable gain and frequency response.

The electrically operated attenuator provides an attenuation of microwave power controlled by an applied d.c. voltage. A commercial D'Arsonval system[2] is used to obtain angular axis displacement proportional to applied voltage. A mica vane is mounted on the system shaft as illustrated in Fig. 3. The mica vane is coated with graphite as indicated by the shaded areas so that angular displacement of the vane about the system axis changes the attenuation of the microwave power. In order to minimize frequency pulling of the power source caused by changes in its load impedance resulting from rotation of the attenuator vane, the vane was made an odd number of guide quarter-wave-lengths long and electrically symmetrical about its axis of rotation. The axis was centrally located with respect to the wave guide. The input voltage standing wave ratio for this arrangement was less than 1.1 to 1 at 9300 Mc, and was nearly independent of the angular position of the vane. This mechanism can be developed for any microwave frequency and any waveguide size.

[1] The "Microsen D-C Amplifier," manufactured by Manning, Maxwell, and Moore, Inc., Bridgeport, Connecticut, was considered suitable for this application.

[2] A Brush Magnetic Recording Penmotor, manufactured by the Brush Development Company, Cleveland, Ohio, was found suitable for this application.

descriptive of the dynamic properties of the D'Arsonval system which is a form of servo mechanism. The attenuation-phase relationships for servo transfer functions is discussed in the literature.[3] A sufficient condition for stability of the feed-back system, derived from the Nyquist criterion,[4] is that the gain of the feed-back loop be less than unity for all frequencies for which the phase angle of the transfer coefficient of the feed-back loop is between $(n\pi)/2$ and $(3n\pi)/2$, where n is any integer. It was found experimentally that the phase angle of the transfer coefficient of the D'Arsonval system alone exceeded $\pi/2$ at 25 c.p.s. In order to satisfy the sufficient condition for stability, an amplifier was selected which had a very large voltage gain in the frequency range from zero to 3 c.p.s. and essentially zero gain at all frequencies above 5 c.p.s. Hence, the stabilization factor will have its maximum value in the frequency range of zero to 3 c.p.s. and be very small at higher frequencies.

MEASURED STABILIZATION CHARACTERISTICS

The power input to the network was increased 100 percent in discrete steps and the power output was measured at each step. The results are shown in Fig. 4 and represent the response of the network to variations of zero frequency. The dashed line represents the response of the network with the feed-back loop open. The (Power) stabilization factor at zero frequency for this network is 21, determined from the initial slope of the network response curve.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 7 JULY, 1950

A Recording Fluxmeter of High Accuracy and Sensitivity

P. P. Cioffi
Bell Telephone Laboratories, Inc., Murray Hill, New Jersey

(Received March 6, 1950)

A recording fluxmeter has been developed which employs one or two integrators and a double element L and N Speedomax recorder for tracing magnetization curves directly on standard coordinate paper. The response of the recorder pen drive mechanism is proportional to the flux density, B, and is controlled by the B integrator. The response of the paper drive mechanism is proportional to the magnetizing force, H, and is controlled either by the magnetizing current, when the specimen is in the form of a ring, or by the H integrator when the specimen is in the form of a bar. Ayrton shunt networks provide flexible B and H scale adjustments. High accuracy and sensitivity are obtained by minimizing the causes of drift. At maximum sensitivity, four interlinkages give a deflection of one mm.

INTRODUCTION

FOR many years the ballistic galvanometer has been widely employed for obtaining magnetization curves and hysteresis loops of magnetic materials. The method is reliable, but, because it is slow and laborious, a number of investigators have devised hysteresigraphs for facilitating magnetic measurements.[1] Such instruments have been operated either by slowly changing d.c. magnetization or by a.c. magnetization. The d.c. hysteresigraph[2] generally employs a galvanometer or fluxmeter for the integrating element and inaccuracies result because of uncontrolled galvanometer drift. The a.c.[3] method can only be applied for measurements on thin or laminated materials because of eddy current shielding. With such instruments the curves have been traced directly on photographic paper by a reflected beam of light or have been presented on a cathode-ray tube and subsequently photographed. Such hysteresigraphs, however, are not sufficiently convenient in routine measurements because of the delay in obtaining the photographic record and the necessity of scaling the coordinates of points on the curves to obtain numerical results. Also, depending upon the method of integration, the results may be of questionable accuracy. For these reasons the ballistic method is still the most generally applied method in precise magnetic measurements.

In considering the design of a recording fluxmeter of greater flexibility and accuracy, the objective was to obtain an ink trace of the curves directly on standard coordinate paper and to provide means for readily adjusting the scale of the curves to the paper. In this manner a direct reading scale could be provided and the results could be read from the curves directly after tracing. The attainment of these objectives was dependent upon the availability of a suitable integrating and recording system. The Edgar photoelectric fluxmeter[4] suggested an integrator which could be adapted to a commercial recorder such as the Leeds & Northrup Speedomax.[5] This paper describes the application of these devices in a recording fluxmeter characterized by high accuracy, sensitivity and flexibility of scale adjustment.

PRINCIPLE OF OPERATION

To obtain the magnetization curve and hysteresis loop of a ring specimen with this fluxmeter, the specimen is uniformly wound with two coils. The primary winding is used for producing the magnetizing force by energizing it by a direct current which can be changed continuously, by means of a slidewire potentiometer. The magnetizing force, H, for such a specimen is proportional to the magnetizing current. The secondary winding is connected to the integrating element of the fluxmeter which converts the change in flux interlinking the search coil to a change in current proportional to the flux density, B, in the specimen in a manner which will be described later. The two currents, one proportional to B and the other proportional to H, are passed through two separate networks which respectively adjust the scale of the two independent mechanisms of a double element Leeds & Northrup Speedomax recorder. One of these mechanisms, the B element, drives the pen proportionally to B, while the second mechanism, the H element, drives the paper drum proportionally to H. By continuously increasing the magnetizing current from zero to a positive value followed by a cyclic reversal of the same value, the pen and paper drum of the recorder are simultaneously driven proportionally respectively to B and H in the specimen and the magnetization curve and hysteresis loop are traced. If, while tracing a curve, retrogressions of the magnetizing current are made, minor loops are obtained at any desired position, as shown in Fig. 1.

---

[5] A. J. Williams, Jr., Trans. AIEE 57, 565 (1938).

For tracing the magnetization curve and hysteresis loops of samples in the form of straight bars, the magnetizing force is supplied by a solenoidal field or the field between the poles of an electromagnet. Since in this case the field in the specimen is not strictly proportional to magnetizing current, the field must be measured independently. This is accomplished by means of a Chattock magnetic potentiometer coil[6, 7] whose ends span the *B* search coil and are in contact with the specimen, as shown in Fig. 2. This potentiometer is connected to a second fluxmeter (*H* integrator) which, like the *B* integrator, converts changes in *H* in the specimen to a current proportional to it. This current is now passed through the *H* control network to drive the paper drum of the recorder. By a slow cyclic change of the magnetizing current the magnetization curve and hysteresis loop may be drawn as simply and accurately as for a toroidal specimen. An example of such a curve for a straight bar is shown in Fig. 3.

Because of the infinite time constant of the integrators, the rate of tracing the magnetization curves and hysteresis loops can be varied from approximately one-quarter minute to 5 minutes or longer, depending upon the specimen. For specimens of high permeability, having loops with steep sides, the eddy currents set up in the specimens cause the flux to lag behind the magnetizing force if its rate of change is too rapid. For this reason, the rate of change of magnetization is always kept slow enough to insure that the motion of the pen is in step with the motion of the chart.

The integrating circuit resembles the familiar ballistic galvanometer circuit in which the search coil is connected in series with a galvanometer and the secondary of a mutual inductance coil. Unlike the ballistic method, however, Edgar showed that the galvanometer can be used approximately as a null instrument by opposing the search coil interlinkages by equal interlinkages from the mutual inductance secondary coil. This is accomplished by splitting the light beam from the galvanometer between two photo-cells connected in a bridge circuit and applying the voltage unbalance, resulting from the change in light distribution as the galvanometer tends to deflect, to the grid of a vacuum tube in the primary circuit of the mutual inductance. The change in primary current so obtained is a measure of the change in search coil interlinkages, which is used to drive the *B* element of the recorder.

The *B* and *H* integrators are housed in individual cabinets approximately 30 in. wide by 18 in. deep and 72 in. high, provided with relay rack mountings for the various control panels. The power supplies are in a standard relay rack size cabinet. The double element recorder and its amplifier circuits are mounted on a separate frame. Since the *B* and *H* integrating circuits

are identical, only the *B* integrator, together with the magnetizing circuit, is shown in the diagram of Fig. 4. When bar samples are tested the *H* integrator is connected to the *H* control network of the recorder in place of the magnetizing circuit.

POSSIBLE CAUSES OF ERROR

The fluxmeter is capable of high accuracy, stability and sensitivity. Its successful operation is due to the painstaking care in all details of its design and construction in order to eliminate or compensate drift over the entire scale. Drift of the mutual inductance current, arising from uncontrolled drift of the galvanometer, could result in large errors. In order to maintain a high over-all accuracy the objective was to limit errors due to drift to the order of 0.1 percent in a period of approximately 5 minutes—usually longer than is required to trace a hysteresis loop.

The principal causes of galvanometer drift are as follows: (a) Thermal e.m.f.'s arising in the galvanometer circuit. (b) Mechanical instability due to vibrations. (c) The restoring torque of the galvanometer suspension resulting from the small displacement necessary to initiate and maintain the current change in the mutual inductance. (d) Leakage currents into the galvanometer circuit from the neighboring higher potential circuits.

The method of correcting drift to achieve the required degree of stability is described in the following section.

Other sources of error are in the calibration of the mutual inductance coil and in the recorder and its input control networks.

STABILITY OF THE GALVANOMETER CIRCUIT

The galvanometer or secondary circuit of the integrating system consists of the galvanometer, the search coil, the mutual inductance secondary and a galvanometer control circuit. The procedure in setting up this circuit to prevent instability from thermal e.m.f.'s, was to reduce the number of circuit junctions wherever possible and to prevent significant temperature gradients in the junctions between the various circuit elements which could not be avoided. This is accomplished by providing isothermal enclosures for parts of the circuit where thermal e.m.f.'s are likely to arise.

The galvanometer control circuit is a bridge for balancing out galvanometer drift due to any residual thermal e.m.f. It is also used for the initial adjustment of the primary current of the mutual inductance coil by momentarily unbalancing the circuit in the appropriate direction by the scale shift switches shown in the circuit diagram.

The arrangement of the optical system is shown in Fig. 5. It consists of a lamp, a concave galvanometer mirror, a right angle prism and photo-cells. The mirror and prism are front coated with an evaporated aluminum film. Light from the lamp illuminates a slit in front of the galvanometer mirror which reflects the light beam to the prism. The prism edge between the right angle faces splits the light beam and each part is reflected by a prism face onto the cathode of a photo-cell located at each side of the prism.

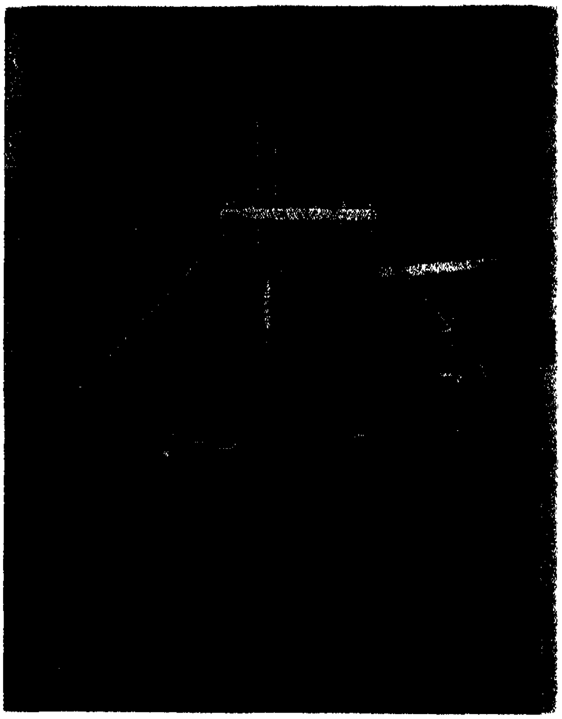

FIG. 5. The optical system of the recording fluxmeter.

The lamp, galvanometer and prism and photo-cell assembly are mounted on a brass plate. Optical bench parts permit easy adjustment and focusing of the optical system. The vacuum tubes for supplying the mutual inductance primary current are also mounted on this plate to permit direct connections between them and the photo-cells.

Mechanical stability of the galvanometer and its optical system is achieved by means of a suspension hung from the cabinet housing. It consists of a damped spring connected through a fine piano wire link, to one point of a framework attached to an extending above the plate. This link assures that the plate remains permanently level. The incoming leads are supported from a terminal block fastened to a second link also attached to the spring suspension. A corresponding terminal block attached to the plate directly below is connected to the circuit elements on the plate and the two blocks are interconnected through flexible coils of fine wire.

Provision is made to anchor the table rigidly so as to avoid setting the system into vibration whenever zero adjustments of the galvanometer are required. This is accomplished by an elevator platform, directly below, which picks up the plate on three adjustable screw supports without change of plate level. The elevator platform is attached to the shaft of a piston which is pneumatically operated. The operation is smooth and gentle and no perceptible disturbance is imparted to the suspension system when it disengages from the plate. Any residual motion is damped out magnetically by means of a copper disk attached at each end of the plate, free to move in the air-gap field of a strong permanent magnet.

Because of the small, but definite, galvanometer deflection necessary for a given mutual inductance current, a slow downward drift will result unless the restoring torque of the galvanometer coil suspension is balanced out. Suitable compensation is provided by an adjustable voltage tapped from the mutual inductance circuit and applied across the resistance in the galvanometer circuit.

THE RECORDER AND AYRTON SHUNT CONTROLLER

The two element Speedomax recorder was specially built by Leeds and Northrup for this application. The units are essentially high speed, self-balancing slide wire potentiometers for measuring unknown voltages. Compensation of slide wire wear is made by an adjustment of the slide wire current. The potentiometer slide wires of the two units are similar and the potential drop is 0.4 millivolt per half-inch or main division, δ, of the coordinate scale.

The networks for adjusting the B and H scales are Ayrton shunts, also supplied by L and N and are shown schematically in Fig. 4. The input side R_B of one network is connected in series with the mutual inductance of the B integrator and the input side R_H of the other is connected in series with the magnetizing coil or the mutual inductance of the H integrator as the case may be. The recorder elements are connected across the 16-ohm output resistances of the shunt arms in series with an adjustable voltage from a battery source to permit scale shifting for locating the curve with respect to the chosen origin on the paper. The corresponding decade resistances in R_B and R_1 and in R_H and R_1' are double decked and connected so that the sum of R_B and R_1 and the sum of R_H and R_1' remain unchanged for all settings. The recorder elements thus operate from a substantially constant input resistance. From the circuit constants, the product of the mutual inductance current I_B and the Ayrton shunt resistance setting R_B is given by

$$I_B R_B = 0.1\delta_B \text{ volt} = E_B. \tag{1}$$

If I_B is the change in primary current of the mutual inductance M caused by a change in interlinkages in a search coil of n turns around a specimen of sectional area A cm^2, the flux density in the specimen is given by

$$B = (M10^8/nA)(E_B/R_B). \tag{2}$$

From Eq. (2) R_H is determined for any scale of B chosen with respect to E_B. Similarly the magnetizing force for a toroidal specimen is given by

$$H = (4N/10D_m)(E_H/R_H), \tag{3}$$

where N is the number of turns of the magnetizing winding and D_m is the mean diameter of the specimen. The resistance setting R_H for the required H scale can be determined from this relationship.

When the magnetic field in a bar sample is measured with the H integrator and a Chattock potentiometer coil, the scale setting is also readily determined and depends upon whether the nA or MMF constant of the potentiometer is given.

The intrinsic magnetization curve, $(B-H)$ *vs.* H, may be obtained by subtracting a voltage E_H'' from E_B' by a predetermined setting of R_4' in terms of known constants.

Any part of the magnetization curve or hysteresis loop may be magnified by appropriate scale expansions.

ACCURACY AND SENSITIVITY

The accuracy is dependent upon the mutual inductance and upon the recorder and its associated Ayrton shunt controllers. The accuracy of the mutual inductance is estimated to be 0.25 percent and the accuracy of the recorder and controller is given as 0.25 percent, giving an over-all accuracy of 0.5 percent. Actually the accuracy is found to be somewhat better than this estimate.

At maximum sensitivity, only 4 interlinkages are required for a deflection of one mm. This is to be compared with sensitivities of ordinary ballistic galvanometers requiring 100 to 500 interlinkages for a mm deflection.

The accuracy and sensitivity are independent of the galvanometer circuit resistance.

CONCLUSIONS

The recording fluxmeter described is an exceptionally sensitive and flexible instrument. It has been very valuable in extensive investigations of magnetic materials. Its maximum sensitivity is many times greater than that of the conventional ballistic galvanometer. The B and H scales can be adjusted for a wide range of sensitivity and constants of the specimen. The calibration is provided simply by the scale settings which are determined in advance from known constants. Magnetization curves and major and minor hysteresis loops of ring and bar samples can be traced in a few minutes compared to the several hours required by the ballistic method.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 7 JULY, 1950

Simple Variable Space Infra-Red Absorption Cell

JOHN U. WHITE*
The Perkin-Elmer Corporation, Glenbrook, Connecticut

(Received March 8, 1950)

A variable space liquid absorption cell is described for use in the infra-red spectral region. Its range of thicknesses from 5 mm to less than 10 μ makes it suitable for the compensation of absorption by solvents in a double beam spectrophotometer; its accuracy and reproducibility are sufficient for most direct qualitative and quantitative measurements. The minimum volume is approximately one cc, and the leakage is negligible. Its windows of rocksalt may easily be removed and repolished.

VARIABLE thickness liquid absorption cells have been available for use in the visible and ultraviolet parts of the spectrum for many years.[1] More recently descriptions of cells suitable for use in the infra-red have been published by Barr,[2] Smith,[3] and Gordon.[4] Each of these has many good features but none is satisfactory for the present purpose. For use with the Perkin-Elmer Model 12[5] and Model 21[6-8] Infra-Red Spectrometers, the following features were considered important:

(1) angular aperture of f-4 and useful area $\frac{3}{4}$ in. in diameter,
(2) range up to 5 mm,
(3) accuracy of thickness setting within a few μ,
(4) leak-proof for volatile liquids,
(5) windows that are easily removed and repolished,
(6) ruggedness and convenience of use.

The cell described by Gordon and Powell would be satisfactory except for the fragility of the fine thread and the limited range imposed by the flexible diaphragm method of sealing it. The present cell is to a large extent a modification of theirs with the substitution of a double nut employing coarser differential threads and a long cylinder and piston for the liquid seal. It is readily demountable with a design that requires only one flat surface on each window with no precise orientation between it and the other surfaces.

The cell is illustrated schematically in Fig. 1. It has a useful window area three-quarters of an inch in diameter with a clear aperture over this area of f-4. It is 4.88 in. long and 3.25 in. in diameter, excluding the filling needles, *F*. It employs a close fitting cylinder, *C*, and piston, *P*, to keep the windows, *W*, parallel to each other and to minimize leakage between the moving parts. Motion is controlled by the differential nut, *N*, on the two threads, *TC*, and *TF*, with the large compression spring, *S*, to press the windows toward each other and remove backlash. Thread pitches of 1 and 0.8 mm give a differential piston advance of 0.2 mm for every turn of the nut. The precision cylinders and the threads are completely enclosed to protect them from damage. Molycote* is used as a lubricant.

Of the maximum possible separation of 7 millimeters, 5 are calibrated for use. Two additional millimeters are for overrun and for take-up for gradual changes due to repolishing the inner window. The scale may be read to 1μ using millimeter and hundredth millimeter calibrations on the nut, and tenth millimeter and μ-index lines on the outside of the case. To adjust the scale zero, the index lines may be moved until the scale reading agrees with the cell thickness at some measured setting. The small piece with the tenth millimeter index lines may be moved by loosening two screws. To move the μ-index lines the outer case must be loosened and turned. These scales are illustrated in the photograph shown in Fig. 2, where the separation is set to 0.245μ.

The windows are rocksalt, 70×10 mm and 36×8 mm. The large one is held against the ground flat seat, *FS*, on the end of the cylinder by pressure screws on a steel ring. As it is seated on the side facing the inner window, this side must be flat, but there is no

[*] Molycote is the trade name for a molybdenum sulfide dry lubricant manufactured by The Alpha Corporation, Greenwich, Connecticut.

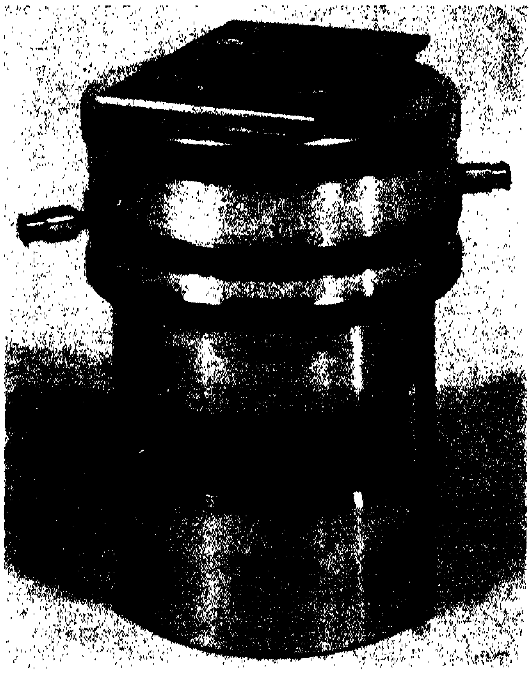

FIG. 2. Photograph of variable space liquid cell.

strict requirement on the flatness of the other side or the parallelism of the two. The small window has a spherical bevel and is held in a mating spherical seat, *SS*, in the piston. Its orientation is adjustable by changing the pressure on its retaining screws, *A*. By loosening one and tightening another, it can be slid slightly in its seat until the visible interference fringes observed under a mercury arc indicate it to be parallel to the outer windows. The windows are enclosed except for the area actually used.

The cell is filled by inserting a hypodermic syringe into one of the needles pressed into the cylinder. It has a minimum volume of about one to two cc in the closed position, depending on how far the small window protrudes through the end of the piston. The windows appear to make tight joints with their lapped seats, and losses of samples along the ground cylinders are small. In tests with the cell filled with carbon disulfide the miniscus had not appeared in the window area after four hours.

The differential thread and double nut were used to make the scale easier to read and to avoid relative rotation between the inner and outer cylinders. If the cylinders were permitted to rotate as they would with a single thread drive, the cell could only be closed if both windows were exactly square on the axis, and any contact between them would result in twisting scratches. The method of mounting salt plates with retaining rings and push screws has been found best to avoid the twisting and scratching that results when a threaded retaining ring is screwed directly against the window.

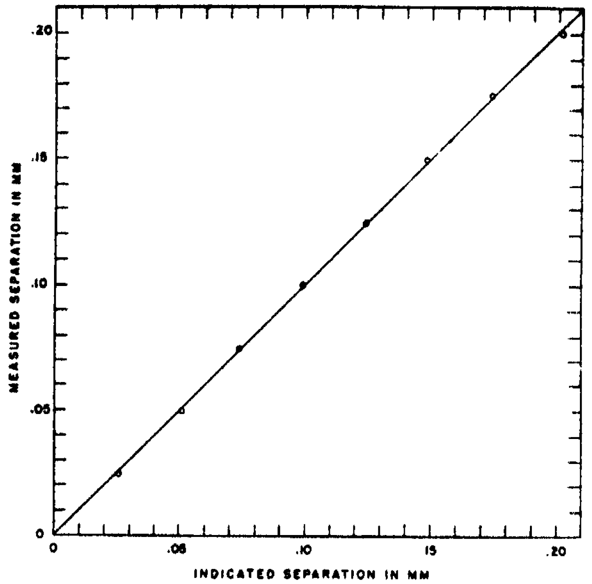

FIG. 3. Calibration curve of variable space liquid cell. An index correction of 0.005 mm has been applied.

The adjustment for parallelism proved adequate during preliminary experiments with an annular ring of rocksalt on the end of the outer cylinder as a seat for the large window. The ring was polished simultaneously with the inner window to make them both parallel and coplanar.

In testing the cell visible and infra-red interference fringes were used. Observation of the reflected fringes in mercury green light indicated that the two windows remained parallel within about two wave-lengths as their separation was changed. The reproducibility of setting over short times was tested by measuring the separation for five repeat settings to the same scale reading from the same direction. The mean departure from the mean was 1.0μ, with a maximum departure of 1.6μ. The difference between the mean separations at the same setting approached from opposite directions was 6.4μ. Over long times the scale must be readjusted to take account of changes in the rocksalt windows. The accuracy of the scale is shown in Fig. 3, where the measured distance between the windows is plotted against scale reading. The calibration is essentially a straight line with a sinusoidal variation of approximately one μ superimposed on it. This performance indicates that the cell is accurate enough for most qualitative and quantitative analyses at thicknesses greater than 0.1 mm. The adjustment is smooth enough to permit accurate compensation for the absorption bands of the solvent in a solution by successive trial and error settings until the bands are eliminated from the record. Approximate compensation is obtainable directly by setting the cell to the thickness calculated to be equivalent to the solvent content of the sample.

Duration of Scintillations from Organic Phosphors

J. O. ELLIOT, S. H. LIEBSON, R. D. MYERS, AND C. F. RAVILIOUS
Electricity Division, Naval Research Laboratory, Washington, D. C.

(Received January 25, 1950)

Measurements have been made on the time of decay of scintillations from organic phosphors irradiated with gamma-rays. Interference between the output pulse from a photo-multiplier and its reflection from a shorted line is used to determine the time constants.

SEVERAL authors[1–4] have reported measurements of the duration of light flashes from organic phosphors when excited by gamma-radiation. In each case a photo-multiplier tube was used as a detector of the light flash and its output pulses were fed either directly to oscilloscopes or through fast amplifiers and then to oscilloscopes. The pulse time was determined from the oscilloscope tracing.

The present investigation employed a shorted line technique to measure pulse decay times. The output of a 931-*A* photo-multiplier was fed into an *RG8U* coaxial cable, with a short-circuited variable length side arm, as shown in Fig. 1; the resultant of each original pulse and its out-of-phase reflection from the shorted line was rectified by a germanium crystal and was fed to a preamplifier, amplifier, and ten-channel discriminator and scaler. Curves of counting rate *vs.* length of shorted cable for a given pulse height setting of the discriminator were taken. These curves should exhibit a steady counting rate for long lines and should show a decreasing counting rate for lines of length less than the critical length corresponding to the beginning of interference between a pulse and its out-of-phase reflection.

Germanium crystals were selected by oscilloscopically observing their rectification properties for pulses using a long length side arm with first an open-circuit termination and then a short-circuit termination. All the diodes tested exhibited similar rectification characteristics. The error introduced by imperfect rectification is well within the the range of the experimental error.

Reflections from the germanium crystal were minimized by keeping the length of line between the crystal and the shorted line junction as small as possible. The load output of the photo-multiplier and the cathode follower input were resistances equal to the characteristic impedance of the lines, so that no reflections occurred at these points.

Oscilloscopic observations[2] have shown the scintillation pulses of organic phosphors to have exponential decays. Due to statistical fluctuations, individual pulses will deviate from the simple exponential shape; however, since the method presented here is a statistical method in principle, the pulse may be assumed to be exponential in character, as shown in Fig. 2. If the amplifier and scaler are peak voltage operated, no change in counting rate for a given discriminator setting should be expected until the reflected pulse detracts from the peak of the original pulse. However, if the time constant of the amplifier is much longer than the width of the input pulses, an integrating effect is obtained and the triggering of the scaler is dependent on the area under the pulse. With such a time constant, no change in count rate should be observed until the reflected pulse starts to overlap the photo-multiplier output pulse.

Since the shape of the output pulse of the photo-multiplier is assumed to be of the form $e^{-t/\tau}$, the over-all

response of the system will be of the form $e^{-nt/\tau}$, where n is a constant describing the non-linearity of the entire rectification and amplification system. A measurement of n over the desired pulse duration range (10^{-9} to 10^{-7} sec.) proved to be quite difficult. A pulse source with accompanying attenuator was substituted for the photo-multiplier in Fig. 1, and n was obtained by measuring the voltage ratio produced at the amplifier output by a known voltage ratio from the pulse source. This pulse source showed n to be a constant for 2.5×10^{-8} sec. pulses and for 2.5×10^{-7} sec. pulses. A reliable determination of n for 10^{-9} sec. pulses was impossible due to the unavailability of such a pulse source. A further check on the accuracy of the determination of n was made by Dr. R. C. Waddel of this Laboratory, who measured the decay constants for the same phosphor samples used in this experiment by oscillographic techniques and whose results agree with the ones presented here within the error indicated in Table II. Dr. Waddel undertook a further verification of n at higher frequencies by measuring twice the mean deviation for the dark noise pulses of a photo-multiplier and obtained 4.5×10^{-9} sec. which agrees fairly well with the value presented below considering the assumptions, as stated below, that must be made to obtain a value for dark noise pulses with the shorted-line apparatus. Subsequent calibrations for different diodes were made by finding the value of n required to obtain the same values for the decay constants of the standard anthracene and stilbene crystals as those presented here.

TABLE II. Decay constants in seconds.

Author	Phosphor Anthracene (%)		Stilbene (%)	
NRL	3.4×10^{-8} sec.	±10	1.3×10^{-8} sec.	±20
Bell[3] and Kelley[2]	3.5	±10	1.0	±20
Hofstadter[1]	3.0	±30	1.5	±30

Referring to Fig. 2, the area that would appear at the discriminator-scaler input due to the original photo-multiplier pulse alone would be proportional to

$$\int_0^\infty e^{-nt/\tau}dt = \tau/n;$$

this is also the area that would appear if the variable length side-arm of Fig. 1 were infinite in length. The desired length of shorted line to measure the decay constant τ/n of this pulse is that line which gives a reflected pulse whose leading edge occurs at a time t' after the leading edge of the original photo-multiplier pulse, where t' is the time required for the amplitude of the original pulse to fall to $1/e$ of its peak value. t' then is τ/n. The resultant area of the original pulse and the reflected pulse from the desired length of shorted line appearing at the discriminator-scaler input

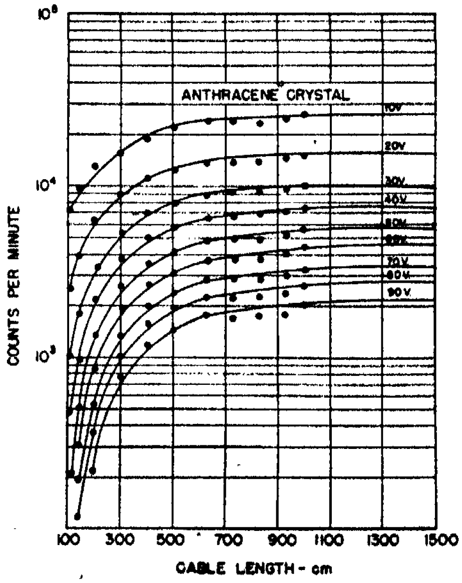

FIG. 3. Anthracene counting rate *vs.* shorted cable length for various pulse height discrimination levels.

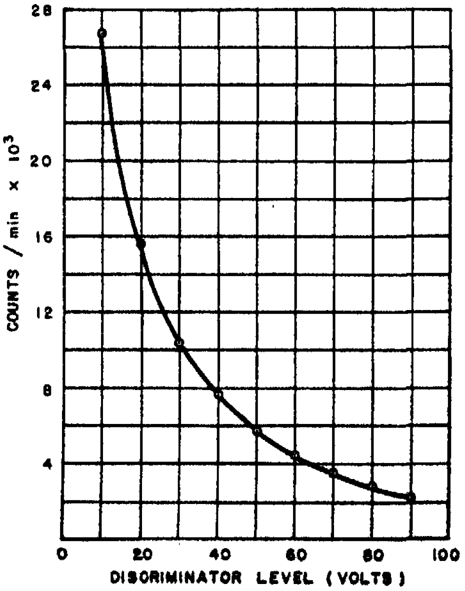

FIG. 4. Anthracene counting rate *vs.* pulse height discrimination level for the infinitely long shorted line.

would be proportional to

$$\int_0^{\tau/n} e^{-nt/\tau}dt=\tau(1-1/e)/n,$$

taking into account the action of the diode (again refer to Fig. 2). The ratio of the areas appearing at the discriminator-scaler input for the desired shorted line and the infinite line is $1-1/e$ or 0.632. Thus the constant τ/n may be determined for anthracene from a curve of the counting rate *vs.* the shorted cable length for different discriminator settings as shown in Fig. 3 and from the data for the counting rate *vs.* discriminator settings for the infinite line as shown in Fig. 4. This determination is made for a given discrimination level of Fig. 3 by finding that length of shorted line which gives the same counting rate as the infinite line gives (Fig. 4) at a discriminator setting 1/0.632 greater. The determinations in the case of anthracene are presented in Table I where it is seen that τ/n is independent of the discriminator setting. From the average value of τ/n, from the constant for the diode used, and from a measured value of 1.98×10^{10} cm/sec. for the velocity of propagation in *RG8U* cable, the duration τ of the scintillations of anthracene may be found. Similar measurements and analyses were made for the scintillations of stilbene. All measurements were made with the phosphors at room temperature using a 10 microcurie radium gamma-ray source. The photomultiplier was cooled to liquid nitrogen temperature to reduce the dark noise. Table II presents the results of these measurements, together with determinations by other authors for the same phosphors using oscillographic methods.

In view of the mechanism of the production of noise pulses, it would seem more reasonable to assume a Gaussian distribution for their time duration. Using the same type of analysis but adjusting the constants to fit a Gaussian shape rather than exponential shape, similar measurements on dark noise pulses yielded a value of 6×10^{-9} sec. for twice the mean deviation.

No attempt has been made to correct the values in Table II for the spread in photo-multiplier time.

The anthracene single crystal samples were obtained from the Harshaw Chemical Company. The stilbene crystals were prepared by Dr. S. Zerfoss and Mr. L. R. Johnson of the Crystal Section of this Laboratory.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 7 JULY, 1950

Instrument for Directional Studies of Cosmic-Ray Intensity

H. W. BOEHMER AND J. E. COOLIDGE*
Department of Physics, University of Colorado, Boulder, Colorado

(Received March 13, 1950)

In order to obtain a versatile instrument for directional cosmic-ray studies, and to investigate an indicated correlation of the soft component of cosmic radiation with the present cosmic-ray burst studies being carried on at the University of Colorado a dual cosmic-ray telescope was constructed. Each bank of the telescope consists of five counter trays with nine Geiger counters in each tray. The electronic circuits are connected to give three triple consecutive coincidence trains: 1, 2, and 3; 2, 3, and 4; 3, 4, and 5. By the insertion of eight centimeter-thick lead blocks covering the sensitive area of a Geiger tray between trays 3 and 4, and 4 and 5; a separation of the components of the radiation is possible. The telescope is adjustable in zenith in 15 degree intervals from 0 to 75 degrees from the vertical. However, in azimuth, in order to investigate asymmetry characteristics, two positions 180 degrees apart are employed. The control of the telescope is entirely automatic with the recording of data being obtained by means of periodic photographs of the indicating panel, showing the counting rate, zenith and azimuthal positions, and the time and date of the measurement. The telescope changes in zenith and in azimuth every forty minutes; the changes in zenith and azimuth being displaced twenty minutes. A cycle of operation, which consists of the step change in zenith from 0 to 75 degrees with the associated alternate azimuthal changes, requires four hours.

SINCE the initial measurements of the East-West asymmetry of cosmic radiation by B. Rossi,[1] T. H. Johnson and J. C. Street,[2] and T. H. Johnson,[3] many elaborate instruments have been employed to determine the nature of the asymmetry and associated phenomena. One characteristic which is common to many measurements is that the data are obtained over a relatively short time interval. Other measurements have been handicapped by the necessity of manual operation. In order, therefore, to obtain a versatile instrument for directional cosmic-ray studies and to investigate possible correlations of the components of cosmic radiation with the present cosmic-ray burst studies and solar studies being carried on at the University of Colorado, a dual cosmic-ray counter telescope was constructed. The telescope was designed to be fully automatic, requiring only routine checks of its operation and semi-weekly attention to the recording apparatus. This work began in the fall of 1947 and was sponsored by an ONR grant N6onr-231, T.O. V. The instrument began its operation in September, 1948 and ran continuously except for occasional repair and adjustment until June, 1949 at which time it was temporarily shut down because of the termination of the cosmic-ray burst studies.

[3] T. H. Johnson, Phys. Rev. 45, 569 (1934), and Phys. Rev. 43, 703 (1933).

With the help of the voluminous data which were obtained during this nine-month operation, interesting results concerning the over-all characteristics of East-West asymmetry along with its seasonal and daily variations are expected. At the present time only a part of the data has been analyzed and these preliminary results are to be reported elsewhere. The purpose of this paper is to describe the apparatus.

GENERAL DESCRIPTION OF APPARATUS

The instrument (Fig. 1) consists of 2 telescope banks which can be positioned in zenith at 15° intervals from 0–75° by means of a motor driven lead screw. In order to facilitate asymmetry measurements, the telescope is turned back and forth through a 180° azimuthal variation at suitable intervals of time. This arrangement allows each bank of the telescope to divide its recording time equally between each direction at a given zenith angle.

TELESCOPE BANKS

The configuration of the telescope banks is the same as that employed in a vertical dual unit constructed at the Bartol Research Foundation.[4] It consists of 5 trays (designated as trays 1, 2, 3, 4, and 5 numbering from the top down) of Geiger counters spaced 5.5 in. apart, each tray containing 9 counters. The counters are supported by means of polystyrene strips which are grooved to hold the counters in close proximity (Fig. 2). In order to insure a low leakage, the leads from the Geiger counters are brought directly to the coincidence circuits through screw mounts in polystyrene strips. It was originally planned to use a ceresin wax to insure a low surface leakage. The polystyrene alone, however, gave a measured value of leakage current of less than 1 microampere which was deemed satisfactory. The dry climate of Colorado does not present the problem of surface leakage that causes trouble in measurements made in more humid regions.

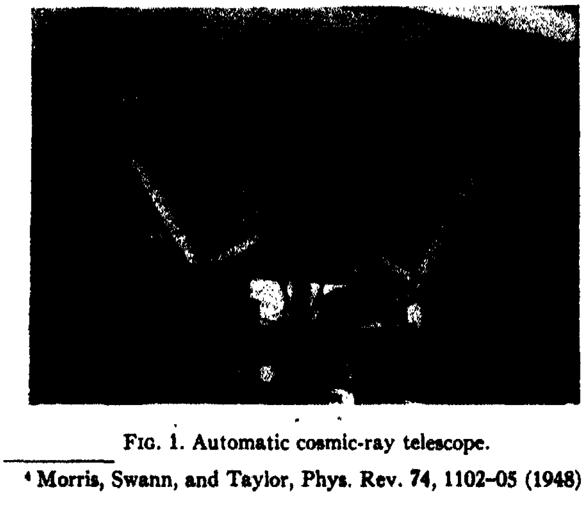

FIG. 1. Automatic cosmic-ray telescope.

The counters used in the telescope were designed and constructed at the Bartol Foundation. The counter consists of a glass cylindrical envelope in which are mounted a thin-walled (0.005 in.) copper tube 4 in. long, 0.395 in. outside diameter, and a three-mil tungsten wire as the anode. The gas employed in the tube is 94 percent argon and 6 percent oxygen at a total pressure of about 14 centimeters of mercury. A standard resistance quenching circuit was employed which results in a recovery time for the counter circuit of approximately 3.5×10^{-3} seconds. (An IRC 500 megohm resistor is used). Because of the relatively low counting rate, this recovery time results in a counter tray efficiency of 99.2 percent when considering the probability of losing counts due to rays passing through a counter during its recovery period.

The directional effect is achieved in the usual manner by use of coincidence circuits—the particular circuit employed being a standard triple coincidence circuit of the Rossi type (Fig. 3). The desirable low capacity in the Geiger circuit and also a compact circuit design is effected by mounting the quenching resistors and associated electronic circuits directly on the Geiger counter trays.

FIG. 2. Tray element of telescope.

In order that the characteristics of the soft, medium, and hard components of the radiation can be investigated, lead blocks 8 cm in thickness are mounted between trays 3 and 4 and trays 4 and 5. The trays are connected in triple coincidence schemes with coincidences 1-2-3, 2-3-4, and 3-4-5 being recorded for each telescope bank. Impulses registered for coincidence 1-2-3 will give a measure of the total radiation striking in the solid angle and tray area of the coincidence at the particular zenith angle of the telescope. In like manner, coincidences registered for 2-3-4 and 3-4-5 indicate the radiation of sufficient energy to pass through 8 cm and 16 cm of lead respectively, striking in the solid angle and tray area defined by the coincidences.

ZENITH POSITIONING

The adjustment in zenith angle is accomplished by means of a motor driven lead screw which pivots the banks around axes through the outer corners of the individual telescope banks. The connections to the lead screw from the individual banks are made by means of two tie rods on the ends of which are connected yokes—the yokes in turn are connected to the drive nut. The importance of this method of construction is the balanced load produced on the lead screw in the horizontal direction. With a common point of support through their individual tie rod yokes at the drive nut steel support pins, the horizontal components of the forces necessary to produce equilibrium exactly balance while the vertical components add. Because of the large mechanical advantage obtained through the screw and bevel gear system employed in the lead screw drive, a torque of only 12 in.-oz is necessary to produce the angular change under its most severe loading conditions. It is interesting to note that when the telescope banks are directed 75° from the vertical, the stress in the tie rods is a maximum, but the loading on the drive screw is very small. This condition is accomplished by means of the mechanical advantage afforded by the horizontal position of the tie rods.

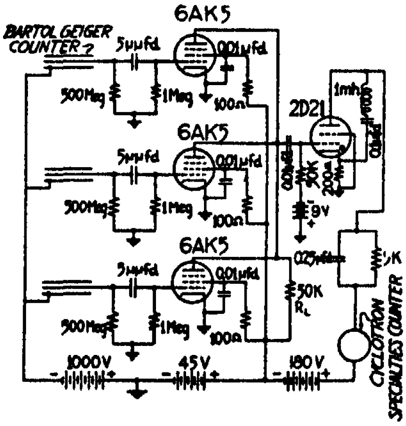

FIG. 3. Coincidence circuit.

The positioning control for zenith is activated by micro-switches connected directly to the base of one of the telescope banks. As the bank is pivoted by the motor driven lead screw an arm connected directly to the bank rotates with the bank and closes the proper set of micro-switches. Alongside each positioning micro-switch is a second switch which indicates the position of the telescope in zenith by lights on the main panel. This indicating contact is displaced slightly forward so as to insure the indication of the position before the control system has stopped the telescope. Such a direct method of controlling and indicating the position of the banks directly from one of the banks leaves no chance for error in the positioning or its indication. A schematic diagram for the zenith control is given in Fig. 4. The heart of the control is the Hayden timing motor (a) which makes one revolution every 40 minutes. A brush contact attached to the drive shaft of the motor closes control contact (b) which in turn activates coils "*c*" and "*d*." Coil "*c*" energizes the camera control circuit while coil "*d*" closes a hold-in contact for the circuit; i.e., allows the original motor-closed contact to open without changing the condition of the circuit and applies voltage to the zenith drive motor through the reversing relay (*e*). Assuming that the initial position of the telescope is vertical, the banks will be driven to the 15° position where the brush attached to the bank will close relay "*f*" through contacts on the zenith control and the contacts of the impulse relay "*g*." On the closing of the relay "*f*," the relay coil "*d*" is deactivated, turning off the motor and closing the coil of the impulse relay through the normally open contact of the relay "*f*." Thus, the impulse relay is switched to its other stable position, which opens the circuit to relay "*f*" and cocks the telescope control for its necessary zenith change. This cocking of the circuit is facilitated by having alternate position contacts with the (0-30-60) and (15-45-75) contacts connected to each side of the single pole double throw impulse relay. Depending then on the position of the impulse relay, the circuit is controlled by that set of zenith contacts corresponding to the position of the relay. As the positioning of the telescope is done in consecutive steps, the operation may be accomplished by switching the impulse relay at each step, setting the circuit for the next change. The time necessary for each zenith change is approximately 45 seconds. The next zenith change occurs 40 min. later when the same cycle of relay operation described above takes place. Following the zenith change, the camera circuit is pulsed through the adjoining contact to that of the main zenith control contact (*b*) by the Hayden motor-driven brush contact approximately 60 seconds after the start of the zenith change.

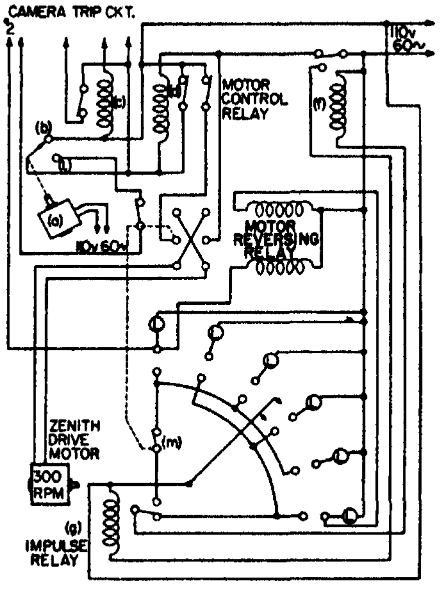

FIG. 4. Zenith control.

This system of change of zenith angle takes place in 15° intervals until a direction of 75° from the vertical is reached. At this position a cycle of relay operation is the same as in other positions but the motor relay is also reversed by the zenith 75° indicator contact which excites the reversing relay coil along with lighting the indicator light. In order that the telescope may return directly to the vertical, it is necessary to have the motor reversing relay interrupt the return to the impulse relay (*m*) which is common to zenith contacts (0-30-60). At the vertical position the system is returned to its normal operation ready for its necessary change to 15°. In order that a picture will not be taken during the return to the vertical (approximately 3 minutes is required for the return), the motor reversing relay also opens the camera control lead adjacent to the main zenith control contact (*b*). At the vertical, however, the camera is pulsed by a parallel circuit to that which is used at other position changes. The latter camera circuit is necessary in order that the main control will be free for operation for the change to 15°.

AZIMUTH POSITIONING

In order to investigate asymmetry of cosmic radiation, the telescope is set alternately in two positions of azimuth 180° apart, the positions of the banks simply being exchanged. This positioning is achieved by means of a worm gear drive which rotates the telescope through the 180° change. In order to avoid the necessity of slip rings and brushes, the telescope is rotated back and forth through the 180° change.

The positioning control in azimuth is accomplished by means of micro-switches operated directly by an arm attached to the telescope which not only controls the relay circuits necessary to the motor drive but also lights the indicator azimuth lamps on the meter panel to indicate the position of the telescope in azimuth. The 180° change is made in approximately 20 seconds.

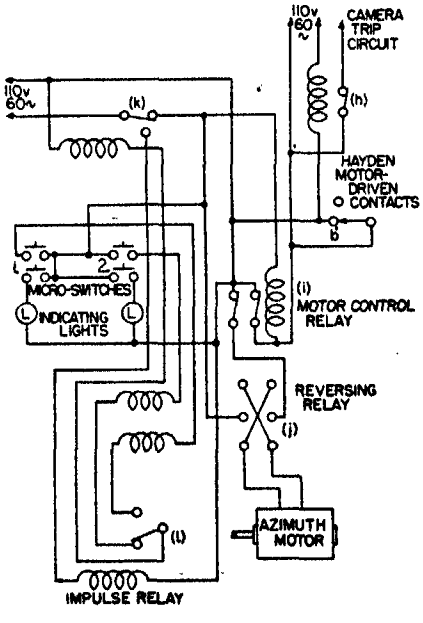

FIG. 5. Azimuth control.

The main control for azimuth is a second set of contacts activated by the Hayden motor driven brush contact. Relay "*h*" (Fig. 5), controls the camera circuit while "*i*" locks the circuit and drives the motor through the reversing relay (*j*). The azimuthal positions at 180° are controlled by micro-switches (1), (2). On contact, "2" being closed, the reversing relay is changed and relay "*k*" is opened. The opening of "*k*" releases the circuit, and on the closing of its normally open contact, relay coil "*l*" is excited. This switches the impulse relay to its other stable position. The relay control system is now set for the return through the 180° interval which occurs 40 minutes later. The camera circuit is pulsed after each azimuthal change.

RECORDING

The recording of coincidences occurring in each telescope bank is made by means of electromechanical counters manufactured by the Cyclotron Specialties Company of California. Together with the indicating lights of zenith and azimuth position and a 24-hour clock, the 6 electromechanical counters are mounted on a panel. The recording of data is accomplished, therefore, by means of a periodic photograph of this panel. As described in the discussions of zenith and azimuth control above, pictures are taken before and after each position change, enabling us to take into consideration the counts registered during the change which therefore could not be used in any calculations of the angular characteristics of the cosmic radiation. The camera employed is a war surplus motor driven gun camera which is pulsed so as to take a 3-frame picture. In order that the film will not be "fogged" in case the internal camera shutter remains open after being pulsed, an external shutter is employed which is pulsed and made to remain open by the same circuit that pulses the camera. This method requires the change of a 50-foot film cartridge every five days.

The camera control is illustrated in Fig. 6. Camera circuit No. 1 is activated by relays "*c*" and "*h*" of the zenith and azimuth control systems respectively. When relay "*a*" of the camera control is closed, the condenser "*c*" discharges by means of its normally open contacts through relay coil "*b*." The length of time that relay "*b*" will remain closed and (thus the time the camera motor will run) is determined by the RC time constant of the condenser and relay coil. The latter discharge time is adjusted so that a 3-frame picture is taken. The advantage of this type of control is that the length of time over which voltage is applied to the camera is independent of the length of time that the control relays in zenith and azimuth are closed. In order that 2 consecutive pictures may be taken at the vertical position, once on the return to the vertical and again just as it leaves that position, a parallel camera circuit is needed. This latter circuit is activated through the vertical indicator light contact on the zenith control.

COUNTING CHARACTERISTICS

Because of the random character of radiation to be measured, a counting rate determined from a finite time of recording is subject to statistical fluctuations which may be calculated from the theory of probability. The application of the probability theory to Geiger counter measurements has been discussed by many investigators.[5,6] All of these discussions are based on the Poisson distribution law which states that if N is the average number of counts in a time interval, T, supposed to be evaluated from an infinitely long period of observation, the probability that the number of counts recorded in any particular interval of duration, T, will be n, is given by

$$P_n=(N^n\times e^N)/N!.$$

Although in actual practice the quantity n is directly measured and the desired quantity is N, Rainwater and Wu[6] show that Poisson's formula is applicable to this problem. The standard deviation, which is defined as the amount by which any given measurement may be expected to be deviated from the mean value, is given by the formula

$$G=n^{\frac{1}{2}},$$

with the probable error given by $P_G=0.6745n^{\frac{1}{2}}$.

In the practice of making telescopic direction readings, the corrections that must be made to the observed counting rate are stated by T. H. Johnson[5] as (1) the difference between the actual and the effective area of the Geiger tube; (2) the variation of "j" (the rate per unit solid angle per second per unit area) over the effective aperture of the counters; (3) the probability that an ionizing ray can pass through the train without producing discharge of all counters; (4) the probability that false counts will occur when nearly simultaneous, but unassociated, rays pass through the counters; (5) the probability that two or more associated rays will pass through the train simultaneously and be recorded as a single count; (6) the probability that a group of associated rays from the side will discharge the counters simultaneously although no single ray has passed through the train; (7) the probability that two or more coincidences will occur within the action time of the mechanical recording device so that only one will be recorded; (8) the absorption of rays within the counter walls. Johnson discusses these considerations in general in his article, and we will discuss their application to the particular problem of the counter telescope described here.

(1) Because of the use of single layer trays of Geiger counters in forming the elements of the telescope, the problem of area efficiency becomes not the difference between the actual and effective area of a single tube, but that of the difference between the actual and effective area of a tray of tubes. The actual area of the tray (the actual area is defined as the area defined by the outer extremities of the tray of counters) is 116 sq. cm, with an effective area (the effective area is defined as that area through which an ionizing particle may pass and produce a discharge in a counter) of only 90 sq. cm. Thus, the active area consists of only 78 percent of the actual area. Each tray is an element of a three-coincidence train resulting in an over-all area counting efficiency of $(0.78)^3$ or 46.5 percent (E_A).

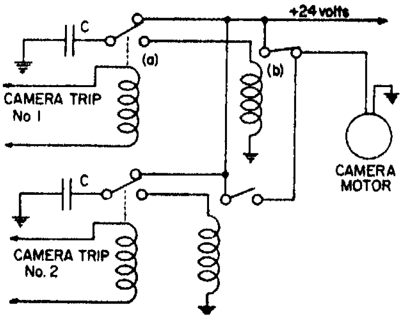

FIG. 6. Camera control.

(2) The variation of "j" over the aperture of the telescope presents no problem in the investigation of asymmetry as only comparative measurements as a function of position and time are required. However, in calculations of direction intensities, the variation of "j" over the aperture of the telescope can be accounted for by use of equations derived by Witmer and Pomerantz.[7] Witmer and Pomerantz calculate the average path length of particles passing through the coincidence train. In this calculation it is necessary to assume the angular distribution of the radiation being measured. If a cosine squared distribution is assumed, the number of counts can be expressed in terms of the intensity $I(0)$ as

$$N=[I(0)L^4A^2]/\lambda^6,$$

where A is the area of a train, L, the length of the train, λ is the average path length through the coincidence train. Therefore, from a measure of N, $I(0)$ can be calculated.

Effect (3) has been discussed in many papers and texts[8] and in this application results in a tray efficiency of 97 percent or an over-all coincidence counting efficiency of 90 percent (E_T).

(4) The probability that false counts will occur when any simultaneous but unassociated rays pass through the counter can be calculated. However, this accidental counting rate may be conveniently included in an experimental determination of the total accidental rate

[8] S. A. Korff, *Electron and Nuclear Counters* (D. Van Nostrand Company, Inc., New York, 1947).

due to both unassociated and associated (those due to showers) rays. This latter measurement will be described later.

The probability that a group of associated rays from the side will discharge the counter simultaneously although no single ray has passed through the train is a function of the showers produced in the surrounding structure or frame of the telescope. Due to the complexity of the structure, the number of such showers would be difficult to predict theoretically. However, it is possible to measure experimentally the number of accidental counts due to this shower production; the measurement includes those due to accidentals as discussed in Section 4. The technique consists of connecting trays 1 and 2 in bank number one of the telescope in coincidence with tray number three of bank number two when the telescope is in the vertical position. By this arrangement we have a coincidence train which is out of line and, therefore, can only be discharged by associated rays from the side or unassociated rays that pass through the train elements nearly simultaneously. An accidental counting rate of 0.16±0.008 counts/minute was observed.

As it is desired to keep the background count to a minimum, arrangements can be made to keep accidentals to a low value. One method of accomplishing this, as mentioned by Johnson and employed by the Bartol Foundation, is to shield the tray common to all coincidences (in this application tray No. 3, Fig. 2) with 1 in. lead aprons so as to absorb the soft shower particles. However, this method did not seem to be helpful in this application; in fact, the aprons had a detrimental effect. The greater number of counts obtained with the lead aprons in position indicated that their effect in producing showers was greater than their effect in absorbing shower particles.

A more suitable method of limiting the shower-produced accidentals is to install anticoincidence circuits. The anticoincidence circuits are arranged with anticoincidence Geiger counters lying adjacent to the sides of the common tray; if a tube in the tray and one of the adjacent anticoincidence counters are discharged simultaneously, the coincidence circuit will be prevented from recording a coincidence. This system would have the detrimental effect of increasing the dead time of coincidence, but with an effective anticoincidence area of less than half that of a telescope tray, this effect would be small. At the present time, no anticoincidence circuits are employed in the telescope. In any arrangement for limiting the accidental count, it is still necessary to measure the accidental count as indicated earlier in this section.

Because of the low counting rate of the telescope, the probability of two or more coincidences occurring within the action time of the mechanical recording device is very small. The efficiency of the mechanical counter differs from 100 percent by less than $\frac{1}{10}$ of 1 percent. From these efficiency calculations and measurements of accidentals, an adjusted counting rate can be determined from the measured values of the telescope. Assume that R_r is the rate recorded. Then the adjusted rate is

$$R_T=\frac{R_r-R_a}{E_T\times E_a}=\frac{R_r-0.16}{0.42},$$

where E_T is the efficiency of the coincidence train to count a single pulse (90 percent) and E_a the area efficiency of the train (46.5 percent) and R_a, the shower accidental counting rate as determined by experiment. (0.16 count/minute.)

The over-all counting efficiency $E_T\times E_a$ discussed above was checked experimentally. The experimental method consisted of a measurement with the telescope connected in a four-consecutive tray (1-2-3-4) coincidence followed by a triple coincidence measurement in which tray number three was omitted (1-2-4). In this manner we defined the same solid angle by a four- and three-tray coincidence. The ratio of the two counting rates when so connected gives the efficiency of an individual tray. The over-all counting efficiency of a four-tray coincidence is $E_4=(E_1)^4$ where E_1 is the efficiency of a single tray. In like fashion, the corresponding over-all efficiency of a three-tray coincidence defining the same solid angle as the four-tray coincidence is $E_3=(E_1)^3$. If N_0 is the actual number of rays traversing the coincidence in a given time, the number recorded by the four-tray coincidence would be $N_4=E_4N_0$ while in the corresponding three-tray coincidence, $N_3=E_3N_0$. The ratio of N_4 to N_3 is

$$\frac{N_4}{N_3}=\frac{E_4N_0}{E_3N_0}=\frac{(E_1)^4}{(E_1)^3}=E_1.$$

The single tray efficiency so determined gives a value of 77 percent which when cubed to obtain the triple consecutive tray coincidence efficiency gives a value of 44 percent.

Thus the adjusted rate based on experimental measurements is

$$R_T=(R_r-0.16)/0.44.$$

The authors wish to express their appreciation to Dr. James W. Broxon for his patient guidance in the construction of the telescope.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 7 JULY, 1950

Measurement of Secondary Electron Emission from Dielectric Surfaces

HOWARD L. HEYDT*
Servomechanisms Laboratory, Massachusetts Institute of Technology, Cambridge, Massachusetts

(Received March 23, 1950)

A technique is developed for the rapid and precise measurement of the secondary electron emission properties of certain dielectric surfaces. The dielectric surface is bombarded by primary electrons having energies which produce a secondary emission ratio greater than unity. This establishes the surface potential at a known value. With the known potential difference between the dielectric surface and primary electron source, the energies of the primary electrons are automatically determined for the first instant of surface bombardment. The net current to the dielectric surface at any moment is measured by using a cathode-ray oscillograph to observe the transient current to a metal plate which backs the dielectric. The method has been used to study metallic surfaces and has yielded results which agree very closely with those obtained using the conventional d.c. method of measurement.

INTRODUCTION

WHEN a stream of electrons strikes the surface of any solid body, some secondary electrons are always released by that body. These secondary electrons may or may not escape from the surface. The path taken depends, at least in part, upon the nature of the electric and magnetic fields in the vicinity of the emission and on the composition of the emitting surface. The average number of secondary electrons released by each primary (incident) electron is known as the secondary emission ratio. Normally, a curve showing the variation of the secondary emission ratio with primary electron energy is used to characterize any surface with regard to the ability of that surface to yield secondary electrons. Surface structure and the angle of incidence of the primary beam, however, are known to affect this curve. In addition, it is believed that the secondary emission from certain complex surfaces may be a function of the previous bombardment of that surface, and it is possible that the emission may also be a function of the current density of the primary beam.

It is readily seen that the secondary electron current available from a particular surface is a function of several factors, some of which may not be known or which cannot easily be controlled. This makes repeatable results difficult to obtain and probably accounts for some lack of published data on the secondary emission properties of various surfaces.

The here-to-be described measurement technique was developed for the purpose of studying the variation of the secondary emission properties of certain surfaces which are dielectric in nature. The surfaces in question were of interest because of their possible suitability as storage surfaces in electrostatic storage tubes which will probably be used extensively as the storage medium in high speed electronic computers. It was assumed that there existed a possibility for a variation of secondary emission properties of certain complex surfaces with time and surface bombardment. Little information pertaining to the variation of secondary emission characteristics is found in the literature. In a few instances, however, it has been implied that certain changes in emitting properties will take place.[1,2]

SECONDARY EMISSION MEASUREMENTS ON DIELECTRICS

Obtaining data for the preparation of a secondary emission curve for any surface necessitates (1) a means for the measurement of the energy of the bombarding electrons and (2) a means for measuring the current to and from the bombarded surface. When a metallic surface is used as the secondary emitter the problem is simply solved by using a voltmeter between the target and the primary electron source and a current meter in series with the target. When a dielectric surface is used as a secondary emitter, however, such a measurement method is obviously not applicable. A "dynamic" measurement method must be employed, in which consideration is given to the charging and discharging of the capacitance between the front surface of the dielectric and the metal back-plate to the dielectric. This back-plate shall be henceforth referred to as the signal plate.

Serious consideration of a method for measuring secondary electron emission from dielectrics has appeared only in the last decade. Two forms of the dynamic method were proposed in 1940.[3,4]

The first phase of the method herein proposed consists of establishing the potential of the dielectric surface at a known value. When the potential of the surface is known with respect to the potential of the primary electron source, the velocity of the primary electrons as they strike the surface is automatically determined. For the case of a dielectric surface, this velocity exists only instantaneously after bombardment by primary electrons begins. To establish the surface potential, use is made of the fact that the surface potential will assume an average value nearly equal to the collector potential provided the surface is bombarded sufficiently long with primary electrons having energies which produce a secondary emission ratio greater than unity.

If the signal plate, the secondary electron collector, and the primary electron source are connected together through suitable electrical paths, the current to the signal plate will be identical in magnitude to the net current leaving the dielectric surface at any moment. This is made possible since the signal plate and surface are joined by an effective condenser. Observation of the transient signal plate current by means of a cathode-ray oscillograph provides, consequently, an adequate means for measuring the net current leaving the surface.

DETAILED METHOD OF MEASUREMENT

Tube for Testing Surfaces

All measurements were made on surfaces contained in cylindrical glass tubes. Each tube contained an electron gun at one end and a target assembly at the other, as is shown in Fig. 1. During the operation of the tube, the electron beam is positioned into the hole of the circular nickel aperture plate which also serves as the secondary electron collector. A small distance behind the collector, and parallel to it, is the surface to be tested. In this investigation the surfaces studied were composed of a layer of beryllium on a base of aluminum oxide, Al_2O_3. Each surface was produced by evaporating beryllium onto the surface of an anodized aluminum disk. The aluminum disk served as the signal plate and the Al_2O_3 became the dielectric separating the signal plate and surface. A new tube was prepared and sealed off for every surface studied.

Establishing the Dielectric Surface Potential

The method of surface potential stabilization can be illustrated by reference to Fig. 2, in which the circuit associated with the target is shown. Surface potential stabilization for primary velocities at which the secondary emission ratio exceeds unity implies that the flow of secondary electrons from the surface to the collector shall just equal the flow of primary electrons to the surface. Such a situation could be brought about if the stabilized surface potential were to be a few volts positive with respect to the collector potential. A slight retarding action would then be exerted by the collector on the secondaries emitted by the dielectric surface. There is a definite energy distribution of the secondary electrons and only those secondaries with energies greater than the retarding potential could ever reach the collector. Actually, such a retarding potential does exist which so adjusts itself that the net current to the surface does equal zero and the stable surface potential is realized.

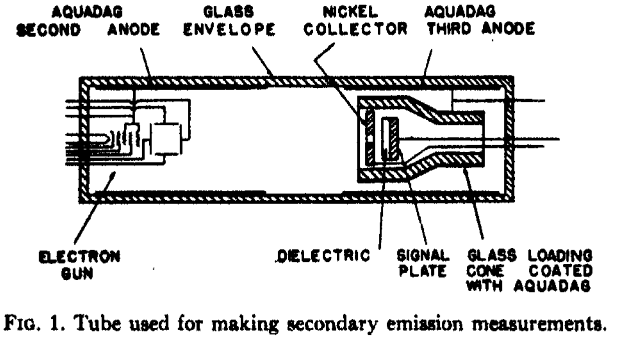

FIG. 1. Tube used for making secondary emission measurements.

After the dielectric surface potential has been stabilized at approximately the collector potential the primary beam may be turned off. If the dielectric is good, the charge on its surface will remain at least temporarily, and the surface potential may be assumed to be at collector potential.

To make an actual secondary emission measurement using the circuit illustrated, the surface potential is stabilized using the method just described, with the signal plate connected to ground (center position of the selector switch). Next, with the primary beam off, the d.c. potential of the signal plate is switched to the more negative value of 50 volts below ground potential. The dielectric surface potential now becomes 50 volts less than its stabilized value, assuming (1) that there has been no appreciable loss of charge from the surface and (2) that the capacitance between the dielectric surface and the signal plate is considerably greater than the capacitance between the surface and all other electrodes in the tube. When the primary beam is again switched on, the primary electrons will instantaneously strike the dielectric surface with energies which are known. The energy of each of the initial primary electrons is fixed by the known initial difference in potential between the dielectric surface and the cathode of the electron gun. This energy is conveniently expressed in volts. It is seen that the energy of these initial primary electrons is equal to

$$\begin{bmatrix}\text{cathode-to-}\\ \text{collector}\\ \text{potential}\end{bmatrix} + \begin{bmatrix}\text{collector-to-surface}\\ \text{retarding potential}\\ \text{at stabilization}\end{bmatrix} - 50 \text{ volts.}$$

The retarding potential is only a few volts and can usually be neglected in comparison to the other potentials involved. Varying the potential of the cathode with respect to the collector potential provides a means for controlling the energies of the bombarding primary electrons.

The first phase of the secondary emission measurement has now been accomplished since the initial energy of any bombarding primary electrons will be known. The collector will be 50 volts positive with respect to the surface at the first instant of bombardment, so that all secondaries released by the surface at the first instant of bombardment should be picked up by the collector. The next phase of the measurement is to determine the magnitudes of the secondary and primary currents at the moment when the primary electron energy is known.

Measuring the Current to the Dielectric Surface

The primary beam, having been turned off during the switching of the signal plate potential, is again turned on, causing an electron current I_p to flow to the dielectric surface. Nearly all the secondary electrons released by the surface should be attracted by the collector, thus producing an initial secondary electron current I_s away from the surface. There is a net electron flow away from the dielectric surface at the first instant equal to $I_s - I_p$. Because of the capacitance between the dielectric surface and the signal plate, an identical electron current flow to the signal plate takes place through the external network. It is this external current which is measured in order to determine the secondary emission ratio at the established primary velocity. The current to the signal plate through the external network has an initial value $I_s - I_p$ for the stabilizing and switching conditions just outlined. The signal plate current is, of course, transient in nature, for if the primary beam were left on sufficiently long the surface would be stabilized and no net current to the dielectric would exist. Observation of the signal plate current by means of a cathode-ray oscillograph is employed as a simple and relatively precise means of determining the initial value of the signal plate current.

If, after surface potential stabilization, the signal plate potential is switched more positive by 50 volts, practically all of the secondary electrons will lack sufficient energy to reach the collector at the first instant of primary electron bombardment. These secondary electrons will be repelled back to the surface from which they were emitted and the signal plate current, consequently, will be equal to the primary current I_p at this time.

The secondary emission ratio can now be calculated from the relation

$$\delta = \frac{I_s}{I_p} = \frac{(I_s - I_p) + I_p}{I_p}.$$

This ratio, in turn, can be expressed in terms of the relative beam deflections in the C.R.O. for I_p and $I_s - I_p$. Such a secondary emission ratio exists only for a primary electron energy equal to the established cathode-to-surface potential. Since only the initial values of $I_s - I_p$ and I_p are of interest, the primary beam need be pulsed on only for a very short interval during the current measurements.

Equivalent Target Circuit

The parameters of the external circuit have a bearing on the measurement method and are worth considering. Figure 3 shows the equivalent circuit associated with the target after the surface potential has been stabilized and the signal plate potential switched positive or negative by 50 volts. R_0 and C_0 are the front-to-back resistance and capacitance respectively of the dielectric surface. C_{eq} approximately represents the parallel combination of the signal plate-to-ground capacitance and the input capacitance to the video amplifier. R_{eq} represents the approximate parallel resistance combination of R and the $1M$ coupling resistor. If the time constant $R_{eq}C_{eq}$ is made very small, then a very short time after the primary beam is pulsed on for a current measurement, the voltage across R_{eq} will be proportional to either $I_s - I_p$ or I_p. This voltage is amplified and applied to the deflection plates of a cathode-ray oscillograph. The resulting beam deflections occurring in the oscillograph are proportional to $I_s - I_p$ or I_p.

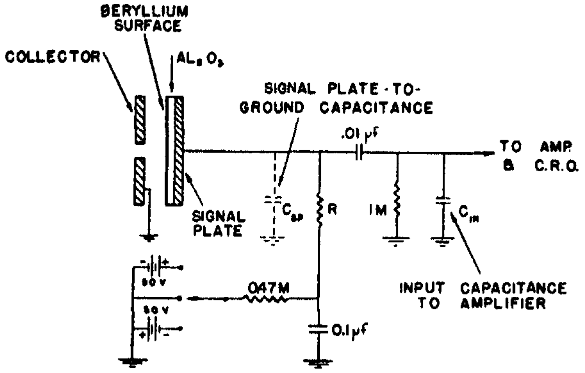

FIG. 2. Target connections and associated circuit.

A variation in the measurement method consists of making the time constant $R_{eq}C_{eq}$ large, so that when the primary beam is pulsed on to make a current measurement, the potential change across C_{eq} is proportional to the charge added to or removed from the dielectric surface. If the duration of the primary beam pulse is very short, the change of charge on C_{eq} or the change in voltage across C_{eq} will be nearly a linear function of time. In such a case, the total voltage change across C_{eq} for a given duration of primary beam pulse will be approximately proportional to the initial value of $I_s - I_p$ or I_p.

Sample oscillograph indications for both the current and charge type of secondary emission measurement are illustrated in Fig. 4.

In a typical secondary emission measurement on the surfaces studied in this investigation, representative values for the various constants were approximately as follows:

$I_p = 30$ μa.
Pulse duration = 1.0 μsec.
$C_0 = 250$ μμf.
$R_0 = 10^{12}\Omega$

	R_{eq}	Signal plate potential change for a current to or from surface of 30 μa
Current method	1000 ohms	0.03 volt
Charge method	500,000	0.3

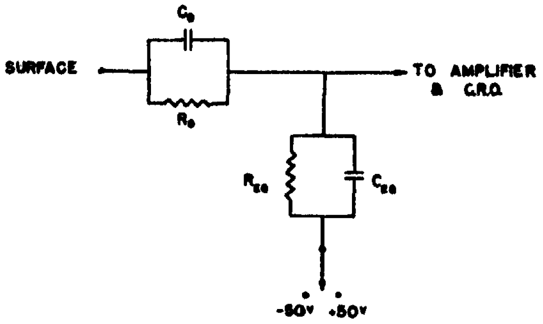

FIG. 3. Equivalent target circuit.

Since the method of measuring charge provided the greater signal plate potential change, the charge method was generally used in making measurements. If the possibility exists for an appreciable change in the current to the surface during the time of the beam pulse, then the current measurement method should be employed.

CONCLUSIONS

The dynamic secondary emission measurement technique which has been described is believed to be sufficiently precise for most purposes. As a check on the measurement technique, the following method was found useful: A special research tube was employed containing a polished nickel disk in place of the usual dielectric surface. Connection to the disk could be made through a 250-$\mu\mu f$ capacitance, thus simulating the effect of the capacitance of a target composed of a dielectric material. Consequently, a dynamic secondary emission measurement could be made on the nickel. Since a direct connection to the nickel surface was also available, a d.c. secondary emission measurement could be made. The difference between the secondary emission curves obtained for the nickel surface using both the d.c. and dynamic methods was practically indistinguishable. An advantage of the proposed method is considered to be the speed and simplicity of measurement. Since only relative deflections of the oscillograph beam are required, no calibration of the oscillograph is necessary.

It is desirable to ascertain frequently that the signal plate potential is always switched the same amount. A switching potential of 50 volts as used in this investigation is not a fixed quantity, of course. It is necessary, however, that at the positive signal plate potential practically all secondaries leaving the dielectric surface be repelled back to that surface. Similarly, at the negative signal plate potential practically all secondaries released by the surface should be picked up by the collector. The minimum signal plate switching potentials can be determined from a plot of signal plate current *vs.* switching potential. Such a curve is a prerequisite to the proper interpretation of the results of any secondary emission measurement.

The effect of surface contamination by particles from the cathode of the electron gun is certainly important. No real protection from such contamination was afforded in the type research tube used, and the effect of the contamination must be considered in evaluating the results of any measurements. Shielding the surface from the cathode is definitely a consideration for future designs of the tube used for testing surfaces.

The method is not without disadvantages. With the type of research tube employed, proper positioning of the beam into the aperture of the collector is absolutely essential in making successful measurements. The beam must also be focused as sharply as possible. If these precautions are not followed the effect of the beam striking the edge of the aperture will considerably impair the accuracy of the measurements. The beam positioning is chiefly a function of the cathode-to-collector potential, which means that positioning must be performed before each current measurement. Much of the difficulty probably can be solved, however, by proper design of the tube used for surface testing. The problem of carefully positioning the beam into the aperture for each measurement can become tedious, particularly if many readings are to be made. Even with the best positioning, some primaries must strike the edge of the aperture and affect the measurements. Although this difficulty was anticipated, the aperture plate was used because it simulated a condition under which the test surface would actually be employed. A new tube has subsequently been used which contains no aperture plate and which requires no beam positioning. A single Aquadag coating, tied to the second anode of the electron gun, serves as the secondary electron collector. Exploiting the possibilities of such a tube seems desirable since such a tube would further speed and simplify secondary emission measurements.

Provided all factors affecting secondary emission are fixed or known, the measurement method presented should be generally applicable. It is desired to emphasize, however, that this paper is merely intended to

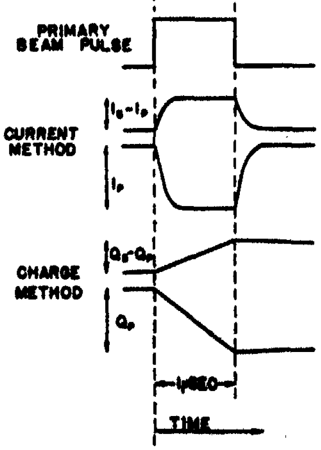

FIG. 4. Oscillograph indications obtained during the measurement of secondary emission.

present a method. Secondary emission data on a particular surface would be valuable only to those who would use the surface under the identical conditions existing when the data was obtained.

ACKNOWLEDGMENTS

The experimental work on which this paper is based was performed in the Servomechanisms Laboratory of the Massachusetts Institute of Technology. The author is sincerely grateful for the facilities and technical assistance made available to him by Mr. Jay W. Forrester, Director of Project Whirlwind, and by Mr. Patrick Youtz. A High Speed Expansion Valve for Cloud-Chamber Control*

R. P. Shutt and W. L. Whittemore
Brookhaven National Laboratory, Upton, Long Island, New York

(Received March 20, 1950)

In order to keep the width of cloud-chamber tracks down to less than 1 mm the time delay between passage of a ray and completion of an expansion must be 10^{-2} sec. or less. When Geiger counter control is employed it may be difficult to obtain a sufficiently fast acting expansion control valve, particularly for a large cloud chamber. A valve combining a number of principles not all used by others has been constructed. By balancing pressures the movable valve parts can be made very light despite a large valve opening, and the controlling electromagnet can be quite small. Calculations were made concerning all the important design features. Even a small electromagnet must be laminated to insure sufficiently fast decay of its magnetic field. Most of the remaining time delay is caused by the aerodynamic resistance at the valve opening. For a valve diameter of 5.6 cm expansions are completed in 8×10^{-3} sec. With a power consumption of 0.17 watt a small vacuum tube is sufficient for operation. By balancing pressures one could construct a much larger valve operating as fast as the valve described with only a slight increase in power consumption.

INTRODUCTION

A CLOUD chamber essentially consists of a cylindrical glass container sealed by a flexible diaphragm. Usually air pressure applied against the diaphragm from the outside is used to compress the gas inside the chamber. In order to expand the cloud chamber the air is released through a valve, thus allowing the internal pressure to push the diaphragm outward.

When a cloud chamber is controlled by Geiger counters, it is necessary to complete expansions in a very short time after the event setting off the counters has occurred. The accuracy of measurements of curvature and angles to be performed on a cloud chamber photograph is limited by the width and distortions of the tracks. The track width also affects the intensity and contrast of illumination necessary for photography. Tracks are distorted by turbulent motion of the cloud chamber gas during and after an expansion. This effect can be reduced to lateral deviations of considerably less than 1 millimeter by proper design and temperature control of the cloud chamber. For most applications it therefore appears to be practical to aim for a track width of somewhat less than 1 mm.

Blackett[1] has shown that in argon at approximately normal pressure a track of ions formed by a charged particle diffuses to a mean width which is proportional to the square root of the time elapsed and equal to 1 millimeter in 1/70 sec. Ion diffusion is terminated almost immediately when the supersaturation necessary for drop formation has been reached in the cloud chamber. This can be seen in the following way.

In an investigation of the growth of drops in a cloud chamber, Hazen[2] has shown that the square of the drop radius a increases proportionally to the time t after supersaturation has been reached

$$a^2 = Kt, \tag{1}$$

where the value of the proportionality constant K lies somewhere between 10^{-6} and 10^{-5} (c.g.s. units), depending on the gas and vapor used in the cloud chamber.

The mean square of the displacement $d\langle X^2\rangle_{Av}$ due to Brownian movement of the drop during the time dt is given by

$$d\langle X^2\rangle_{Av} = \frac{kTdt}{3\pi\eta a}, \tag{2}$$

where k is Boltzmann's constant, T the absolute temperature, and η the viscosity of the gas. Substituting expression (1) for the time dependent radius a in (2) and integrating one finds

$$\langle X^2\rangle_{\mathrm{Av}}=\frac{2kT}{3\pi\eta K^{\frac{1}{2}}}t^{\frac{1}{2}}, \tag{3}$$

as an estimate for the movement of the growing drop. Substituting values for the constants, $T=300$°K, and $t=0.1$ sec. for the time of growth of the drop, one finds a value of approximately 10^{-3} cm for the root-mean-square of the displacement of the drop at the time it is photographed. Since this value is negligibly small as compared to the acceptable displacement caused by the diffusion of the free ions before the expansion of the cloud chamber one has to be concerned only with the delay between passage of an ionizing ray through the cloud chamber and the termination of the expansion. According to Blackett's result mentioned above this delay should be less than 10^{-2} sec. in order to obtain track widths of less than 1 mm.

The expansion valve for a cloud chamber usually consists of an electromagnet holding a valve disk against a self-sealing gasket. After passing through vacuum tube circuits in a negligibly short time, the pulse from the Geiger counters acts to decrease the field in the magnet, allowing the valve disk to be pushed open by the air pressure inside. While air escapes through the valve opening, the cloud chamber is expanding. The following time delays have to be considered. First, there is the decay time, t_1, of the field in the holding magnet. t_1 depends on the electrical constants and on the shape and structure of the magnet. The yoke of the magnet acts as a secondary winding inside which strong electric currents may be set up, delaying the decay time of the field. These currents can be made negligibly small by laminating the magnet material. Secondly, t_2 will designate the time during which air flows through the valve opening, while the valve disk is in motion and thereafter. The valve opens the faster, the smaller the mass of the valve disk assembly can be made. The aerodynamic resistance of the valve air duct is determined by its shape and size. Of course t_2 decreases as the size of the valve opening is increased, but usually t_1 increases correspondingly because of the larger size of the magnet required. Finally, the cloud-chamber diaphragm takes a certain time to fly back. However, because of their light weight the rubber diaphragms and pistons used in most designs can move practically as fast as the outflowing air slowed down by the aerodynamic resistance at the valve opening. Therefore, unless the valve opening should be made exceptionally large, only t_1 and t_2 need be considered.

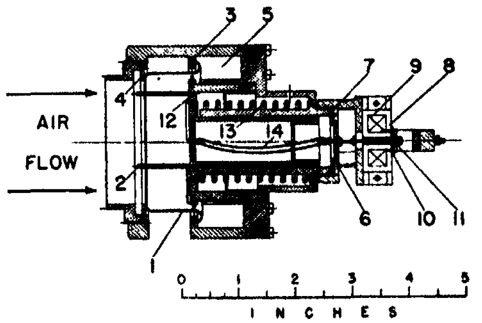

FIG. 1. Diagram of high speed expansion valve for cloud-chamber control. The whole assembly is screwed into a hole in the back compartment of the cloud chamber.

DESIGN OF EXPANSION VALVE

Various designs have been employed successfully by many workers. However, for two large cloud chambers to be used at this laboratory it appeared useful to construct a new valve combining a number of advantages not all of which have been found in previous designs. The valve to be described combines large size of the valve air duct with a short opening time, small electric power requirements, and simple operation. By applying the principles involved twice in succession one could control an even larger valve with a small amount of power and still have sufficiently fast expansions. A description of the valve will now be given. Later a number of generally applicable theoretical considerations will be used to calculate some operating characteristics of this valve for comparison with experimental data.

Reference is made to Fig. 1. The valve disk consists of a cylindrical cup with turned-out rim (1), spun of magnesium or aluminum sheet about 0.015 in. thick. The motion of the cup is guided by three pins (2), passing through small holes in the bottom of the cup. If the cup is pushed to the left against gaskets (3) and (4), air admitted into the back compartment of the cloud chamber leaks through the small holes around pins (2) in the bottom of the cup into the air chamber formed by cup (1) and container (5), thus building up equal pressure at both sides of the cup. Since the area sealed by gasket (3) at the rim of the cup is larger than the area sealed by gasket (4) at the bottom, the resultant force keeps the cup in the initial position, thus sealing the cloud chamber and air chamber (5) as long as air pressure is applied. Since the pressures at both sides of the flat bottom of the cup are equal and since the large curvature of the cylindrical section of the cup serves well to withstand the pressure difference between cloud chamber back and the outside atmosphere, one can make the cup material very thin and of light weight. The air chamber (5) is sealed by a small Lucite valve disk (6) held against gasket (7) by the magnet assembly. The yoke (8) of the magnet is made of two straight arrays of steel laminations, 0.020 in. thick, bent around a field coil (9) consisting of 3000 turns of 0.004 in. Formex-coated copper wire. The laminations are insulated electrically by a thin coat of varnish. The armature consists of two small steel strips (10), 1 in. ×0.093 in. ×0.020 in., pinned to a Lucite holder (11). 0.17 watt of power is consumed to hold this valve closed. Thus a small electronic power tube is sufficient for operation.

When the field in the magnet is decreased sufficiently the valve assembly, consisting of parts (6), (10), and (11), opens and air escapes from the air chamber (5). The small holes in cup (1) cannot pass a sufficient amount of air to keep up the pressure in (5). Thus, as soon as this pressure has dropped somewhat the forces on the cup become unbalanced, the cup is pushed to the right and air now escapes through the big opening in gasket (4), letting the cloud chamber expand. The cup flies open very rapidly because of its small mass (6 to 10 g for the present design) and also because it can move quite freely, since it is not attached to any resetting device such as a spring. In order to reset cup (1) after an expansion, piston (12) has been provided. When the cloud chamber is compressed this piston is pushed to the right by the air pressure in chamber (5), compressing spring (13). Immediately after an expansion the spring pushes the piston to the left, thus resetting cup (1) for the next compression. Due to its large mass and friction in its air seals the piston moves slowly so that it cannot interfere with the fast motion of the cup. By means of a rubber band (14) attached to the piston (12) the small valve disk (6) is also reset automatically. Two valves of this type were built and have been operated successfully for six months.

CALCULATION OF ELECTROMAGNET

In order to insure proper dimensions for the components of the valve, approximate calculations of its operating characteristics have been made. The results will be stated at this point.

First the decay time t_1 of the field in the holding magnet will be calculated. Since the yoke forms an electrical secondary circuit, one should consider the whole magnet as a transformer and solve the corresponding equations. However, we may simplify the problem by considering first the decay time t_1' of the electric current in the field coil alone and then showing separately how the decay time t_1'' of the secondary current in the iron can be kept negligibly small.

The armature is attracted by the yoke with a force F (dyne) which must be approximately equal to the force exerted by the pressure difference Δp on the valve disk. From the field energy in the magnet one finds

$$F=\frac{AB^2}{8\pi}\approx\pi r^2\Delta p, \tag{4}$$

with B (gauss) for the flux density, A (cm^2) for the constant cross section of the yoke, and r (cm) for the radius of the valve opening. One has also

$$B=\frac{4\pi}{10}\frac{ni}{(b/\mu)+x}, \tag{5}$$

where ni stands for the number of Ampere-turns in the field coil, b (cm) for the length of the magnetic circuit, μ for the permeability of the iron, and x (cm) for the sum of all air-gaps.

Finally, the e.m.f. induced in the field coil by the decaying magnetic field is

$$E=-10^{-8}nA(dB/dt). \tag{6}$$

From (4), (5), and (6) one finds

$$t_1'=2\times10^{-7}(F/P)[(b/\mu)+x], \tag{7}$$

where P (watt) is the power consumption.

In the present design we have $r=0.8$ cm, $\Delta p=0.5$ atm. For cold-rolled steel $B=4500$ gauss with $\mu\approx1000$ is quite far from saturation and leads to a practical value for $A=1.25$ cm^2. x is assumed to be 0.01 cm which is probably conservatively large. Putting $b=4$ cm enables one to accommodate a field coil consisting of 3000 turns of copper wire 0.004 in. in diameter without overheating. The coil resistance is 600 ohm. One finds $i=15$ mA, $P=0.17$ watt and $t_1'=17\times10^{-3}$ sec. This is the decay constant when the field coil is short-circuited. A series resistor or vacuum tube providing 10,000 ohm of additional resistance at the time of expansion makes $t_1'=10^{-3}$ sec. with an induced peak voltage at the coil terminals of 160 volt. A low power vacuum tube thus can be used for control of the valve.

From (7) one can see that for a desired t_1' the instantaneous power consumption P is proportional to F, and therefore to the area of the valve opening. For a large valve this leads to quite large peak currents or voltages, making fast operation rather difficult. Thus a fast cloud-chamber valve can be operated most simply if a small electromagnet is employed.

We shall now turn to the calculation of t_1'', the effect of "eddy currents" induced in the yoke material. Making use of (5) and (6) for average values only we find

$$t_1''=\frac{10^{-9}\pi wdb}{[(b/\mu)+x]\rho[(d/w)+(w/d)]}. \tag{8}$$

wd (cm^2) is the cross section of *one* of the laminations. ρ (ohm-cm) is the resistivity of the iron, the other quantities having been defined previously.

Choosing laminations $d=0.05$ cm thick and $w=0.25$ cm wide, we find $t_1''=2.2\times10^{-4}$ sec., which is small compared to $t_1'=10^{-3}$ sec. as had been mentioned above.

We conclude that the magnet constructed permits the valve disk to start moving about 10^{-3} sec. after the field coil has been deenergized, leaving a resistance of 10,000 ohm or its equivalent in series with the coil resistance. A very simple and direct measurement, making use of an oscilloscope, showed indeed a delay of 10^{-3} sec.

It may be of interest that for a ring-shaped magnet one finds

$$t_1''=\frac{4\pi10^{-9}d^2b}{\rho[(b/\mu)+x]}, \tag{9}$$

where d now stands for the width of the cross section through which the magnetic flux passes. For a large available ring magnet $t_1''=0.2$ sec. was predicted, and 0.15 sec. was found experimentally, which again shows that these simplified calculations give approximations sufficient for the purpose.

CALCULATION OF AIR RESISTANCE

Calculation of t_2, the time during which the air escapes from the rear compartment of the cloud chamber, follows. This time is determined by the aerodynamic resistance in the valve which varies as a function of time while the valve is opening. Approximately, the air pushes against the valve disk area πr^2 with a time-varying pressure difference $\Delta p(t)$. Thus we have

$$m\ddot{y}=\Delta p(t)\pi r^2, \tag{10}$$

where $m(g)$ is the mass of the moving parts of the valve and y (cm) the distance through which the valve disk has moved at the time t.

The air then passes through a cylindrical opening of area $2\pi r y$ around the edge of the valve disk. Calling $M(t)$ (g) the mass of air passing through this opening per unit time one has

$$\dot{M}(t)=2\pi r y(t)v(t)D(t), \tag{11}$$

where $v(t)$ is the velocity of the escaping air and $D(t)$ its density. Three more equations are needed to express the time dependence of $\Delta p(t)$, $v(t)$, and $D(t)$, and the integration of the problem becomes quite tedious. Therefore we make the following assumptions. For $\Delta p(t)$ and $D(t)$ we put their average values Δp and D, respectively, found from the known conditions at beginning and end of the period considered, neglecting effects, such as cooling of the air due to expansion, etc.

Referring to standard texts on frictional effects in air ducts one finds that, except for relatively long ducts, most of the losses in pressure occur at irregularities such as abrupt bends and sudden expansions and constrictions in the ducts, and that the pressure loss experienced is of the order of $Dv^2/2$ for every pronounced change in direction of flow. Therefore we shall assume that all of the change in pressure between inside and outside takes place at the valve opening and is

$$\Delta p\approx Dv^2/2 \tag{12}$$

from which the average velocity of flow can immediately be calculated once the average values for Δp and D are given.

With these simplifications (10) and (11) can easily be integrated. One finds

$$t=\frac{0.6}{r(\Delta p)^{\frac{1}{2}}}\left(\frac{Mm}{D^{\frac{1}{2}}}\right)^{\frac{1}{3}} \quad \text{for} \quad t<t_0 \tag{13}$$

$$t=\frac{2}{3}t_0+\frac{0.22M}{r^2(\Delta pD)^{\frac{1}{2}}} \quad \text{for} \quad t>t_0 \tag{14}$$

$$t_0=\left(\frac{m}{\pi r\Delta p}\right)^{\frac{1}{2}}, \tag{15}$$

where t is the time taken for the mass M of air to flow through the valve opening. t_0 is the time taken by the valve disk to open fully to a value of $y=r/2$.

By means of formulas (13)–(15), we can now predict more approximate data for our valve. For the small valve disk, held by the electromagnet, we have $m=1.4$ g and $r=0.8$ cm. The volume of the air chamber (5) is 75 cm^3. Thus the delay due to air chamber (5) amounts to $t_2'=1.5\times10^{-3}$ sec.

For cup (1) with $m=10$ g, $r=2.8$ cm, and a volume of 2400 cm^3 of air to flow out upon expansion, one finds $t_2''=5.6\times10^{-3}$ sec. Adding $t_2'+t_2''$ on has $t_2=7.1\times10^{-3}$ sec. It is of interest to note that most of this delay is due to the air resistance at the main valve opening, even though the latter is relatively large.

Finally, the total delay between breaking the current through the field coil and completion of the expansion should be $t_1+t_2=8\times10^{-3}$ sec. which was confirmed by experiment.

In a conventionally designed valve of the present size it would be difficult to make m less than 300 g, resulting in a time delay of 11×10^{-3} sec. for t_2'' alone. This is twice as long as the corresponding time delay for the present design.

ACKNOWLEDGMENT

Single Element Verniers Reading Two or Three Dimensions

ROBERT E. LEWIS
Physics Research Department, Armour Research Foundation, Illinois Institute of Technology, Chicago, Illinois

(Received October 20, 1949)

By superimposing concentric radial elements on rectangular coordinate rulings, vernier systems may be constructed reading in two or three dimensions without the necessity of any particular angular orientation.

A two-dimensional vernier may consist of one transparent element ruled with concentric circles. The observed tangencies of the circles, with regard to a rectangular grid placed in contact, provide the reading of the additional decimal of the coordinates of the fiducial center of the circles on the grid.

A three-dimensional vernier system may be established by means of a binocular optical system presenting images of spheres concentric with the locating point and images of coordinate boxes in the same space. The tangency of a vernier sphere and coordinate plane indicates the last decimal of the reading.

Angular orientation may be indicated by radial lines near the points of tangency.

I. INTRODUCTION

THE familiar linear vernier scale reading system, named after its inventor Pierre Vernier in 1631, permits linear or angular measure to a degree of accuracy many times greater than is possible by using a conventional scale. Even if the vernier device is graduated so that 10 divisions on it equal 11 or 9 divisions on the main scale, the accuracy of reading is extended by one decimal place.

The well-recognized value of a vernier rests on the sharpness of vision and accuracy of judgment of separations. Whether the vernier is read with or without magnification, the image entering the eye contains the same geometrical relations. It may then be said that the success of the vernier rests on the ability of the viewer to judge the coincidence of two end-to-end lines or ruled elements, instead of the relative position of a line some distance between two others. Furthermore, this process of coincidence recognition is assisted by the presentation of a line pattern to guide the judgment of the viewer.

A common vernier drawn on a linear or circular scale permits reading with vernier-enhanced accuracy in but one dimension. To attain two-dimensional readings, two separate sets of scales and verniers are usually used. These scales require accurately aligned sliding ways or bearings to permit translation to read various locations in a plane.

Three-dimensional measurement with common vernier scales differs only by the addition of another set of accurately aligned ways and scale with reading vernier. Thus, to read four points not in a plane, movement of vernier scales along several precision ways is required. The maintenance of alignment between ways is subject to wear as well as to numerous other problems. The cost of accurate systems for the reading of measurements in several dimensions is often measured more in terms of the labor involved in translating than in terms of the cost of the equipment. These restrictions often lead to the discarding of the vernier system, the measurer relying only on sufficient magnification of the critical dimension to permit more accurate estimation.

II. TWO-DIMENSIONAL VERNIER OF ONE ELEMENT

A basic form of the two-dimensional vernier of one element only may be developed by, what is in effect, the revolution of a one-dimensional vernier in a plane about the fiducial point. This is then superimposed on a rectangular grid of x and y coordinates. This requires that one or both of the superimposed elements be on a transparent or perforated material.

The two-dimensional vernier, therefore, may consist of ten concentric circles about a fiducial point. The radii of the circles are such that ten circles equal nine divisions on the rectangular grid. Thus, with the fiducial point at origin, vernier circle 1.0 is tangent to lines through (9,0), (0,9), (−9,0), and (0,−9). It is evident that the application of the vernier circles requires recognition of tangency which is thus viewed by eye as the coincidence of a line and arc. This corresponds in

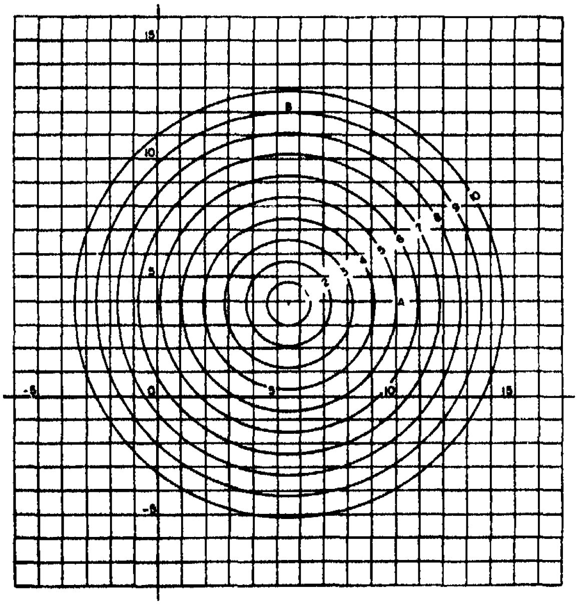

FIG. 1. A single two-dimensional vernier. The fiducial element point is set at $x=5$, $y=3$. The vernier establishes this point as $x=5.5$, $y=3.9$.

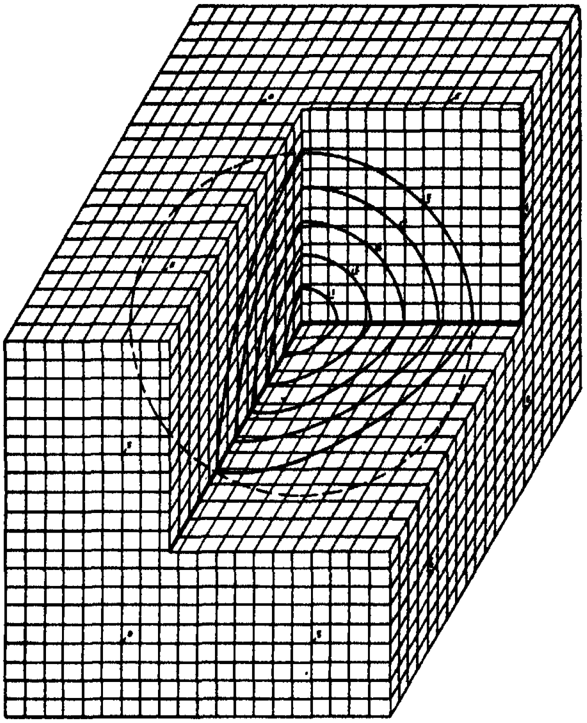

FIG. 2. A single element three-dimensional vernier, whose practical use depends on some kind of stereoscopic optical system (not shown). The cutaway shows the fiducial point at (1.3, 2.4, 0.2).

function to the recognition of the coincidence of lines in a linear vernier, and to the extent that the eye can recognize linear and tangent coincidence equally well, to the same extent the accuracy of the two-dimensional single element vernier is of the same order as the linear common vernier.

A vernier reading is tangent to two x coordinate lines separated by 180°, and likewise to two y coordinate lines separated by 180°. The tangencies in the first two quadrants represent positive vernier increments, while those in the third and fourth quadrants are negative increments. In Fig. 1 the position is read (5.5, 3.9) as the fiducial point is in the (5, 3) coordinate rectangle and the vernier is tangent at 0.5 to x coordinate lines indicated by point A, and likewise tangent to 0.9 for y coordinate lines indicated as point B. The additional negative increment readings at points opposite to A and B correspond to an ordinary linear vernier which is zero centered.

III. THREE-DIMENSIONAL VERNIER OF ONE ELEMENT

By revolving a linear vernier about a fiducial point in three-dimensional space, a set of vernier spheres is developed. These will then be read by tangency to coordinate planes in a cubical-space system. Such a system is realized by using stereoscopic methods which permit the establishment of one image within another. Recognition of tangency then becomes a problem of stereoscopic depth. Optical stereoscopic range-finders have been designed to take advantage of the increased accuracy attainable by the recognition of coincidence.

The difficulty of graphical representation of the solid shape is, perhaps, the same as that of supplying a means of identifying the surface of a sphere without obscuring another, or without obscuring the planes. Figure 2 is a cutaway drawing of a solid vernier at (1.3, 2.4, 0.2). The reduction of the number of spheres reduces the problem only by adding planes. Recognition of the surfaces involved may be assisted by presenting the spheres and planes as ruled surfaces covered with small spots much like dust particles. Careful dispersion of the spots will permit viewing through successive layers, as the binocular position of two spots in line for one eye, but in separate planes, will not produce spots in the two-eye images which are superimposed and interfering.

The application of such a system depends on the stereoscopic equipment used, details of which are beyond the scope of this paper.

IV. DISCUSSION AND CONCLUSION

The rotation of the vernier indicator has no influence on the reading of the location of the fiducial point in space. This characteristic is particularly interesting for it eliminates the necessity of translation of the reading device by means of precision ways at right angles. The right-angle relationship is maintained by the reference grid system, which construction eliminates misalignment errors that occur through wear of the ways.

Angular orientation of the vernier systems, when desired, may be indicated by polar location of the tangencies. Figure 3 shows a vernier reading (8.2, 12.4) at 60° to x axis or 150° when read on the y axis. The ac-

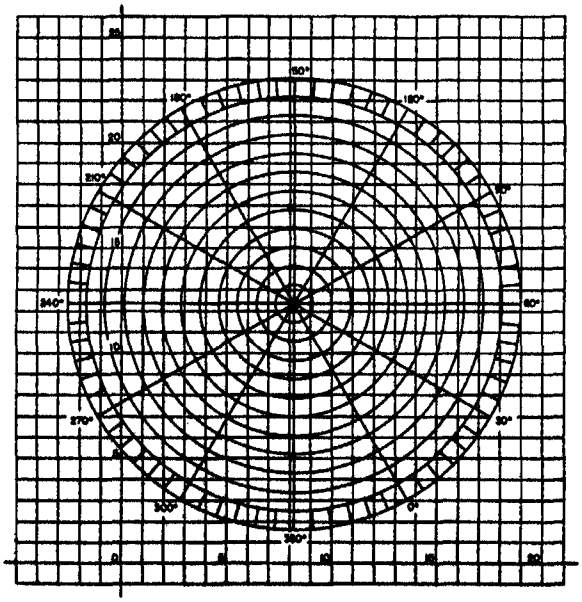

FIG. 3. A single element two-dimensional vernier ruled to indicate polar angle. The fiducial point is at $x=8.2$, $y=12.4$, polar angle $=60°$ to x axis.

curacy of interpretation of angular orientation by tangency is not the same order as that of other vernier readings. However, in certain cases, intersecting coordinate lines may permit improved accuracy.

The usefulness of the two-dimensional system is dependent on the plane-to-plane contact or equivalent of the vernier and grid. To observe the tangency characteristics of the pattern, one element must be transparent, perforated, or otherwise optically superimposed upon the other element.

The similarity between the tangency relation in reading grid and circle coincidence and the other patterns[1] suggests that finer two- and three-dimensional vernier readings may be obtained by further pattern development. Similar studies of the visibility of line elements and endings[2] may reveal higher resolution with known systems.

V. ACKNOWLEDGMENTS

The author wishes to acknowledge the suggestions and encouragement of Mr. Howard T. Betz of Armour Research Foundation of Illinois Institute of Technology. This work is a development of research originally sponsored by the Jones and Lamson Company of Springfield, Vermont.[3]

Coincidence Circuit for a Scintillation Detector of Radiation

W. C. Elmore
Swarthmore College, Swarthmore, Pennsylvania

(Received March 30, 1950)

This paper describes a very simple low level coincidence circuit of moderate speed, which is suitable for use with two or more multiplier photo-tubes in a scintillation detector of radiation. The operation of the circuit is analyzed, and performance data given to show its effectiveness in eliminating spurious counts due to noise pulses in the photo-tubes. Some useful modifications of the circuit are suggested.

THE modern scintillation detector of nuclear radiation, based on a multiplier photo-tube and a suitable phosphor, has prompted the development of low level coincidence circuits that operate directly between two photo-tubes.[1] These circuits utilize the non-linear property of germanium diodes, such as the 1N34, and make it unnecessary to employ separate amplifiers with each photo-tube, although an amplifier must be used between the output of the coincidence circuit and the pulse-recording equipment. In the present report a new coincidence circuit of this type will be described, together with performance data obtained with two 931-A multiplier photo-tubes arranged to view the same sodium-iodide phosphor. The coincidence circuit in this case serves to reduce the background counting rate due to noise pulses from the photo-tubes. Its use, however, is not restricted to this application.

The version of the coincidence circuit whose performance has been studied in greatest detail is that given in Fig. 1, in which the coincidence circuit is shown connected between the anodes of two 931-A tubes. The potentiometer R_4 permits the bias currents that enter the diode-resistor network to be balanced, and the variable resistors R_5 and R_6 permit the amplifications of the two photo-tubes to be equalized. These controls are convenient in an experimental set-up, but can be omitted, or made screw-driver controls in a permanent set-up.

A qualitative notion of how the coincidence circuit operates may be had by noting that about one-tenth of the steady bias current for each branch of the circuit flows through the resistance R_3. A negative pulse of current occurring at the anode of the photo-tube T-1, for instance, serves to lower the potential of that anode, and hence to cut off one-half of the current to R_3 on account of the high back resistance of the diode D_1. Most of the missing current is then supplied through the diode D_2 from a source impedance approximately equal to R_2. Since $R_2 \ll R_3$, the potential difference across R_3 drops only slightly, giving a small anti-coincident output pulse. When pulses of current occur simultaneously at the anodes of both photo-tubes, both diodes tend to be cut off and the potential across R_3 drops an amount set by the smaller of the two current pulses, giving a much larger coincident output pulse.

A more precise account of the operation of the coincidence circuit will be based on Fig. 2, which shows the basic portion of the circuit, and Fig. 3, which shows

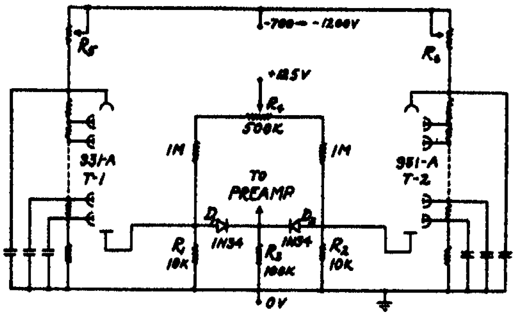

FIG. 1. Coincidence circuit connected between two 931-A multiplier photo-tubes.

experimentally determined curves relating the two currents I_1 and I_2 to the potential V_g (with respect to ground). These curves were obtained from the circuit of Fig. 2 with $R_1=R_2=10^4$ ohms and $R_3=10^5$ ohms using a portable potentiometer to measure V_g as a function of the two currents. The lack of symmetry in the characteristic curves is due to differences in the two diodes.

Let us consider first how the circuit operates leaving out of account the stray capacitance C_1, C_2, and C_3, whose presence in the circuit will be considered later. Suppose then that steady bias currents of 0.1 ma are flowing into each side of the coincidence circuit, biasing it at point x in Fig. 3, so that V_g is 0.9 volt. If now a pulse of negative current of magnitude 0.03 ma, for example, occurs at the anode of the photo-tube T-1, and none at the anode of T-2, the current I_1 is momentarily decreased 0.03 ma, whereas I_2 is unchanged in value. This situation is represented in Fig. 3 by the operating path x–y. It is clear that during the current pulse the potential V_g drops to that at point y, and then returns to its original value when the current pulse ends, causing a negative voltage pulse of about 0.07 volt to be impressed on the grid of the amplifier.

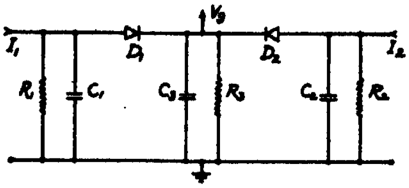

FIG. 2. Basic part of coincidence circuit, including stray capacitances.

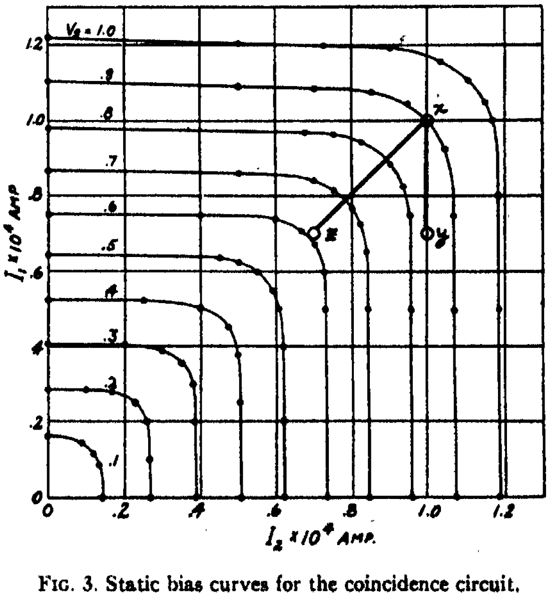

FIG. 3. Static bias curves for the coincidence circuit.

Next suppose that current pulses of 0.03 ma occur simultaneously at the anodes of both T-1 and T-2, such that an operating path x–z is followed. A negative voltage pulse of amplitude 0.29 volt is then impressed on the grid of the amplifier. The coincident pulses in general have a considerably greater amplitude than the anticoincident pulses; and can be distinguished from the latter by a conventional pulse-height discriminator after an amplification of about 250. Figure 3 enables one to estimate the amplitude of output pulses for combinations of coincident currents of differing magnitudes, provided the current pulses have a duration long compared with the RC time constants associated with the coincidence circuit, or provided the effects of the stray capacitances are taken into account. Some curves showing the output pulse amplitude as a function of the joint magnitudes of the two anode current pulses are given in Fig. 4. These curves have been derived from Fig. 3.

Let us now consider in an approximate manner how the stray capacitances $C_1=C_2$ and C_3 alter the operation of the circuit for short pulses of current. The capacitance between the electrodes of the diodes can be neglected on account of its small value. To simplify the discussion we shall assume that the diodes are ideal, i.e., that they have zero resistance when conducting, and infinite resistance when non-conducting.

Suppose first of all that large coincident pulses of current having a long duration occur simultaneously at the anodes of both T-1 and T-2, so that both anodes drop abruptly to ground potential or below. In such a case V_g drops exponentially to zero from its original value ($V_{og}=0.9$ volt) with a time constant R_3C_3, as shown by curve 1 in Fig. 5. Next assume, as might be expected under normal operating conditions, that both anodes drop in potential perhaps 0.3 volt. The output signal then has the form shown by curve 2 in Fig. 5. With $R_3=10^5$ ohms and $C_3=7.5\ \mu\mu f$, the rise time of the step (10 to 90 percent response) is about 0.3 μsec., the precise value depending, of course, on the amplitude of the pulse. When the current pulses end, the circuit recovers to its initial state with the diodes conducting, and therefore with a time constant computed from the parallel combination of resistors and capacitors in Fig. 2. For the present circuit this time constant is estimated to be about 0.15 μsec., i.e., somewhat shorter than the decay constant (0.25 μsec.) of the NaI(Tl) phosphor for which the circuit values used here have been selected.

If the current pulses at the photo-tube anodes do not cause the potential to drop as rapidly as that indicated by curve 1 in Fig. 5, then the diodes do not cut off and the transient response of the circuit is set entirely by the 0.15-μsec. time constant, and, of course, by the form of the coincident current pulses from the photo-tube anodes. For example, suppose that the current at each anode, in response to a scintillation, has the form

$$i = i_m e^{-t/T}, \quad t \geq 0$$

where T is the decay time of the phosphor. On account of symmetry in the coincidence circuit, the output pulse v_0 is found by supposing this current to flow into the capacitance $C = C_1 + \frac{1}{2}C_3$ shunted by the resistance $R = 2R_1R_3/(R_1 + 2R_3)$. A simple analysis shows that

$$v_0 = [i_m RT/(T-RC)](e^{-t/T} - e^{-t/RC}).$$

The maximum rate of change of v_0 occurs at $t=0$ and has the value i_m/C. The two diodes are cut off if this rate is greater than V_{og}/R_3C_3, which is the absolute value of the initial slope of curve 1 in Fig. 5, that is, if

$$i_m \geq (CV_{og}/C_3R_3).$$

The approximate values $C = 15\ \mu\mu$f, $C_3 = 7.5\ \mu\mu$f, $V_{og} = 0.9$ volt, and $R_3 = 10^5$ ohms give $i_m \geq 0.018$ ma, so that for currents greater that this value the diodes are temporarily cut off. Coincident scintillations from a NaI(Tl) phosphor produce output pulses having a rise time of about 0.3 μsec., with a trailing edge that decays with a 0.25-μsec. time constant. The larger pulses all have the same rate of rise.

The value 10^4 ohms for the resistances $R_1 = R_2$ has been chosen to reduce the magnitude of the current pulses required of the photo-tubes, without increasing the duration of the output pulses appreciably over that set by the decay constant of the sodium-iodide phosphor. It is also desirable that the resistance R_3 be large compared with the forward resistance of the diodes, and with R_1, but not so large that it significantly increases the rise time of the output pulses.

The speed of the coincidence circuit can be increased considerably by decreasing all resistances in proportion and increasing in the same proportion the magnitude of the output current pulses from the photo-tubes. It is found that the static bias curves of Fig. 3 very closely represent curves taken with resistances reduced tenfold, provided the current scales in the figure are increased by a factor of ten. An even greater increase in speed of the coincidence circuit should be possible before the finite forward resistance of the diodes begins to limit its effectiveness of operation.

The extent to which the circuit reduces the background counting rate due to noise pulses in the photo-tubes has been investigated by obtaining integral counting rate bias curves for various conditions of the circuit. For these measurements two 931-A tubes were selected from a group of twenty as having roughly identical sensitivities, and reasonably good signal-to-noise ratios. The sodium-iodide phosphor, contained in a sealed $\frac{3}{4}$-in. diameter quartz tube,[2] was located midway between the two photo-tubes separated 2.5 in. center-to-center. Two flat polished sheets of aluminum were mounted on opposite sides of the phosphor so as to extend from one photo-tube to the other, and thus to improve the otherwise poor optical coupling between the phosphor and the two photo-tubes. A weak Co-60 source was placed in a standard position near the phosphor as a source of γ-rays. Both the source and the phosphor were removed when background noise was measured.

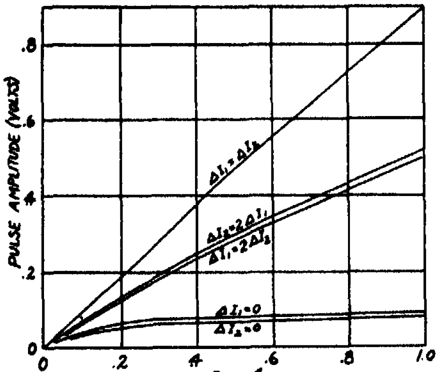

FIG. 4. Output pulse amplitude as a function of the two photo-tube currents.

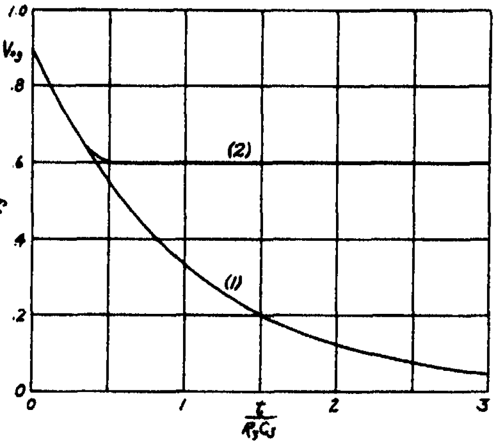

FIG. 5. Output pulse wave forms.

The amplifier, which was stabilized by inverse feedback, had a mid-band gain of 290, and a rise time of 0.08 μsec. It contained no "clipping" time constant, its frequency response extending from well below 20 kc to an upper half-power point of 4.15 Mc. To minimize capacitive loading of the coincidence circuit, the input stage (a Type 6AK5 pentode) was mounted very near the tube sockets for the photo-tubes, and coupled to

---

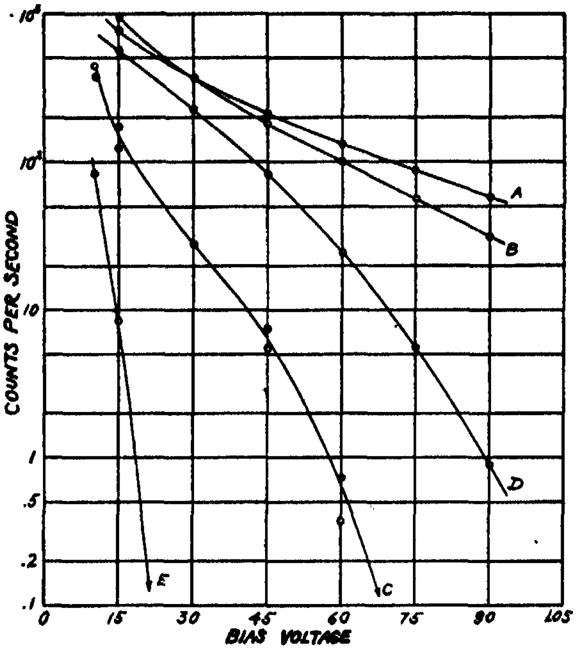

FIG. 6. Integral counting rate bias curves.

the main amplifier by a cathode follower stage. If the utmost in speed is desired, the input stage should be a cathode follower, and stray wiring capacitance kept at a minimum by a careful layout of parts.

The integral bias curves were taken using a Schmitt trigger circuit as a pulse-height discriminator or selector[3] followed by a scale-of-100 counter. The counting rates for the two photo-tubes were first equalized at a bias of 30 volts by adjusting R_5 and R_6 in Fig. 1, with the anode of first one, then the other photo-tube connected temporarily to ground. The coincidence circuit was then balanced by adjusting R_4 to give a minimum noise counting rate with the discriminator bias set at a low value. Curves A and B of Fig. 6 show the source-plus-noise bias curves for the individual photo-tubes. These curves were obtained with one or the other anode of the photo-tubes grounded, thus putting a steady coincident signal into one or the other side of the coincidence circuit. The noise bias curves were taken in a similar fashion with the phosphor and source removed, and are given by curve C which has been drawn through both sets of points. The coincidence circuit was then put into operation and curve D obtained for coincident pulses from the source, and curve E for the coincident noise pulses with the phosphor and source removed.

It is evident that the coincidence circuit is very effective in reducing the noise background provided the discriminator bias is set at about 22.5 volts, or above. According to Fig. 4, anticoincident noise pulses as great as 0.08 volt can be expected to occur, corresponding to output pulses of amplitude $0.08 \times 290 = 23.2$ volts, in agreement with this observation. Since the resolving time of the coincidence circuit described here is perhaps 0.5 μsec., a simple calculation shows that the counting rate due to accidental coincidences between noise pulses in the two photo-tubes should be negligible.

An undesirable effect exhibited by the counting arrangement tested is that the coincident bias curve (D) falls off with increasing bias more rapidly than the bias curves for the individual photo-tubes. This effect indicates that different amounts of light reach the two photo-tubes depending on the position in the phosphor at which a γ-ray makes an interaction with the phosphor. The amplitude of a coincident output pulse, of course, is set by the smaller of the two input pulses from the photo-tubes. The correlation in the amplitudes of coincident pulses could no doubt be increased by improving the optical coupling between the phosphor and the two photo-tubes. An ideal arrangement, although difficult to achieve in practice, would be one in which all the light emitted by the phosphor is gathered and then divided equally between the two photo-tubes.

A direct measurement of the resolving time of the coincidence circuit has not been made. As pointed out earlier, the resolving time of the present circuit designed for a sodium-iodide phosphor can be reduced tenfold, and possibly 100-fold by decreasing the values of the resistances in the circuit a suitable amount. For a shorter resolving time to be of practical importance, one of the faster organic phosphors must be substituted for the sodium-iodide phosphor. With these changes it would appear possible to realize a resolving time of 10^{-8} sec. or less with a coincidence circuit of the sort described.

It is worth noting that the coincidence circuit can be readily modified so that any number of photo-tubes can be connected in coincidence. Each additional tube is coupled to the resistance R_3 through a diode, with a separate bias control for each branch of the coincidence circuit. It appears possible to use the coincidence circuit for Geiger-Müller tubes of the self-quenching variety, without the need for amplification, or pulse inversion between the tubes and the coincidence circuit. Indeed, the present circuit may be considered as a low level modification of the high level diode coincidence circuits described by Howland, Schroeder, and Shipman[4] which require a separate amplifier for each G-M tube.

The author is greatly indebted to the Research Corporation for supporting his work.

A 100,000,000-Frame-per-Second Camera

M. SULTANOFF
Terminal Ballistic Laboratory, Aberdeen Proving Ground, Maryland

(Received March 22, 1950)

Shock waves close to the edge of explosive charges have been successfully photographed at rates exceeding 100,000,000 frames per second. These ultra-high framing rates are obtained with a multislit focal plane shutter which is transported optically across the film plane by a rotating mirror. Linear shutter speeds up to 3000 meters per second are easily obtained, and the resulting framing rates with the proper selection of slit widths can be varied from 10^6 to 10^9 frames per second. Each individual frame is composed of a series of lines, and the degree of "discontinuity" across each frame is proportional to the total number of frames.

INTRODUCTION

THE experimental studies of the shock and detonation which accompany explosive reactions have been hampered by the lack of ultra-high speed instrumentation. Short duration optical studies are particularly required for the investigation of self-luminous detonation and shock waves.

The velocity of these transients average about 8 mm per microsecond. Therefore, usable photographic exposures of these transients must not exceed 10^{-7} sec. Kerr cell shutters[1] have been used to obtain a single or a few successive short duration exposures, while multilens cameras[2] have produced continuous short duration exposures, but at rates which are not adequately high. The O'Brien-Milne camera,[3] which is rated at 10,000,000 frames per second, but which displays poor resolving power, could not be obtained commercially, and its precise optical system made it impractical to build locally.

A motion picture camera which employs simple optical and mechanical systems to obtain up to 300 successive 4×4 in. frames at rates which can be varied from 10^5 to 10^9 frames per second, and which exhibits satisfactory resolving power, is described in this paper.

THEORY OF GRID FRAMING

The standard variable slit focal plane shutter in common use exposes a time-space record as it travels across the film plane. Although the slit moves slowly across the film, the exposure time can be made extremely short by reducing the width of the slit.

The framing grid is a focal plane shutter with a series of parallel slits placed at regular intervals across it. This shutter, therefore, is only required to move the distance between two successive slits to expose the entire film. To understand how this grid records successive frames, consider a series of optically clear slits 0.0005 in. wide, cut at 0.015 intervals across a 4×4 in. optically opaque plate. If this grid is held in a fixed position on a 4×5 in. photographic plate, a single exposure made through it would consist of a set of parallel lines which occupy only 1/30 of the total picture area with an over-all dimension of 4×4 in. A sample exposure of this type is shown in Fig. 1. By moving the grid across the film perpendicularly to the slits for a distance of 0.0005 in., and exposing a second still picture in this new position, a second series of lines lying alongside of the first set and again occupying only 1/30 of the total picture area will be produced. Thirty such single pictures will result from only 0.015 in. movement of the grid, and will expose the entire film area. To the casual observer the resulting picture will be an indistinguishable jumble. However, by proper positioning of the grid, any one of the thirty exposures can be studied separately. This type of grid framing has been used for years in animated greeting cards and photographic advertisements.

If the photographic object is moving, and if the grid

is moved at a uniform rate across the film for a distance of 0.015 in., the resulting picture can be viewed through the grid as thirty separate exposures, one at a time, or, by viewing through the grid moving at any uniform speed, flickerless motion pictures will be observed. This adaptation of grid framing was described in a paper delivered by Dr. Fordyce Tuttle of the Kodak Company at the Society of Motion Picture Engineers Symposium which was held in New York City on April 6, 1949.

At this laboratory we have been successful in combining a stationary framing grid with a rotating mirror to obtain framing rates in excess of 10^8 frames per second.

THE ROTATING MIRROR GRID COMBINATION

The optimum slit width for the multi-slit focal plane shutter appears to be of the order of 0.0001 in. A shutter with 0.0001 in. slits is required to move 10,000 in. per second to produce 10^8 frames per second. It is impractical to accelerate to, maintain, and decelerate from such high velocities with a linearly moving shutter. A rotating focal plane shutter, on the other hand, has the double disadvantage of requiring tapered radial slits and the combination of a large diameter and high rotational velocity. A method for moving the image of the shutter across the film plane by reflection from a rotating mirror was obviously a simple solution to this problem. The rotating mirror optical system in a Bowen RC-3 Rotating Mirror Camera,[4] although not adequate for this application, was available at this installation, and it was modified to take a 4×4 in. multislit framing grid and a 4×5 in. camera back.

A first lens is used to image the event on the grid. The combine event-grid is then focused by a second lens, whose image, after reflection from the rotating

[4] I. S. Bowen, *The CIT Rotating Mirror Camera* (Mod. 2) (April 27, 1945).

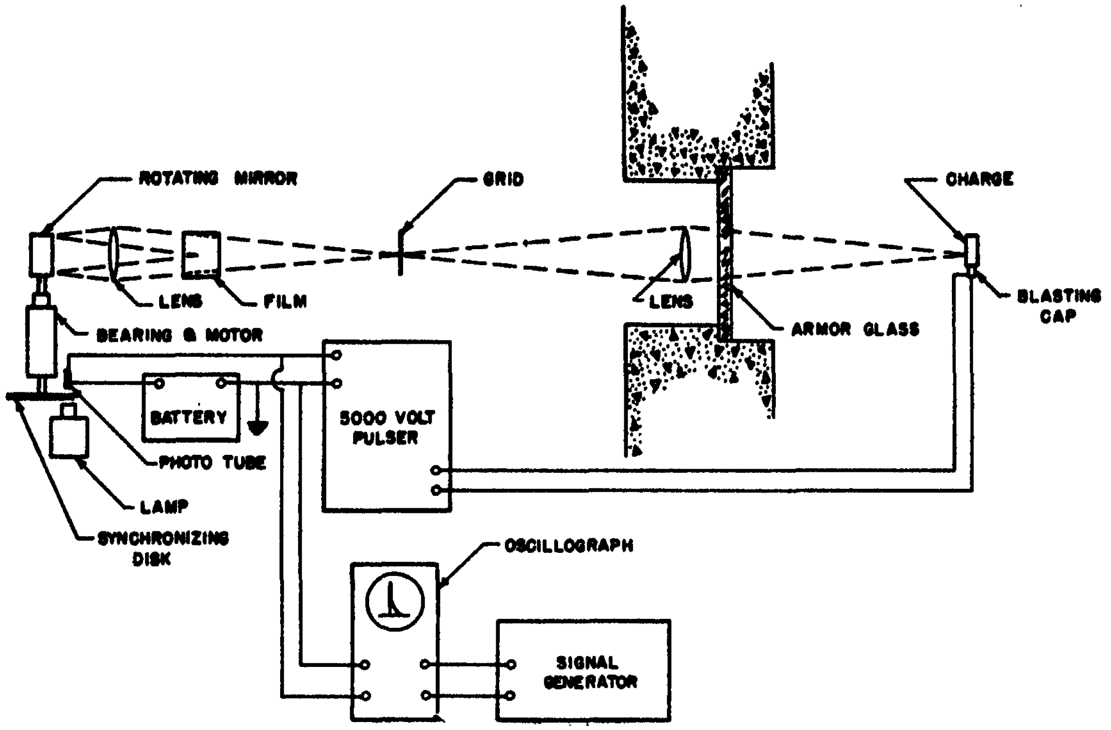

FIG. 4. Synchronizing circuit for ultra-high speed camera.

mirror, falls on the film plane as shown in Fig. 2. The photograph formed by the reflected grid differs from that formed through a grid moving across the film plane in that the latter records a varying time varying space image, while the former, by virtue of the subjects fixed position with respect to the grid, records a fixed space varying time record which is particularly suited to the studies of detonation and shock waves.

FRAMING RATE

The continuous motion of the image across the film does not form the well-defined frame of the intermittent or the rotating prism type cameras. An infinite number of viewing positions of the framing grid are possible, leaving the framing rate undetermined. However, since the exposure time of any increment of film is equal to the time it takes a slit to move its own width, the reciprocal of this time is taken as the framing rate. Thus, each consecutive frame is viewed by moving the grid one slit width per frame.

The rotational speed of the mirror being used can be varied up to 500 RPS, with a 20 in. optical arm the maximum image speed is 0.122 in. per microsecond. The exposure time with a 0.0005 in. slit at the full rotational speed of the mirror is 4×10^{-9} sec., or 2.5×10^{8} frames per second. With a 0.0001 in. slit the framing rate is 1.25×10^{9} frames per second. With suitable optics, it is believed that sufficient light will be available from detonation and shock phenomena to take pictures at the rate of one billion frames per second.

THE CONTRIBUTION OF THE GRID TO THE RESOLVING POWER AND TOTAL NUMBER OF FRAMES

The resolving power, or more exactly, the measure of the "discontinuity" across the picture because of the nature of its line structure, expressed in lines per inch, is equal to the number of slits per inch. The number of slits per inch is determined by the slit width and the number of frames required. That is, with a 0.0005 in. slit if 30 frames are desired, the space between the slits must be 30 times 0.0005 in. or 0.015 in. Such a grid will have a "resolving power" across the slits of $1/0.0005+0.015$ or about 65 lines per inch. With a 0.0001 in. slit and the same resolving power, 150 consecutive frames are obtainable.

The total exposure time, with no double exposures, is the product of the exposure time per frame and the total number of frames without double exposures. With 30 frames taken at 100,000,000 per second the total exposure time is 3×10^{-7} sec. All of the pictures taken up to the present time have been of self-luminous shock waves. Double exposures are prevented by quenching the shock wave in an atmosphere of propane at a predetermined time. However, for investigating shock velocities, it has been found convenient to get multiple exposures (Figs. 3a and 3b), which permits the measurement of distance as a function of time on each individual frame.

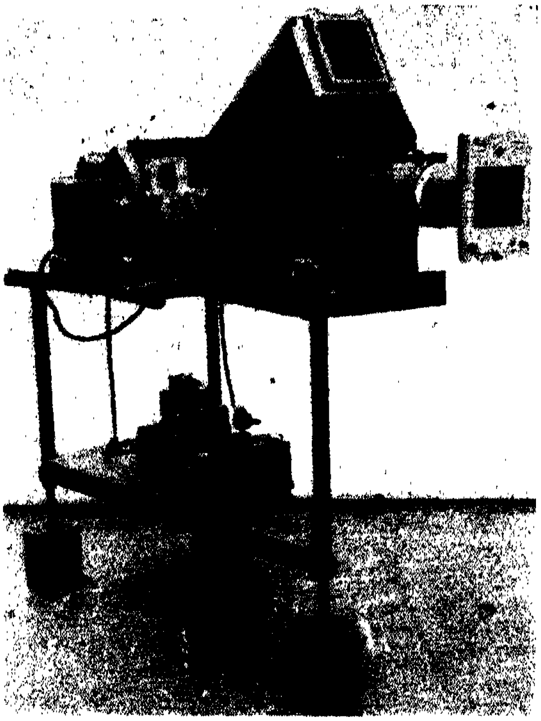

FIG. 5. ¾ front view of camera showing grid in position.

COMPONENTS OF THE ULTRA-HIGH SPEED CAMERA

The components of this camera, shown in Figs. 4 and 5 are described below.

1. First imaging lens. One of a number of high quality large aperture photograph objectives which are available is used depending on the size of the charge and the magnification of image desired at the framing grid. All of these lenses are long focal lengths (12 to 40 in.) as required by the physical set-up in the blast chamber. (Fig. 4.) 2. Framing grid. The grids most easily obtained and reasonably priced are made on opaque coated optical glass 4×4×⅛ in. by Max Levy, Photolithographers of Philadelphia. The 0.0005 in. and 0.0001 in. slits are cut with corresponding flat diamond points on a dividing engine. 3. Second imaging lens. This lens has a focal length of 360 mm. With the 1:1 magnification from the grid to the film plane the mirror can be placed to given an effective optical lever of about 20 in. Several photographic objectives with aperatures of about *f*:4.5 have been tested. A high quality process lens corrected for a flat field appears to resolve the slits most accurately. 4. Rotating mirror. The 1 in. square face octagonal mirror in the Bowen rotating mirror camera is the aperature stop of the system. A 2 in. square flat mirror designed to rotate around an axis in the plane of its face will not only take advantage of all of the light from the second lens but will eliminate the complicated form of the focal plane. 5. Film plane. A standard 4×5 in. camera back is being used as illustrated. 6. Synchronizing circuit. A hole in the wheel which drives the mirror passes a beam of light to a phototube which in turn fires a thyrotron. This thyrotron, operating at 400 volts then fires the charge directly or is used to trigger a timing circuit depending on the time requirements for the particular charge.

PHOTOGRAPHIC TECHNIQUE

Kodak Tri-X panchromatic plates have produced images of good density at exposures times of 10^{-8} sec. These plates are processed in Kodak D19 developer for 20 minutes at 60°F. Base fog "latensification" of these plates has been used to obtain good image densities with developing times as short as 8 minutes at 65°F.

REVIEWING THE FILM

Since the magnification from the grid to the film plane is 1:1, the negatives or contact printed positives can be viewed by placing the grid directly over them. Motion pictures can be observed by moving the photographic plate across the grid and frame by frame viewing is accomplished with a micrometer feed. Measurements are made at 10× magnification with a Bausch and Lomb contour projector. The sample reproductions in this report were made by enlarging through the grid properly positioned on a positive plate.

CONCLUSIONS

The fundamental features of the design described in this report indicate limitless possibilities for obtaining ultra high speed photographs of self-luminous phenomena. Probably, with the use of explosive type flash bombs, or with Edgerton type lights, non-luminous subjects can also be photographed at rates exceeding 10^8 frames per second.

Book Reviews

The Cyclotron

By W. B. Mann. Third edition. Pp. 92+xi, Figs. 31. Methuen and Company, Ltd., London; John Wiley and Sons, Inc., New York, 1948. Price $1.25.

This book is one of the series of Monographs on Physical Subjects published by Methuen and Company. It is the intention of this series "to supply readers of average scientific attainment with a compact statement of the modern position in each subject." The present volume presents a lucid and detailed account of the development and construction of cyclotrons of the prewar period. (The latest reference given is the paper published by Lawrence and his group at Berkeley in 1939 describing their 60-inch cyclotron.) In view of the fact that present attention in the accelerator fields is focused on synchrocyclotrons and cyclosynchrotrons designed to accelerate protons to energies in the billion volt range, it might have been worth while to include some remarks on these new developments in the new edition. However, as ordinary cyclotrons are and will probably continue to be widely used, the present volume is a valuable introduction to their design and operation.

The first four sentences of this book take the reader from the discovery of artificial radioactivity by Rutherford in 1919 to the development of the cyclotron and the electrostatic generator in the early 1930's. The problem of resonance acceleration is introduced with a review of the work of Wideröe and Lawrence, Sloan and others on the linear resonance accelerator for heavy ions.

The limitations of this method are discussed and serve to emphasize the ingenuity of Lawrence in overcoming these difficulties with his magnetic resonance accelerator. (It should, however, be remarked that the former method has recently been used by Alvarez to attain 32-Mev protons.) The author proceeds to describe the basic principles of the cyclotron. Some calculations and curves are given which serve to orient the reader; mention is made of the difficulties to be faced in future developments resulting from the relativistic increase in mass at high energy. Detailed consideration is then given to the design and construction of the vacuum chamber, magnet, and the r-f system. Many references are made to the work of other laboratories as well as to the work at Berkeley. The final chapter is a very brief review of typical applications of the cyclotron, or rather its products, to nuclear physics, chemistry, and medicine.

The reader who is unfamiliar with but interested in the design and operation of cyclotrons will enjoy this little (pocket-size) book. The usual textbook descriptions cannot give the reader the same appreciation of the amount of ingenuity and engineering which are necessary in order to proceed from the remarkably simple resonance formula to a beam of energetic ions.

Princeton University

Kinematic Relativity

By E. A. Milne. Pp. 238+viii, 6¼×9¼ in. Oxford University Press, London, 1948. Price $5.00.

E. A. Milne's cosmological theory, named by him "kinematic relativity," stands apart from most of the generally recognized physical theories. It has been hitherto almost inaccessible, inasmuch as the earlier work, *Relativity, Gravitation, and World Structure* (Oxford University Press, London, 1935), was dated almost the day it appeared, and a series of papers by Milne which appeared in the *Proceedings of the Royal Society* and elsewhere after 1935 were very hard to read. The present volume was written at a time when the foundations of the theory had settled down, even though Milne has continued to work out its applications in various fields of physics.

Kinematic relativity as a theory is distinguished from other physical theories primarily by its almost completely abstract, *a*-physical character. The starting point of the theory is an abstract space possessing three plus one dimensions, in which every observer is at first permitted to introduce his own frame of space-time coordinates. However, by means of an exchange of light signals, two observers can, if they so wish, regraduate their clocks in such a manner that their private times become "congruent." This expression (Milne's) denotes such a graduation of clocks that each of the two observers "sees" (with the help of light signals) the other observer's clock delayed relative to his own by the same (time-dependent) amount. Or, putting it differently: Each observer can by observations express the relationship of the other observer's time to his own by means of a function:

Observer "1": $t_2=f_1(t_1)$.
Observer "2": $t_1=f_2(t_2)$.

Here t_1 is the time kept by "1"'s clock as observed by himself; t_2 is "2"'s clock time as observed by "1". Thus f_1 is the summary of the raw data assembled by "1" who observes "2"'s clock at a distance and compares the remote clock dial with his own. Analogous meanings are attached to the symbols occurring in the second line above. The state of *congruence* is achieved when the two functions f_1 and f_2 are *the same function*. By means of regraduation, *two* observers can always achieve congruence if only the initial functions f_1 and f_2 (before regraduation) are monotonically increasing.

The next question tackled by Milne is the characterization of a *set* of observers (more than two) who are in such a relationship to each other that they can achieve universal congruence, i.e., that they can regraduate their clocks so that after regraduation any two of them use congruent time in the sense defined above. A set of observers in this state are called an *equivalence*.

Milne's basic assumption is that in the physical Universe such a set of observers can be introduced and that they are connected with the individual galaxies. Granted this basic assumption, Milne can show that in his Universe there exists a certain over-all isotropy and homogeneity.

In all that follows, it is very difficult for the reader to gauge properly the roles played by the axioms and those by the deductive proofs. At first sight, many of Milne's assumptions appear innocuous and even self-evident, so-called symmetry assumptions or, at any rate, assumptions concerning qualitative aspects of nature only. On closer inspection, the assumptions turn out to be very definite quantitative assumptions. Two examples will illustrate this point.

First, let us consider the assumption that there exists an equivalence of observers as defined previously. The power of this assumption can be studied best if we discuss it in the light of some other theory of the physical Universe, and such alternatives are provided by the special and by the general theories of relativity. Let us start with the special theory, i.e., with an assumption of a flat (quasi-Euclidean) space in which the velocity of light is a universal constant. In such a space, Milne equivalences can be constructed without difficulty. As a first equivalence, take a number of observers who are all at rest relative to each other. Given any two observers A and B, both A and B will find permanently that the other observer's clock is slow compared to his own, by an amount constant in time and equal to their mutual distance, divided by c. Another equivalence can be constructed by a set of observers stationed on all the straight, time-like lines passing through one world point. If these observers calibrate their clocks so as to show proper time counting from the world point of coincidence, or any unique function of this proper time (such as the logarithm, if they wish to provide a range for the time from negative to positive infinity), the relationship between any two observers of the equivalence will again be symmetric. If the point of convergence lies in the past, we shall have, in the language of Milne, an expanding Universe; if it lies in the future, the Universe will contract.

Now consider as our theoretical vantage point the general theory of relativity, and let us assume that light rays travel along so-called zero-geodesics. (This assumption in general relativity corresponds to the adoption of geometrical optics; it is certainly well taken if we use light of sufficiently short wave-length to permit the clear-cut transmission of signals.) Let us consider in this Riemannian space-time a situation that corresponds to the so-called Schwarzschild solution; a single particle in whose neighborhood the space is strongly curved, but so that at spatial infinity the curvature tends toward zero. In this space, we can set up an equivalence again, but in a peculiar fashion. It is well known that in the Schwarzschild solution of the field equations we can introduce "static" coordinates, i.e., coordinates in terms of which the geometry is time-independent and so that $g_{i4}=0$. However, the world lines along which x, y, and z are constant are not geodesics, i.e., a free particle will not stay permanently on such a curve, but will be accelerated toward the center $r=0$. Milne's equivalence can now be set up as a set of observers who remain permanently on these world lines, and whose clocks are calibrated to show coordinate time (rather than proper time). This prescription determines both the starting time and the rate of each clock. This system of clocks is an equivalence, but, of course, each observer must be kept at his appointed place by means of an external non-gravitational force. Whether a material particle can be kept in this state is doubtful, since non-gravitational force fields, through the resulting stress, affect the gravitational field.

We are now ready to turn to the second example. Milne "derives" the dynamical behavior of a free particle from the requirement that in terms of the equivalent observers the equations of motion of the particle must contain only elements already provided by the basic conceptual framework. These elements are essentially the present location and the present velocity of the particle. With this assumption, it turns out that the particle will remain at rest with respect to any observer belonging to an equivalence if it is at rest with respect to him initially. Substantially, this proof amounts to the theorem that in a flat space the only curves definable without the introduction of *ad hoc* elements (such as the curvature vector) are the straight lines. Now let us compare Milne's results with the result of the general theory of relativity. According to the general theory of relativity, a free test particle in the field of a Schwarzschild solution will experience acceleration even when initially at rest with respect to a coincident observer of the equivalence. The discrepancy is obvious and inescapable. Its only explanation must be sought in the basic assumptions, since the syllogisms afterward are flawless.

In this reviewer's opinion, Milne's assumptions are actually, and in spite of their deceptively innocuous form, very severe assumptions concerning the nature of the physical Universe; in all probability, the real Universe does not possess the properties ascribed to it by Milne. Milne not only assumes that the Universe is on the whole isotropic and homogeneous, assumptions that might be accepted tentatively (though recent cosmological research by Hubble, Omer, and others tends to cast doubt even on these hypotheses), but he proposes to construct a physical theory in which the only properties of space-time are those determining the trajectories of light rays. Furthermore, in Milne's theory it is not the local directions of the light cones, but the *finite geometrical figures* whose sides are either light rays (zero geodesics) or material observers of an equivalence which are to describe the entire geometry and physics of physical space-time. Interesting as this point of view may be, it appears to this reviewer to be in flagrant contradiction to the known facts about fields of gravitation. Newton's law of gravitation, the observed effects of gravitational fields on the direction and the color of light waves, the precession of the Mercury perihelion, and, last but not least, the equivalence of inertial and gravitational mass, shows conclusively that the geometry of space is tied up with the gravitational potentials (otherwise the principle of equivalence remains unexplained), and that the number of these potentials is greater than one. Just as the existence of the Lorentz force in electrodynamics shows that in the face of a Lorentz transformation the electric potential cannot be a scalar, so does the Coriolis force and the effect of gravitation on light, show that the theory of gravitation cannot get along on one potential. The very fact that the "source" of the static gravitational field is not the proper mass of the particles (a scalar), but the *relativistic mass density* (one component of a tensor), suggest that the number of gravitational potentials is 10. That under these circumstances the detailed properties of physical force fields can be derived from assumptions of homogeneity and isotropy of space alone is, to say the least, not intuitively obvious.

Milne has claimed that in his theory he cannot only explain the inverse-square law of gravitation, but also some of the most important properties of elementary particles, such as the instability of the neutron. Most of Milne's arguments in the construction of his theory reduce to the requirement, reasonable in itself, that theoretical concepts should be derivable from as small a number of independent fundamentals as possible. Thus, even though most of his basic assumptions have little to recommend them to the physicist, some of his subsequent derivations may possibly become valuable components of some other theory.

The book is organized into four parts, entitled (I) "Kinematics," introducing the concepts of congruence and equivalence; (II) "Dynamics," dealing mostly with the behavior of free particles and photons; (III) "Gravitation," deriving Newton's inverse-square law and also giving a theory of spiral nebula genesis; and (IV) "Electrodynamics," discussing besides the laws of the electromagnetic field itself atomic physics and the structure of elementary particles. This part contains a concluding chapter, "General Outlook," which serves as a nice summary of the whole book and indicates in which direction Milne proposes to go.

This reviewer has found Milne's present book considerably more readable than any of his previous work, though a full appreciation and a critical appraisal remain most difficult undertakings. For the reader who wishes to study Milne's theories thoroughly and to form his own opinions, this book can be recommended as the most authoritative presentation.

Peter G. Bergmann
Syracuse University

Der Ultraschall und seine Anwendung in Wissenschaft und Technik

By Ludwig Bergmann. Fifth edition. Pp. 748+viii, Figs. 460. S. Hirzel Verlag., Zürich, 1949. Price $13.00.

It appears from the author's Preface that the fourth edition, if its publication was actually completed, was largely destroyed in the war days of 1945. The continuation of wartime difficulties into the publication of the present edition is to be noted in the very poor quality of the paper used and of the binding. The author points out his own great difficulty in attaining more than mere titles for many of the postwar papers and makes the plea that reprints be sent to him in order that he may provide a more adequate coverage of the field in the next edition. It is to be hoped that his request may bring a generous response both for the sake of the author and for the long-range enrichment of a well-established and outstanding reference work which is unique in its field.

Without access to the fourth edition, which appears incidentally not to have been entered at the Library of Congress, the reviewer can make comparison only with the earlier editions, including the third of 1942. The expansion to be noted is extreme indeed. The author calls attention in his Preface to two new sections in the first part of the book where the excitation, demonstration, and the measurement of ultrasonic waves are treated. These sections discuss the underwater whistle of Janovski and Pohlman and the ultrasonic siren of American origin and constitute the principal changes in Part I.

The expansion in many of the later sections of the book is between two- and threefold and is perhaps most marked in Chapters III and V which deal, respectively, with the immediate application to the study of the properties of materials at ultrasonic frequencies, and with applications further afield as in instrumentation generally, direction finding, testing of materials, physical and colloidal chemistry and application for their biological and medical effects. These two fields of application, one to the study of ultrasonic properties of materials, and the other to bringing about desired effects and conditions for the chemist, the biologist, the physician, and the manufacturer, occupy in the fifth edition considerably more than half of the book.

The bibliography provides some indication of the growth of the field in the years since 1942 and of the expansion of the book from the third to the fifth edition. From 1068 references the number has jumped to 2322. A spot comparison with the Analytical Subject Index to Contemporary Acoustical Literature which is included in the 1938 to 1948 Cumulative Index of *The Journal of the Acoustical Society of America* indicates good coverage by the bibliography which is under review through 1948 so far as the field of ultrasonics proper is concerned. The vast accummulation, however, of wartime and postwar papers supported by the military services in this country and dealing with the field of underwater sound particularly, which has been released in considerable part during the past two or three years, is well covered in the J.A.S.A. Cumulative Index, but appears scarcely to be touched at all in the Bergmann book.

The book is of the encyclopedic type common among German reference works in which are given brief descriptive treatments of the findings of many authors, but with little attempt at critical evaluation of their results. It is a stupendous task to treat the material of 2300 references in a 700-page book. The reviewer has made no attempt to determine what particular postwar papers might be inferred to have been unavailable to the author except in title or in abstract form, or to judge in what way such unavailability on the part of more important papers may have led to the giving of space to lesser items.

Particularly pleasing in the present edition is to find the brief appendix on Ultrasonic Waves in Nature. A practice of inserting in the text the year along with the reference number to the bibliography would be of considerable help to the reader in a work of this sort. The reviewer finds himself writing the year of the reference in the margin beside the text as he reads along after having looked up the reference in the numbered bibliographical list at the back of the book. As a final comment the reviewer regrets that the many factors which go into the pricing of such a book should result in so high a figure.

KARL S. VAN DYKE
Wesleyan University

Hyperfine Structure in Line Spectra and Nuclear Spin

BY S. TOLANSKY. Pp. 120+viii, Figs. 29. Methuen and Company, Ltd., London, 1948; John Wiley and Sons, Inc., New York, 1950. Price $1.50.

This is the postwar revision of Professor Tolansky's well-known introduction to optical hyperfine structure and its use as a tool for investigating nuclear properties. The change from "Fine" to "Hyperfine" in the title is merely one of terminology, so that the general nature of the book remains unchanged. But it has been thoroughly revised, so that the introductory chapter and those on experimental technique, isotope effect, nuclear spins, nuclear magnetic moments, and nuclear electric quadrupole moments are largely new.

After an introduction outlining the scope and purpose of the study of hyperfine structure, a chapter is devoted to the causes of line width in spectral lines and the experimental techniques of producing lines sharp enough for hyperfine structure analysis. Chapter III, on multiplicity in line spectra, develops the notation and the elements of the theory of multiplets from the viewpoint of the vector model. The effect of a nuclear spin is next considered and then extended to hyperfine structure in many-electron spectra. A chapter is devoted to the methods for deriving term interval factors from hyperfine structure patterns and the dependence of interval factor on electron configuration and term type is discussed. This is followed by a discussion of isotope effects in hyperfine structure, including both those ordinarily classed as isotope shifts and the complications due to different isotope magnetic moments. The discussion of hyperfine structure patterns is completed by a chapter on perturbations. Then the results of these and similar investigations are discussed in three chapters on nuclear spins, nuclear magnetic moments, and nuclear electrical quadrupole moments. Finally, the book has brief appendices on hyperfine structure Zeeman effect and the single-particle theory of nuclear spin.

Throughout the book, the vector model is used almost exclusively. Quantum mechanics is only mentioned occasionally when theoretical results are quoted as needed. This is, in fact, the practice usually followed in discussions of hyperfine structure experiments. It permits the presentation of a clear physical picture of the phenomena, and rapid prediction of the effects to be expected. However, in a few places, such as the chapter on perturbations, the introduction of more quantum-mechanical ideas might have simplified the discussion.

The treatment is frequently illustrated by reference to actual experimental results, including many drawn from Professor Tolansky's own researches. In this way the student can acquire a very good idea both of the types of hyperfine structures observed and of their magnitudes. In some places details of the experimental results obscure the underlying principles to some extent, but almost always the connection is clearly brought out.

In a book of this size the author is faced with a difficult problem in the selection of topics to be included, and inevitably there will be some who would have liked to see other subjects discussed. Thus the reviewer would have liked to see some mention of the Fermi-Segrè formula for the calculation of nuclear magnetic moments from hyperfine structure, and a fuller discussion of the theory of isotope shifts in the spectra of many-electron atoms. Nevertheless, one must admire the skill with which Professor Tolansky has condensed so much material into this small book without loss of clarity.

This is still the only book on hyperfine structures in English. It will provide a good introduction to the subject for those who wish to know what hyperfine structures are about, and will serve as an excellent starting point for those planning to work in the field.

A. L. SCHAWLOW
Columbia University

Engineering Mechanics

BY A. HIGDON AND W. B. STILES. Pp. 505+xvii, profusely illustrated. Prentice-Hall, Inc., New York, 1950. Price $5.00.

The authors have set themselves the task of presenting in textbook form the accumulated material and methods of their department in a particular field and at a particular level.

The field covered is broad enough to give a beginning student in Engineering Mechanics a sufficiently wide base and yet it is restricted sufficiently that the work may be adequately covered in a two-semester course. The authors even suggest that the material of the book may be covered in a one-semester course by the omission of certain specified portions.

Of the 491 pages in the book, 227 are devoted to Statics and the remaining 264 to Kinematics, Kinetics, and Mechanical Vibrations. The material covered is basic and one may well say standard; for instance, Statics deals with Basic Concepts, Resultants of Force Systems, Centroids and Center of Gravity, Equilibrium, Friction, and Moments of Inertia; Kinematics covers Absolute Motion and Relative Motion; Kinetics includes Work and Energy, Impulse and Momentum; and a final chapter covers Mechanical Vibrations.

The presentation is highly systematic. For instance, in the chapter on Resultants of Force Systems, the articles deal with Resultant of a collinear force system, Resultant of a concurrent, coplanar force system, Resultant of a parallel coplanar force system, Resultant of a concurrent, non-coplanar force system, Resultant of a parallel, non-coplanar force system, and Resultant of a non-concurrent, non-parallel, and non-coplanar force system.

The material is developed from the relatively few hypotheses of Newtonian mechanics and emphasis is clearly placed upon the student's mastering the developments of the various phases of the subject as well as upon the solution of problems through the use of formulas. The explanations and developments are brief but adequate and the summaries of the results are clear and emphatic.

There is a profusion of problems, well-illustrated by excellent diagrams, which in general are practical and of present-day interest.

Vector notation is introduced and applied to force, linear displacement, velocity, and acceleration but not to angular velocity or acceleration, or to linear or angular impulse and momentum, and in dealing with rigid body, no vector notation is employed.

The only vector manipulations appearing are those of addition and subtraction, and special symbols have been introduced for these two operations. Also the authors employ a system of arrows to indicate directions of forces and couples and sometimes carry this symbolism along with equations of a more complicated sort to indicate the directions of the contributions of the various terms.

Since force is a vector, considerable work must always be done in treating force as such, but the present authors have done this to a minimum. They rather have emphasized the analytical method of dealing with forces, once having shown their vector character. In dealing with frames, for instance, the work is first carried out from an analytical standpoint, followed by the graphic method.

The calculus is employed in such parts of the subject as the calculation of centers of mass, of moments and products of inertia, and of frictional couples. Differential equations are employed very little as, for example, in the solution of the simple harmonic motion equation and some references are made to this solution in the chapter dealing with Mechanical Vibrations.

The treatment of kinetics is based upon Newton's laws, in particular the second and third laws and upon D'Alembert's principle which is stated as follows: "The resultant of the external forces acting upon a system of particles is equal to the resultant of the effective forces (*ma* values) of the particles of the system." This is extended when needed as follows: The sum of the moments of the external forces with respect to the axis of rotation is equal to the sum of the moments of the internal effective forces.

The above principles are employed directly to show that the mass center of a system behaves as if all the external forces of the system were applied to it and that in the two-dimensional case the sum of the moments of the external forces is equal to the product of the moment of inertia and the angular acceleration for a fixed axis or an axis through the center of mass or for an axis that possesses no component of acceleration normal to the line joining it to the center of mass.

It is shown that the whole kinetic energy of a rigid body in the two-dimensional case may be regarded as the linear kinetic energy of any point plus the angular kinetic energy relative to this point plus two terms involving the component velocities of the point, the angular velocity of the body etc., and that if the point is the point is the mass center the last two terms vanish.

Linear and angular impulse and momentum are introduced and the principles of conservation of both linear and angular momentum are brought out.

The general procedure throughout the book is to give a theoretical development of some limited part of a subject, then to work an example when that would be helpful. Whenever possible specific rules for the attack and solution of problems have been listed.

In the opinion of the reviewer, the book presents a good selection of subject matter in the field of Engineering Mechanics but this is secondary to the fact that the book sets forth a process of presenting this subject matter to students at the particular level. In this attainment it would seem that the authors and their associates should be complimented.

MERIT SCOTT
Pennsylvania State College

Albert Einstein: Philosopher-Scientist

BY P. A. SCHILPP. Pp. 781+xvi. Library of Living Philosophers (Vol. 7), Northwestern University, 1949. Price $8.50.

This is the seventh in the series of volumes on living philosophers in which contemporary thinkers praise, criticize, and condemn, and in which the philosopher "replies to his critics." There is also an autobiography and a bibliography. The choice of Einstein as a philosopher was an eminently sensible one; only a mind ignorant of philosophical traditions can believe that a great theoretical physicist can fail to be an eminent philosopher as well.

The contributions of the volume are actually of three sorts. First there are papers that comment on Einstein's special and general theories of relativity *as such*; these papers consider in the main the logical structure of the relativity theories and their relationship to other theories in physics, particularly quantum theory (Sommerfeld, de Broglie, Pauli, Born, Heitler, Menger, Infeld, and von Laue). Second, there are papers that are concerned with the philosophical implications of Einstein's physical theories; these either consider the impact he had on some school (e.g., Frank on positivism, Wenzl on critical realism) or set of schools (Ushenko on contemporary philosophy), or they consider certain philosophical problems that are posed by Einstein's work (Rosenthal-Schneider, Bohr, Margenau, Reichenbach, Bridgman, Lenzen, Northrop, Bachelard, and Dingle). Finally, some contributors have offered extensions of Einstein's theories, or suggested modifications (Robertson, Milne, Lemaitre, and Gödel).

Einstein's reply, though somewhat loosely written, is extremely interesting because it presents in very lucid form his already well-known attitude with respect to quantum theory. Boiled down to its essentials, Einstein's argument runs as follows:

(1) Quantum-mechanical description is a description of *ensembles* of systems (p. 71).

(2) A *complete* description includes not only an account of ensembles, but also of individual systems (p. 667).

(3) The programmatic aim of all physics is a complete description (p. 667).

Whence, it follows that quantum mechanics does not, by itself, satisfy the aims of physics.

To judge from the contributions of Born and Heitler, the majority of the adherents to the quantum faith tend to deny (1); in effect, they object to the "classical" notion of individual systems. Specifically, they do not believe that a system can be represented in common-sense (intelligible) terms, so that the "interpretation" of what is going on cannot be expressed in terms of a difference between, let us say, a single particle and an ensemble of particles. This attitude does deny one tradition of physics: to predict intelligibly, if by "intelligible" we mean "what is generally understandable." Einstein does an excellent job of showing that there is no "intelligible" meaning of certain concepts of quantum description (e.g., time of decay of a radioactive atom), *if* quantum mechanics is not considered as a description of ensembles. But it is not clear that his argument will convince the quantum mechanist, who is presumably satisfied with a program of predictability, regardless of whether or not there is a common intelligibility to all the concepts used.

Einstein's reply is also interesting because it shows beyond any doubt his present adherence to neo-Kantianism (experience requires *a priori* categories, which, however, are not "fixed").

Finally, it is strange that not one pragmatist contributed to a volume in honor of a philosopher, the implications of whose philosophy is (to many pragmatic minds) inherently pragmatic.

The Meaning of Relativity

BY ALBERT EINSTEIN. Third edition. Pp. 150. Princeton University Press, Princeton, New Jersey, 1950. Price $2.50.

The successive editions of this well-known work differ only in that for each an appendix is added covering significant advances since the previous edition. It does not appear necessary, therefore, to review at length the main body of work, which was first published in 1922. Here the reader will find a concise, technical account of the theories of special and general relativity. An outstanding feature is the clear, although brief, presentation of the fundamental concepts from which Einstein derives his theories. The title describes this material very well indeed, provided one regards it as referring to the foundations rather than the implications of the theories.

The first appendix, added in 1945, contains brief comments on a number of advances that had been made over the preceding 22 years and a somewhat more extended discussion of the author's current views concerning cosmology. Here Einstein treats several homogeneous but non-static models of the universe based both on his feelings as to the proper form of natural laws and on experimental data.

The last appendix of 15 pages is concerned with an extension of the general theory of relativity so that it will cover both gravitational and electromagnetic phenomena. A non-symmetric tensor is used as the metric tensor and as the means of correlating the covariant and contravariant components of tensors. The absolute differential calculus needed to deal with such a situation is then treated. Finally, field equations are set up on the basis of concepts of simplicity and symmetry and the requirement that they contain the usual general theory of relativity. It then turns out that the field equations contain new terms originating from the skew-symmetric part of the metric tensor and it appears that the aim is to use these to give something that will reduce to Maxwell's equations under suitable circumstances. The reviewer feels that the average physicist will not find in this appendix any new physical ideas of the kind that made both the special and general theories of relativity so important. It appears that further research and a more extensive discussion of the meaning of the equations will probably be needed before this hope can be realized.

The publishers are to be complimented on turning out a book which is pleasing to the eye, being printed with relatively large type on good paper. However, the number of annoying, although trivial, typographical errors seems large for a third edition.

Leverett Davis, Jr.
California Institute of Technology

Magnetism

By E. C. Stoner. Pp. 136+vi, Figs. 20. John Wiley and Sons, Inc., New York, 1948. Price $1.25.

This is the fourth edition of a small book (131 pages) first published in 1930, and intended, in the words of the author, "for those to whom the subject is not new." The work, in fact, turns out to be a discussion of selected topics in the field of magnetism, essentially the same as in previous editions, and at a level suitable for graduate students in physics and research workers in related fields.

The book is divided into five chapters whose contents are briefly as follows: Chapter I takes up in very sketchy form the quantum theory of atomic energy levels, the quantum numbers n, l, m, s, j, the Landé g-factor, spectroscopic notation, and the Stern-Gerlach version of atomic beam experiments. Chapter II is devoted chiefly to the theory and measurement of the diamagnetic susceptibility of neutral and ionized atoms. A few pages are allotted to molecules and molecular crystals. Chapter III contains a discussion of paramagnetism, primarily of the transition element and rare earth ions. Chapter IV, by far the longest in the book, reviews ferromagnetic phenomena. Chapter V is entitled "Magnetic Properties of the Elements," but actually deals with metals in general, particularly with the degenerate free electron gas, and with partly bound electrons.

The good points about this book are that it has all the virtues of the earlier editions, plus some modifications, particularly the inclusion of a few references to comprehensive works and review articles which can put the student on the trial of many recent original papers. The chief criticism is that the book still is largely written from the point of view of 20 years ago, and is rarely up to date. A few instances will make this situation clear.

In discussing atomic moments, no mention is made of the Lamb and Rutherford experiments, or of the explanation for the difference between the spin and orbital magnetic moments of the electron. At the end of this section, a paragraph on nuclear moments begins, "It should perhaps be mentioned here that there is now definite evidence that the atomic nucleus may have a spin moment associated with it, as was first suggested by Pauli." In the chapter on diamagnetism, there is no mention of superconductivity. In the chapter on paramagnetism, the Weiss magneton is still used in describing experimental results, and no mention is made of microwave absorption. In the chapter on ferromagnetism, there is no mention of recent work on domain structure, or on the properties of the ferrites, or on permanent magnets. There is no mention of antiferromagnetism. In the chapter on the magnetic properties of the elements, six pages are devoted to Kapitza's work on the change of resistance of metals in strong magnetic fields, while Rabi's magnetic resonance technique and its derivatives are not even mentioned. There is nothing on the change of resistance of semiconductors in a magnetic field, or on the Hall effect.

Perhaps all this amounts to the complaint of a hungry man that the sandwich he is offered is not a multi-course dinner. But without a doubt, the bread for this sandwich was sliced quite some time ago.

Massachusetts Institute of Technology

Physical Principles of Oil Production

By Morris Muskat. Pp. 922, profusely illustrated. McGraw-Hill Book Company, Inc., New York, 1949. Price $5.00.

This book deals with problems which are of paramount importance in the recovery of hydrocarbons from oil or gas reservoirs. The occurrence of hydrocarbons in oil bearing rocks is discussed and the basic types of reservoirs are explained. A description is given of the behavior of the physical properties of petroleum fluids. To those accustomed to describing fluids and gases by the classical laws, it will be interesting to learn that the hydrocarbon mixtures which occur in nature show phase diagrams with very peculiar properties. The physical constants of the rock material into which the oil is imbedded and which have a bearing on the recovery of oil are explained. The concepts of porosity and permeability for single fluids and of the relative permeability for multiphase flow are clearly set out. Based on these explanations are mathematical considerations which deal with the production or the recovery of the fluids from reservoirs. These studies are grouped depending on the origin of the energy which forces the fluids into the well bore (General Reservoir Mechanics, Gas Drive Reservoirs, and Complete Water Drive Reservoirs). The "secondary recovery" methods are discussed where water or gas is injected. The depletion of condensate reservoirs is explained and the final chapter deals with the effect of well spacing on oil recovery.

The beauty of this volume lies in the fact that it is not just an enumeration of empirical formulas. For every problem, the basic physical concepts and equations are set out. From them mathematical deductions are obtained as rigorously as possible. In many instances, of course, simplifying assumptions have to be made in order to be able to handle the complicated mathematics. Such simplifications are clearly pointed out and their influence on the rigorous solutions is estimated.

For the petroleum engineer, this volume contains an almost inexhaustible supply of information and thoughts which cannot help but stimulate. For the physicist, a glance at this volume will be an eye-opener to the multitude of problems which exist in oil production and which can be successfully handled with the tools of physics and mathematics.

Gerhard Herzog
The Texas Company

Trilinear Chart of Nuclear Species

By William H. Sullivan. John Wiley and Sons, Inc., New York, 1949. Price $2.50.

The trilinear chart of nuclear species represents the most ambitious effort so far to assemble in easily accessible form the "physical constants data for all experimentally identified nuclear species (nuclides), known from information available by approximately June, 1949." The collection of nuclear data has become a formidable task, and the preparation of the chart might not have been possible without the support received by the author from the National Research Council and the Atomic Energy Commission. On the whole, the chart is very successful. The trilinear coordinate grid chosen makes it very compact, and what is more important, it is remarkably free from error. What additions, changes, and deletions seem desirable are largely due to the very rapid progress in our knowledge of nuclear properties, even in the short time since the chart went to press. The chart is preceded by three pages of explanatory material. Each nuclide is represented by a hexagon. The naturally occurring nuclides are indicated by a pale green field on which the black print stands out very clearly. Artificially produced nuclides are shown on a lavender field. The choice of this color is not very fortunate: the black print is often rather illegible on this background. Why not simply use a white background for artificially produced nuclei, and add a dash of color, e.g., a red border, to indicate radioactive nuclei, artificially produced or naturally occurring? The chart is likely to be brought up to date at frequent intervals, and the greatest simplicity seems desirable. From this point of view, some of the data now contained in it could well be left to tabular summaries. Besides much useful information (e.g., atomic masses, spins, magnetic moments, fission yields, thermal neutron cross sections, properties of radioactive nuclides), there appear some entries which are not vital. Thus "when it is known experimentally that a naturally occurring nuclide is produced artificially, a horizontal lavender strip is placed at the bottom of the hexagon in the area reserved for showing the modes of production." Of course this is not done consistently, and if it were done we might soon expect all naturally occurring nuclides to be so distinguished, from the proton up which has recently been shown to be produced "artificially" when a neutron decays! The modes of production might well be left out in all cases where a nuclide is definitely identified as to charge and mass. The numbers of entries of this type will become too large as time goes on, and even now they represent much information which has more historical than practical value and would better be left to tables with references. The symbols A, B, $\cdots G$ denoting the degree of certainty of the information given might also be sacrificed and replaced by appropriate question marks where needed. At the same time some of the more doubtful material might be left off the chart. The space saved might be used for other important entries, e.g., the total energy release in a radioactive transformation. As a reliable and time-saving guide the trilinear chart should prove invaluable to all connected with nuclear science, be it in research or teaching.

M. Goldhaber
University of Illinois

Crystals and X-Rays

By K. Lonsdale. Pp. 199+viii, Figs. 138+xiii. D. Van Nostrand Company, Inc., New York, 1949. Price $3.75.

The author begins her Foreword: "This is not a textbook for advanced students of x-ray crystallography, although I hope that they may learn something from it. It is based on a course of public lectures given at University College, London, in the spring of 1946, and is designed to interest those who do not now use x-ray crystallography, but who might well do so; and to instruct those who do use x-ray crystallographic methods without altogether understanding the tool that has been put into their hands. If I can persuade these two classes of people to pass on from this book to textbooks which are much more thorough, much more precise and much more specialized, I shall have accomplished an even better task than I set out to perform."

Those who have heard Dr. Lonsdale lecture will remember her disarming expositions of complicated topics. According to the listener's predilection she sends him off comfortably warm with unanticipated comprehension, or else impatient to investigate the fascinating techniques and challenging problems she has suggested. This brief book is written much as the author talks, cursive, pressing continuously but without haste from one development to the next, unambiguous, ignoring no essential matter, authoritative in theory, experienced in the labor, imaginative as to the possibilities.

The seven chapters are titled: Historical Introduction; Generation and Properties of X-Rays; The Geometry of Crystals: X-Ray Methods of Investigation; Geometrical Structure Determination; Determination of Atomic and Electronic Distribution; Extra-Structural Studies; The Importance of the Study of Crystals.

The text contains almost evertything that a tutor should have to say to an acute and self-reliant beginner in x-ray diffraction research. Only perhaps in the second chapter does one sense an omission; by comparison with the detailed discussion of high voltage power supplies very little is said about cameras and spectrometers. The sloughs of tedium and the mazes of trial-and-error are pointed out in fair warning. Thus the discussion of lattice planes includes an explicit and general formula for interplanar distance in terms of crystal lattice constants; I should not like to derive or use this particular formula; yet it makes clear to the neophyte that crystal geometry is elementary, that it is complicated, and that he had better ask for a girl and a calculating machine. Many formulas are considerately presented without a mathematical derivation; but the physical principles are explained, and no reader should be left mystified as to why, for example, the intensity of reflection by a perfect crystal must be calculated with a different formula from that for a mosaic.

Thickly interspersed figures are an essential part of the discussion and sometimes extend it. Thirteen plates, most carrying six reproductions of diffraction photographs, illustrate a variety of phenomena. They are uniformly successful in retaining even the more delicate details referred to in the captions.

Only a few literature references appear in the text and none in footnotes. The legends for many of the figures do contain references. At the end of the book is a list of some 42 "Textbooks for Reference," with nothing whatever (now that his beginner's luck is used up) to help the student choose his next reading. Two or three of the books in this list one would like charitably to guess that Mrs. Lonsdale had never examined.

A number of misleading or incorrect statements appear, but mostly where they generate no further error. It is twice implied that a hot-cathode high voltage rectifier owes its low voltage drop to a vacuum inferior to that in an x-ray tube. The short wavelength limit is said to correspond "to the case where the bombarding electrons give up *all* [italics by the author] their kinetic energy in the production of x-rays." On anomalous scattering: "When an atom has been profoundly disturbed by the removal of an inner electron and is trying to readjust itself it cannot be expected to scatter 'normally'." The formula for integrated intensity on page 118 and in a minor factor that on page 116 are incorrect. Occasionally the author oversells her specialty: "The development of x-ray analysis to give electron density contour maps has led to the realization that many compounds are not completely ionic, nor are they wholly covalent."

I have recommended this book to a few members of the group to whom it is directed; for example, to a young M.D. engaged in research who is scientifically well trained, very slightly experienced in x-ray diffraction, but curious as to its usefulness for his own problems; and also to an isolated research chemist forced to employ x-ray diffraction whether trained for it or not.

Their reports reinforce my own estimate that Mrs. Lonsdale has achieved her purpose very well indeed. Her book can be recommended confidently to scientifically trained executives, research directors, and research workers who wish with the minimum physical effort to decide on sound grounds for themselves the costs and probable rewards from the use of x-ray diffraction. It should be studied also by those vicarious users of x-ray diffraction who rely on results obtained by specialists in the field. It will not often be chosen as a textbook or for reference; yet it is not out of place in the library of the specialist or the student. It is refreshing to read it through, and one is indeed almost certain to learn something.

J. H. Sturdivant
California Institute of Technology

Lehrbrich der Theoretischen Physik

By Walter Weizel. Pp. 771, Figs. 270. Verlag., Julius Springer, Berlin, 1949. In German.

Professor Weizel's textbook in theoretical physics must surely stand as one of the most impressive of its kind ever to be attempted, if for no other reason than its remarkable comprehensiveness. Merely to list the subjects covered in the first volume requires almost ten printed pages. The volume itself is 771 pages long; and a second volume is promised, whose indicated contents are such that the number of pages might very well be doubled.

The book is characterized by extreme systematization. In the first place, the division of the subject matter into two volumes is arrived at by an arbitrary rule, rather rigidly adhered to. The first volume is intended to contain all those subjects in theory which can be treated without knowing anything about the molecular or atomic structure of matter—the "macroscopic" theory of physics. The second volume is to supply the subjects here omitted. Thus, while the first volume includes special and general relativity, along with point dynamics, rigid dynamics, continuum dynamics, electrodynamics, optics, and thermodynamics, we must wait until after we learn quantum theory before we are told about the kinetic theory of gases in the second volume. This arrangement of subject matter, though unconventional, is not necessarily bad; however, one can point out places at which this preoccupation with system prejudices the understandability. For example, in going over from the electrodynamics of the vacuum to that of material media, the author simply introduces the macroscopic constants of the medium in the most arbitrary way. In text books written 40 years ago this was indeed standard practice. The result was usually a deplorable confusion about the meaning of the macroscopic fields, untold arguments about the "difference between B and H," etc. Today we know how the macroscopic fields are to be derived from the microscopic ones and we see how this procedure rips the veil of mystery that otherwise covers the subject.

Exactly the same kind of criticism may be made of thermodynamics in which the concept of entropy is used long before one studies the microscopic theory which gives the notion of entropy vivid meaning.

The book is aimed at a level of mathematical skill corresponding roughly to that of a college senior or beginning graduate student. Each section begins with a short synopsis of the material covered and a list of definitions of symbols. The text is fairly condensed; long conversational passages are rarely resorted to. The derivations are clear and well organized.

In point dynamics one learns, for example, about the translation and rotation of a rigid body, the Hamilton-Jacobi equation, the transition from the Hamilton-Jacobi theory to wave mechanics. Not much is to be found on the three-body problem or on the normal modes of vibration of general systems. In optics one finds a condensed but comprehensible treatment of the geometrical optics of compound systems, of Fresnel and Fraunhofer diffraction, and of crystal optics. These brief remarks are intended only to give some notion as to the degree of completeness with which the various fields are treated.

The work would seem to be quite useful as an "encyclopedia" —a convenient reference work for the student, where a large body of derivations and formulas are to be found. It is somewhat less useful as a textbook, at least to my taste. The author points out in an opening section that a theory is intended as a means of coordinating or ordering the experiments in a certain field. If so, then an account of a theory can hardly be complete without frequent, or continual, reference to the experiments which one is trying to describe. In fact, one finds very few such references to experiment in the book. The theory is usually put forward in an absolute, or dogmatic, way. In particular, I could not find (in my sampling of the subjects covered) any criticism of the theories presented, any observation that a given theory was weak or defective and might possibly require modification in some particular respect.

No exercises are supplied for solution by the student.

Some errors are present but they seem to be very few and do not interfere with understandability.

S. M. Dancoff
University of Illinois

Low Temperature Physics

By L. C. Jackson. Pp. 130+vii, Figs. 33. John Wiley and Sons, Inc., New York, 1948. Price $1.50.

Professor L. C. Jackson of Bristol, England, is well known in this country as one of the leading experimental physicists in the field of low temperature research on the properties of matter. Having done research at Leiden and visited many laboratories in this country and abroad, he has been able to write a monograph which contains an amazing amount of information. This little pocket edition is ideal for someone who wants to get an idea about what scientists are doing in this field of physics. It is well written and it is well balanced with respect to the several subjects which are presented. It very well represents the state of low temperature physics as the war ended.

The surprise comes to this reviewer when he thinks back to the period of the close of the war and sees the changes made in low temperature physics since then. In this country nearly 25 new laboratories have been built, and the quantity and quality of research is most exciting. Such things as the liquefaction of the isotope He_3 and of tritium, the use of microwave radiation to study low temperature conductivity and to study electronic and nuclear magnetic induction are but a few of the new steps taken. Professor Jackson would be the first to admit that his book already needs revision. Indeed, his own work on liquid helium should be included in any account of this field of physics.

In this country the liquefaction of helium is done most widely by use of the Collins cryostat which uses the Claude method. We understand now, due to the work of J. de Boer, the quantum nature of the light gases and how the virial coefficients depend on temperature. The theoretical work of Tisza on liquid helium was years ahead of that by Landau and moreover Tisza properly understood that there was to be expected a temperature wave in the superfluid phase of liquid helium. These things would appear in such a revision. The section on electrical conductivity is very good. We do not agree about the specific heat humps which have been observed having an explanation by the so-called Schottky theory. Also we do not agree that at extreme low temperatures the paramagnetic salts exhibit true ferromagnetism; rather it resembles antiferromagnetism with falling susceptibility with lowering of temperature. And of course we now know that ferromagnetism is characterized by the growth of domains, by the movement of domain walls rather than the abrupt reorientation of a given domain. Such is the nature of progress.

C. F. Squire
Rice Institute

Physiology of the Eye, Vol. I, Optics

By Arthur Linksz. Pp. 334+xii, Figs. 137. Grune and Stratton, New York, 1950. Price $7.50.

This is the first volume of a set of three by Dr. Linksz on the subject of physiological optics. It is divided into three parts, namely, physics of light, 73 pages; geometrical optics, 200 pages; and optics of the eye as an image-forming mechanism, 45 pages. Volume I contains a detailed, but rather elementary, exposition of geometrical optics followed by a discussion of its applications to the theory of ophthalmic lenses and to the lens system of the human eye. The level of presentation of the subject is about that of college physics, but each topic is discussed at much greater length than is customary in such textbooks.

The style is that of a lecturer, repeatedly arguing with an imaginary listener who has learned some optics from a standard text and supposes that he understands things only because he can name them. Dr. Linksz frequently startles this imaginary listener into attention by making use of fantastic statements which seem to contradict commonly accepted knowledge. For example, he makes much ado about a thesis that plane mirrors do not form images. After investigating what they actually do to light, he states that they merely "displace objects optically." At the conclusion of some 14 pages on the peculiar nature of this displacement, he finally concedes that one might use the common term "virtual image" to identify this effect. One assumes here that he is satisfied to have cleared up the meaning of virtual images. But, later on, he repeatedly shows an evident allergy for this common term in discussing images formed by curved mirrors and lenses. He overlooks the fact that the word "virtual" is a brief and accepted equivalent of his phrase that the light "could have come" from a certain region of space as far as an eye or other optical system is concerned which receives the rays.

In the reviewer's opinion, this kind of quibbling about accepted terminology, of which the above is one example, is overdone in this text. It repeatedly makes one wonder if the author knows what he is talking about. Usually one finds, however, after reading many pages, that he really does understand the situation, and explains it very well, but insists only on some novel terminology of his own. Without his lengthy explanations, his terms are usually more misleading than those in current usage.

In his very brief discussion of the nature of light, the author shows that he is not so well informed in regard to physical optics as he is in the field of geometrical optics. Thus he states that the success of Young's experiment depends on the production of two waves of exactly equal intensity. He also states, in connection with the two-calcite experiment, that if one ray from the first calcite is isolated by some means, it will not pass through a second calcite if its axis is at right angles to that of the first. (He should examine the Wollaston double-image prism.) Of course, such misconceptions have nothing to do with ophthalmic optics, the principal subject of this book.

The treatment of distortion by prisms and lenses is particularly good, the refraction of skew rays being explained with the aid of several excellent figures. There is a good discussion of coma and astigmatism, but a mistake is made in saying that the distance between the astigmatic foci decreases with the aperture.

On the whole, this book is an accurate, though often unconventional, treatment of geometrical optics. It is clearly and interestingly written and is copiously illustrated by good figures. It may be used profitably in the study of the simpler types of ophthalmic lenses (there is nothing on bifocals) and as a foundation for the study of physiological optics.

Joseph Valasek
University of Minnesota

Mechanics, Statics and Dynamics

By Merit Scott. Pp. 394+vi, Figs. 249. McGraw-Hill Book Company, Inc., New York, 1949. Price $4.50.

In his Preface, Professor Scott states that the purpose of his book is to provide a classroom text, as well as a reference book, able to serve as a bridge from the first-year course in college physics to work making use of mathematics going beyond calculus. The book is intended to cover a full year's course, and the 25 chapters are evenly divided into two distinct sections on statics and dynamics.

The first eight chapters of the text deal with vector algebra, conditions of equilibrium, and applications of statics, characterized by the chapter headings Frames, Work and Virtual Work, Moments and Products of Inertia, and Friction. In Chapter 9 (Elasticity) the author succeeds in elucidating the concepts of stress and strain with a minimum use of partial derivatives. The next two chapters (Strings and Rods under Normal and Shear Strains, and Structure, Beam and Column) deal with applications and accentuate the use of energy considerations. Ordinary differential equations of the fourth order of necessity occur, but their treatment is very clear. Chapter 12 (Mass Field Strength and Potential) again avoids as far as possible the use of partial derivatives and of line integrals. A chapter on stability concludes the first part on statics.

The discussion of Kinematics is followed by a chapter (15, Dynamics and Energy) of only eight pages, dealing with the principles of dynamics. Special problems are then treated in four chapters labeled Motion in One and Two Dimensions, Motion Subject to Resistance, Vibrations. Chapter 20 (Orbital Motion, Central Forces) gives an easily understood, though short, discussion of planetary motion. The conservation theorems and rigid body motion are taken up in Chapters 21 (Equations of Motion) and 22 (Kinetic Energy and Energy Equation). Interesting applications, including a discussion of vibrations of beams and of air plane resistance are touched upon in the two chapters on Oscillations and on Initial Motion, Impulses and Collisions. In the last chapter (25, Three-Dimensional Mechanics), Euler's equations are derived, and the precession of a top is dealt with. A discussion of line bound vectors is marred by the introduction on page 374 of the notion of "whole angular momentum," i.e., comprising linear as well as angular momentum of a rigid body.

The selection of topics made by Professor Scott shows his appreciation of that great tradition in mechanics which is exemplified by Lamb's three volumes on Statics, Dynamics, and Higher Mechanics.

Many problems are attached to each chapter and much space is devoted to a lucid and simple discussion of problems. Many good diagrams clarify the presentation, and all notations and abbreviations are collected and defined on the first few pages. Teachers of intermediate mechanics will welcome the wealth of answered problems; this feature, as well as ready reference to definitions, may prove valuable to men planning to use Professor Scott's book for reference purposes in their later work in technical mechanics.

In the first two-thirds of the book problems considered in the general physics course are taken up at the beginning of almost every section, and are carefully treated again by means of calculus methods, thus providing good continuity with the basic physics course. The treatment seems to be lucid, except for occasional long groups of equations caused by writing out all intermediate steps. Professor Scott's book appears to be a first-rate text for a basic mechanics course for engineering physicists or engineers given within a physics department, providing in particular excellent practice in problem work.

However, the fundamental ideas of dynamics regarding the equations of motion and the conservation principles do not stand out in his treatment, but are somehow submerged in the great mass of carefully treated special cases. A further drawback is Professor Scott's reticence about the physical basis of mechanics. On page

214 he says: "It is supposed that the reader already possesses a considerable familiarity with Newton's laws so that no comprehensive discussion is necessary," and after a few lines about the classification of forces he concludes his discussion in the basic chapter on dynamics with the words: "The philosophy of these laws is wholly untouched here, except to remark that they are generally regarded as resting upon an experimental basis . . . it is *accordingly considered that the entire subject of dynamics* springs from an experimental basis formulated as Newton's laws." No mention is made of the problems raised already by Mach and others concerning the definition of mass and force.

It is indicative for the tenor of the book that the word atom is not mentioned and that, e.g., the obvious applications of hyperbolic orbits to Rutherford scattering are not touched upon. Similarly, the term "primary frame of reference" appears only in a footnote on page 217. Apparently, the author aims to present the methods of solving dynamical problems without any regard to the development of other fields of physics during the past 50 years.

This reader feels that the value of this text would be greatly enhanced if the clear presentation of the elements of classical mechanics were complemented by some applications of mechanics to problems of interest in modern physics, and in particular, by a stronger emphasis on the ideas necessary for an understanding of the structure of mechanics. Professor Scott's approach might yet be the best way to present mechanics to students who are not primarily interested in the newer developments but who should nevertheless get acquainted with the well-established techniques of solving mechanical problems.

F. T. Adler
University of Wisconsin

The Transuranium Elements

Edited by Glenn T. Seaborg, Joseph J. Katz, and Winston N. Manning. National Nuclear Energy Series Division IV, Vol. 14B. Part I, pp. 859+xxxvi, Part II, pp. 872+xii. McGraw-Hill Book Company, Inc., New York, 1949. Parts I and II. Price $15.00 (not sold separately).

This work consists of more than 150 original research papers dealing with the transuranium elements and describes a truly Herculanean accomplishment. The papers are devoted to four of the transuranium elements, neptunium, plutonium, americium, and curium, cover investigations begun as early as 1940, and include work done in very recent months. There are many more papers concerning plutonium than the other transuranium elements and in turn more papers dealing with neptunium than americium and curium. Several papers on radium, actinium, thorium, protactinium, and uranium are included for reference convenience.

The subject matter of the papers ranges all the way from nuclear physics to analytical chemistry. In Part I twelve papers are concerned with the production of elements 93 and 94, the occurence of 94 in nature and the nuclear properties of 93 and 94. Most of the remainder of the papers have to do with various chemical aspects of plutonium, covering a diversity of topics such as absorption spectra of various plutonium solutions, magnetic susceptibility of plutonium in various oxidation states in aqueous solutions and vapor pressure of plutonium halides. Part II contains about 29 papers dealing with nuclear aspects of plutonium and neptunium and also includes several papers on nuclear properties of actinium and radium. There is also a paper which is concerned with the products of deuteron and helium ion bombardments of Pa^{231} and a paper on the half-life of thorium 227. The remainder of the papers are concerned with various chemical and physical properties of plutonium and neptunium compounds.

The papers vary considerably in the extent of their coverage of a given subject. Thus Paper 16.8, describing a 48-channel pulse-height analyser for alpha-energy measurements, by A. Ghiorso *et al.*, is some 80 pages long, lists 88 references, and has tables giving decay periods and energies for alpha-emitters, as well as complete circuits for the pulse-height analyzer. Paper 6.40, on the thermodynamic properties and high temperature equilibria of plutonium compounds, by L. Brewer *et al.*, is 25 pages in length, lists 51 references, and contains much valuable data. Some of the other papers, however, are rather too short, and not very informative. However, the general tone is excellent.

The typography is good and all figures are beautifully executed. An author index is given, and many of the articles are accompanied by extensive lists of references. However, this reviewer feels that the volumes would have been very greatly improved by a subject index which is unfortunately lacking.

The volumes should be very valuable to anyone interested in the field and will no doubt form the basis for a more integrated treatise at some future time.

Robert D. Fowler
Johns Hopkins University

Electronics-Experimental Techniques

By William C. Elmore and Matthew Sands. Pp. 417, Figs. 182. McGraw-Hill Book Company, Inc., New York, 1949. Price $3.75.

This book, one of the National Nuclear Energy Series, is concerned with the developments in the theory and practice of design of amplifiers and associated equipment that were made at the Los Alamos laboratory during the war years. No one familiar with the art of pulse amplifier construction as practiced by the average physicist before the war can deny that large advances in technique and general understanding have occurred. No small part of this advance originated at Los Alamos with the authors of the present book and their co-workers, making the present book a welcome and useful addition to the literature. It is stated in the preface that no material developed after 1946, and no circuits especially applicable to weapon technology, are included. Within these limits a well-chosen list of topics is presented. The chapter headings indicate the general scope: (1) Circuit Components and Construction Practice, (2) Circuit Elements, (3) Voltage Amplifiers, (4) Electronic Counters, (5) Oscillographs and Associated Equipment, (6) Test and Calibration Equipment, (7) Power Supplies and Control Circuits. The descriptions of the various circuits are in every case sufficiently detailed to permit construction of a working unit from the information given. In addition, a reasonable amount of theoretical background material is included.

The style is clear and readable and the book appears to be commendably free of errors and misprints. The reproduction by the lithoprinting process has no doubt contributed to this reduction of errors by reducing the number of materializations the text goes through between author and book store. The process has also resulted in a very attractive format at a welcome moderate price. Without a doubt this book belongs in the reference library of everyone concerned with the design or building of pulse amplifiers.

University of Rochester

Radioactive Tracer Techniques

By G. K. Schweitzer and I. B. Whitney. Pp. 241+vi, Figs. 13. D. Van Nostrand Company, Inc., New York, 1949. Price $3.25.

This book is intended to "serve as a guide for laboratory work and instruction in the use of radioactive tracers." The Table of Contents shows the topics treated: Chapter 1, Radioactive Hazards; Chapter 2, Operation of a Radiolaboratory; Chapter 3, Construction of a Radiolaboratory; Chapter 4, Working in a

Radiolaboratory; Chapter 5, Basic Experiments; Chapter 6, Chemical Experiments; Chapter 7, Physical Experiments; Chapter 8, Biological Experiments; Chapter 9, Special Preparations.

More than one-third of the book is devoted to the first four chapters. It appears to the reviewer that these chapters could have been condensed considerably, since there is undue repetition and unnecessary details regarding precautions in handling isotopes. K. Z. Morgan's statement, "Radiation need not be feared, but it must be respected," is referred to several times, but unfortunately, the text does little to allay the fears of the novice. Chapter 3 seems unnecessary, since the inclusion of such material as floor plans, materials for floor and wall surfaces of a radio laboratory might well be beyond the scope of the intended reader.

Experiments basic to radioactive measurements are presented in Chapter 5. The operation and use of the Lauritsen electroscope and the Geiger-Müller counter are discussed, as well as the preparation of liquid and solid samples prior to analysis. Several illustrations are included and add much to the clarity of the text. The division of each experiment into Object, Theory, Apparatus and Materials, Procedure, Calculations and Questions, and Other Suggested Experiments should be helpful in executing the experiments properly. The list of general references at the end of each experiment is adequate and pertinent.

The remainder of the book is devoted to special experiments illustrating specific chemical, physical and biological tracer methods, such as Analysis by Isotopic Dilution, Solubility Determination, Half-Life Measurements, Friction Studies, and Body Fluid Volumes. Unfortunately, the wide scope of the book does not permit a detailed presentation of each experiment. Thus, the experiments have limited value in the same sense that an inadequate organic chemistry manual is not useful beyond the exact preparation described, while a good manual will serve as an adequate reference book.

The final chapter and appendix contain information regarding preparation of special isotopes and some information of general interest.

The exposition is generally clear and simple except for the occasional occurrence of ambiguities.

This book is the first of its type in the field of radioactive tracers and may prove useful in elementary laboratory instruction. However, it will be difficult for this type of manual to compete successfully with the other available volumes intended primarily for research workers.

University of Pennsylvania

Electronics in Engineering

By W. Ryland Hill, Pp. 274, Figs. 205. McGraw-Hill Book Company, Inc., New York, 1949. Price $3.50.

This book is intended as a text for a one-quarter or one-semester elective course in electronics to be given to advanced students in other fields of engineering or science to acquaint them with the applications of electronic techniques to their own instrumentation problems. It is hard to review a book designed to such rigid specifications without having had the opportunity of trying it on a class; lacking this experimental check, the reviewer must defer to the author's judgment on questions of choice of material to be covered and the order of presentation. In the present instance the author has followed the introduction of each new device by discussion of illustrative applications, and has leaned heavily on graphic presentation rather than mathematical analysis.

Following an introductory chapter on electrons, ions and photons, Professor Hill takes up the topic of practical thermionic emitters and diodes, and then takes up single phase rectifiers and filters before discussing grid controlled tubes in Chapter 4, which covers triodes, the principles of voltage amplification, and tetrodes and pentodes. Next come chapters on gas-filled tubes, photosensitive devices and control circuits employing thyratrons. Polyphase rectifiers are treated in Chapter 8, followed by practical amplifier circuits, a chapter on feedback, and one on resonance and tuned amplifiers. The last five chapters cover oscillators, amplitude modulation and demodulation, the cathode-ray oscilloscope, transducers (particularly strain gauges) and the vacuum tube voltmeter. The subject of the discharge of a condenser through a resistance is treated in a brief appendix. All but two of the chapters are provided with a short list of problems which appear to require more of the student than simple substitution in a formula.

Naturally, with such an imposing list of subjects to cover in 270 pages, it is impossible to deal with each in much detail, so we find, for example, that only one type of vacuum tube voltmeter is described, though the particular one chosen is excellent for the author's purpose. However, in view of the necessity for compressing the material one wonders at the inclusion of two pages (243–4) of discussion of the ordinary Wheatstone bridge in connection with strain gauges.

The style is rather informal, but the resultant lack of rigor in many places may well be offset by the better hold on the students' attention. Nevertheless, I was a little surprised to read (page 89) that if "finer grained" control of the current through a thyratron is needed the remedy suggested is the rather impractical one of increasing the supply frequency. In discussing the effect of omitting the cathode by-pass condenser (pages 139–140) in a resistance-capacitance coupled voltage amplifier, the author states that it "does no harm" except for a reduction in gain, but fails to point out the effect on frequency response and the improvement in linearity. Also, I was disappointed to see again the old mistake (page 261) of operating a vacuum tube voltmeter at the floating grid potential. Defects of this sort would be serious only in a reference book, and, since this is definitely not a reference work but a text, perhaps they can be overlooked.

J. B. H. Kuper
Brookhaven National Laboratory

Electron-Tube Circuits

By Samuel Seely. Pp. 529+ix, Figs. 469. McGraw-Hill Book Company, Inc., New York. Price $6.00.

In this book the author has attempted to develop in the student a clear, analytical method in studying electronic circuits; to present and analyze the various classes of circuits which find widest application; and to indicate with examples how various basic circuits are combined to achieve complex operations. Sufficient material has been included for a course in radio engineering circuits and for one in non-radio electronic circuits, with an opportunity for the instructor to choose topics to satisfy almost any course requirements. A background in basic a.c. theory and basic electronics is assumed.

In arranging his material the author has been guided by the character of the analysis rather than the application, but, nevertheless, the book falls into a number of major divisions. The first four chapters are devoted to a review of the fundamental properties of vacuum tubes and their basic applications. Next comes a discussion of a variety of untuned amplifiers (including some computer circuits), occupying five chapters. The third section covers tuned circuits, including oscillators, in three chapters. Fourth comes a comprehensive treatment of rectifiers, filters, and regulators, followed by chapters on Amplitude Modulation, Demodulation, and Frequency Modulation and Detection. Finally, there are five chapters on circuits that received considerable attention in connection with radar applications. Some of these circuits have not been treated previously in such detail in any general text.

Each chapter is provided with a well-chosen bibliography and a set of problems formulated so as to require an understanding of the subject matter. Appendices give characteristic curves for the tube types used in the problems and a table of Bessel functions of the first kind. In many places the author has drawn freely on his earlier text, *Electronics*, written with J. Millman.

Considering the mass of material discussed and the great number of equations, it is to be expected that numerous errors have crept in. The author, in his Preface, calls attention to the perennial difficulties with notation, in that in many places he found the I.R.E. standard single subscript notation inadequate. Possibly the attempt to conform to this standard is responsible for some of the cases where the notation used in the text differs from that in the figures. It would have enhanced the value of the book for reference purposes if the author had provided a glossary of his notation.

This reviewer feels that there are already too many synonyms in the English language with no precise shadings of meaning and so regards the author's introduction of the terms "sinor" and "sinor diagram" for rotating vector and vector diagram as superfluous, but this may be a purely personal prejudice. A more serious objection to the book is that in some spots the writing appears to have been hasty, resulting in clumsy sentences and in occasional misstatement of fact. For example, on page 72, we are told that "blocking" may occur in an untuned amplifier when the time constant CR_g is much larger than the period of the highest frequency to be passed by the amplifier. In general the analyses of circuits are quite clearly done, but the description of the "Phasitron" tube and the analysis of the Miller integrating delay circuit stand in marked contrast. Also, the index could be much more complete.

In spite of these technical blemishes, which are not at all likely to lead the serious student astray, the book appears to be an excellent text. Certainly, it is unique in respect to the breadth of material covered, and it seems likely to prove invaluable as a reference work.

Laboratory and Shop Notes

Energy Dependence of the Naphthalene Scintillation Detector*

Jack C. Smeltzer
National Bureau of Standards, Washington, D. C.

December 1, 1949

MEASUREMENTS of the sensitivity of a naphthalene scintillation detector for x-rays with energies of 250 to 1200 kev show that the ratio

$$S=\frac{\text{d.c. current out of photo-multiplier in } \mu\text{a}}{\text{intensity of irradiation in r/min.}}$$

is essentially independent of energy and intensity in this region. The experimental data given in Fig. 1 show that S varied less than 1.5 percent for constant irradiation with variable energy. A companion experiment showed less than two percent variation for tenfold variation of intensity at constant effective energy of 500 kev.

X-rays generated by tube potentials of 500 to 1400 kv as well as gamma-rays for cobalt 60 were used in this determination. Heavy filtration at the higher tube potentials, as shown in Table I, reduced the wide energy spread of the x-ray beam by heavily attenuating the lower energies. The effective energy was then determined from the slope of the attenuation curve[1] for the filtration employed. The effective energy so assigned thus has the same absorption coefficient as that of the filtered x-ray beam. The intensity of irradiation was measured by means of a thimble chamber calibrated against radium to ±1 percent accuracy.

A standard light source was used so that the efficiency of conversion of light to photo-multiplier current could be measured prior to each run. The change in this efficiency during a run was made negligible by holding temperature, potentials, and geometry constant, and by prefatiguing the photo-multiplier. Fatigue of the photo-multiplier[2] at light levels which give anode voltage outputs measurable directly with a potentiometer will change the sensitivity S appreciably during the time required to measure the ionization chamber current. To reduce this change in sensitivity below the probable error of measurement of intensity of irradiation, the photo-multiplier was prefatigued overnight at the light level to be expected from the crystal.

It is desired to determine the sensitivity due solely to the radiation absorbed in the crystal. The light output of the crystal depends upon the electrons traversing it. Some of these originate outside the crystal. If, for instance, a high atomic number material surrounded the crystal, too many electrons would strike the crystal surface.[3] The crystal was therefore inclosed in a shell of material with approximately the same atomic number as that of the crystal so that the electrons traversing the crystal were characteristic of the average atomic number of the crystal. To insure that no electrons generated outside the shell entered the crystal, the shell thickness was made equal to the range of the highest energy electrons in the shell material.

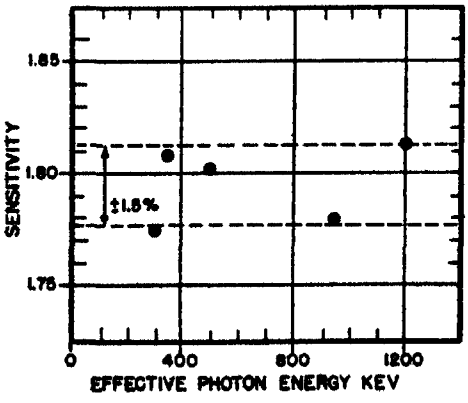

Fig. 1. Energy dependence of the RCA 931-A naphthalene scintillation detector. Sensitivity is the ratio of corrected photo-multiplier current to thimble chamber reading.

Table I.

X-ray tube kilovoltage	X-ray tube current ma	Added filter (mm lead)	Effective energy (kev)
500	1.4	0	250
800	0.5	3.35	350
1000	0.5	9.72	500
1400	0.5	27.10	950

It is estimated that the measurement of each S was acurate to ±1 percent. It is planned to extend the spectral dependence investigations to higher effective energies with the National Bureau of Standards' 50-Mev betatron.

Modification of Electron Microscope for Electron Optical Shadow Method

J. Arol Simpson and Alan Van Bronkhorst
National Bureau of Standards, Washington, D. C.

March 6, 1950

THE detailed investigation by means of the electron optical shadow method[1,2] of magnetic and electric fields of the size predicted by domain theory is best carried out by use of a high resolution electron optical system. Such a system is readily available in the conventional transmission-type electron microscope. It is, however, necessary to have a stage mechanism capable of rotating the specimen around an axis intersecting the optical axis and a means of holding and moving a fine mesh screen axially just behind the back focus of the objective lens. Although these adjustments are sufficient, it is highly desirable that the specimen may be rotated on a second perpendicular axis and that the mesh holder also provide rotation.

The micrographs by this method are a superposition of the specimen image on a shadow image of the mesh. Maximum sensitivity to low fields is obtained by placing the mesh as near the objective lens crossover as possible. Unfortunately, this increases the mesh magnification, reducing the definition of the field. If the specimen and related field are highly magnified, the instrumental field of view is reduced below the extent of the field. In fields with an extent of the order of 100μ, and with the use of the finest available mesh, 1000 mesh per inch,[3] the best compromise between field sensitivity, field definition, and field of view is obtained by reducing magnification of both objective and projector lens. The former is accomplished by raising the object plane approximately 2 cm; the latter by removing the projector polepiece. An EMB microscope has been modified for the electron optical shadow method in such a way that there is no difficulty in reconverting it to more conventional applications. This modification is accomplished by two auxiliary devices: an object stage mechanism, and a holder and control for the fine mesh electrolytic screen.

Figure 1 shows an exterior view of the microscope column with the modified stage mechanism (A) and screen control (B) in place.

The stage mechanism mounts on the specimen control valve port and is sealed with a flat rubber gasket. Figure 2 shows the assembly of the stage mechanism. Provision is made for rotation of the specimen about two perpendicular axes, which intersect on the optical axis of the microscope. The rotations are controlled from outside the vacuum by coaxial shafts (1, 2) passing through U-cup Wilson seals (3, 4). Translation along the axis perpendicular to the optical axis is accomplished by sliding the outer shaft (2)

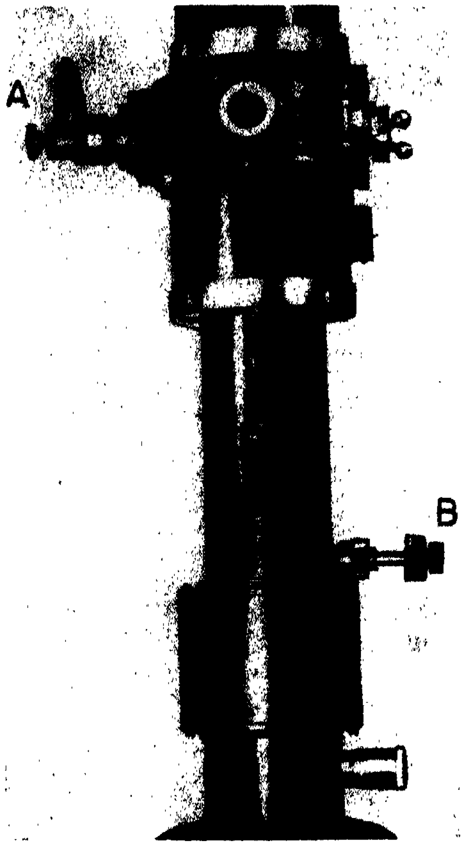

FIG. 1.

by means of a threaded nut (5). For purposes of alignment, the shafts are mounted on a flexible metallic bellows (6) which may be deformed enough to insure the intersection of the axes of rotation on the optical axis.

The screen control, which provides rotation around and translation along the optical axis, is more complicated mechanically because the only available port through which it may be controlled is located just above the projector lens while the screen must be placed some 20 cm above this port. Moreover, since the screen cannot be removed without dismantling the column, in order that the microscope be readily available for other purposes, the intermediate viewing port must not be obscured and a clear bore of at least 1 cm must be maintained.

Figure 3 shows the device finally adopted. Once again coaxial shafts (1, 2) through Wilson seals (3, 4) are used for control. The outer shaft (2) terminates in a bevel gear (5) which drives a long pinion (6). The inner shaft (1) drives, through a set of bevel gears (7), an externally threaded thin-wall tube (8); while the long pinion (6) drives the outer, internally threaded tube (9) by a spur gear (10) which slides on the pinion (6). The screen holder (11) is set on the upper end of the outer tube (12) and may be removed, by a special tool, through the object chamber port after removing the objective pole piece.

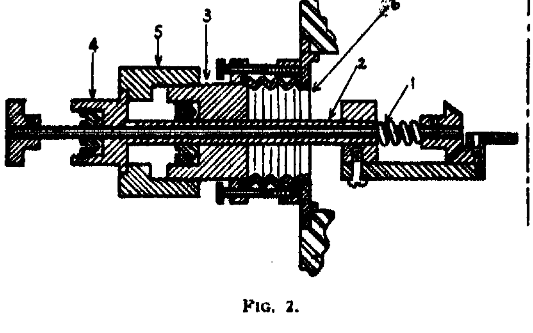

FIG. 2.

The gear ratios are so chosen that if both drives are turned together there is no relative rotation of the threaded tubes and the screen is rotated without translation. If, however, the outer drive is held fixed while the inner one is rotated, the screen is translated without rotation. The total amount of vertical movement thus provided for the screen is about 2½ in., while there is no limit to the amount of rotation.

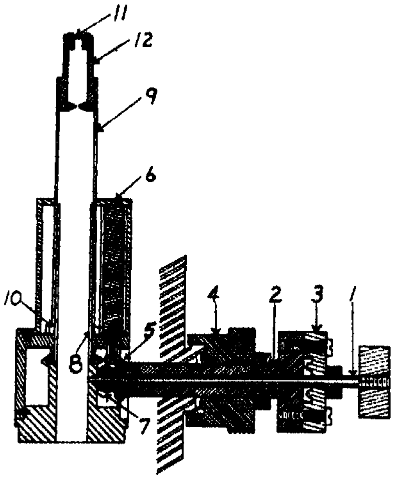

FIG. 3.

Shadowgraphs taken with this instrument of barium titanate and of cobalt crystals have been previously published.[4]

With some change in geometry, other transmission microscopes can also be adapted for this work. In fact, the conversion is probably easier due to the more convenient mechanical construction of other instruments.

Microtome Knife Sharpness

OSCAR W. RICHARDS
Research Laboratory, American Optical Company, Stamford, Connecticut

April 21, 1950

THE current need for cutting very thin sections of less than a micron has renewed interest in the problem of assessing the condition of the microtome knife. The cutting edge of an ideal microtome knife would be a smooth, straight line formed by the intersection of two planes, the knife facets. Such a perfect edge is not obtained, because variations in the microstructure of the steel and abrasive particles do not give a geometrical line, although modern sharpening methods and improved steels approach this ideal.

When the knife is supported by a block, Fig. 1, and illuminated at the proper angle, Fig. 2, only the light reflected from the cutting edge is seen with a microscope and this reflection is the most useful means for evaluating the sharpness of the knife.[1] A magnification of 100 to 120× should be used for routine examination and 400 to 500× for critical study of the edge. A piece of black photo paper placed on the stage of the microscope blocks light from below and gives a black background. The angle of illumination should be set to give the least reflection. A really

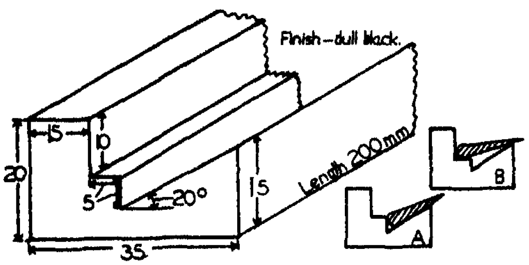

FIG. 1. Block for supporting microtome knife (dimensions in mm). A. Position for examining sharpness. B. Position for observation of polish.

sharp knife edge is seen as a straight, fine line like the left-half of Fig. 3. After some use the edge will appear as the right-half of the figure. Likewise, a poorly sharpened knife will have a broken, wavy line resembling Fig. 4, or even when incompletely sharpened a thicker line.

If the edge is not quite sharp it may be thinned and improved by stropping, but if it is properly honed sharp, then stropping can only round the edge and lessen the sharpness. Too vigorous stropping can overheat the edge and draw its temper.

The facets that produce the cutting edge should be polished smooth and their quality can be examined by placing the knife flat on the microscope stage, Fig. 5, over a piece of black paper, or placed in position B, Fig. 1. Diffused light may reveal the detail of the polish more clearly and can be obtained by placing a ground glass on the front of the illuminator. Unless the facets are smooth, the sections tend to stick and compression is increased.

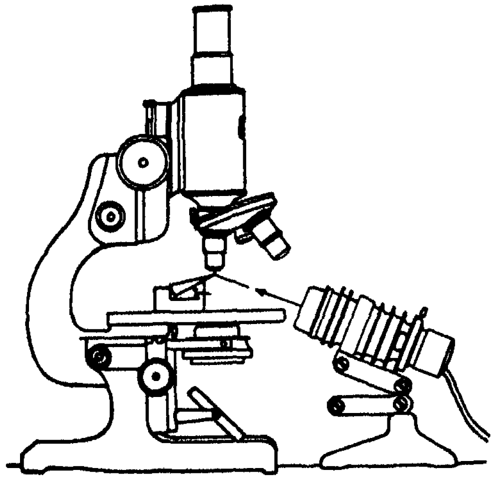

FIG. 2. Method for examining sharpness.

A good edge should be free from nicks which are easily seen if the knife in the last position is illuminated from below to silhouette the edge. They may be measured with a calibrated ocular micrometer. Photo-micrographs are useful for permanent records.

Different materials cut better with different adjustments of the clearance angle between the back facet of the knife and the surface of the block, with different room temperatures and rates of cutting.[2] The clearance angle may,[3] or may not,[4] be critical depending on these conditions, the material being cut and the embedding matrix. An edge rounded from stropping may not require as critical setting of the clearance angle as a very sharp edge. The angle of the cutting edge, between the facets, may be less for softer materials.

FIG. 3. Reflection from knife edge, left half sharp and right half dulled from sectioning.

FIG. 4. Reflection from edge of poorly sharpened knife.

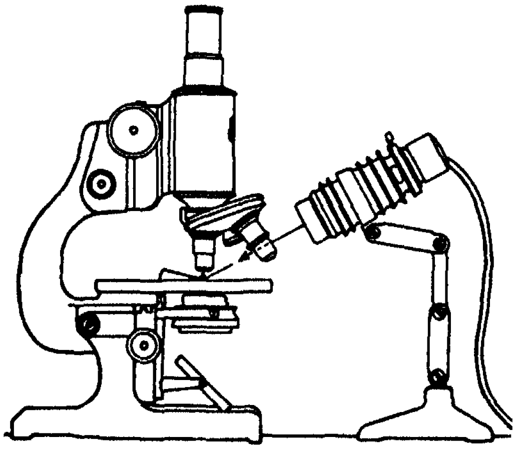

FIG. 5. Method for examining facet polish.

Reports on the problems of fractional micron sectioning will become useful only when the condition of the knife (sharpness, facet polish, facet angle, facet width) and of cutting (material and embedding matrix, temperature, clearance angle and rate of cutting) are known so that different technics and procedures from different laboratories may be compared. Adequate data should lead also to an understanding of the cutting process which will facilitate making better sections adequate for modern microscopy.

Glass Variable Microleaks for Gases*

JOHN J. HOPFIELD
Applied Physics Laboratory, Johns Hopkins University, Silver Spring, Maryland

May 2, 1950

GLASS variable microleaks described below have application in spectroscopy[1] and in positive ray work. The range of flow rates are fixed for any one leak but vary from one leak to another. The following are the maximum and minimum rates of air for a series of such leaks with a differential pressure of 1 atmosphere. The values in cc/hr. n.t.p. are: 9.6−0.012; 6.3−0.015; 4.2±0; 60−0.01; 4.8−0.01; 120−0.15; 40−0.03; 60±0; 4.3−0.2; 40−0.01; 3.6−0.006; 6−0.003.

Method of construction.—The leak can be made by any one experienced in glass blowing. Pyrex glass is preferred. It consists of an inner and an outer tube, with a ring seal at 6 and a spot seal at 7 (Fig. 1). Gas leaks from arm 1 to arm 2 through the crack 8 of the inner tube. The opening through the crack is continuously varied by the twist which arises from pressing arms 1 and 2 together at 3, the point of crossing, where they are left slightly separated. The dimensions shown in Fig. 1 are not critical, but a snug fit of the inner tube into the outer one is desirable. The space left between the arms at 3 for the average leak is 0.5 mm.

A unique feature of such a leak is a crack which is made in the inner tube without completely rupturing it. This may be done in the following way.

(1) Heat one end of the tube for 5 sec. in a torch and then

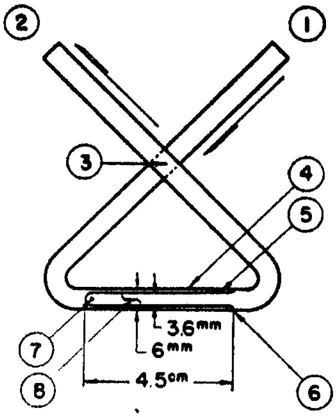

Fig. 1.

quench it by dragging it swiftly across a beaker full of water. The straight crack II,1 results.

(2) Seal off the end II,2 and while still hot quench it in light oil. This makes subsequent operations more sure. Wipe off the oil and flame the end to burn off the residual traces.

(3) Make the ring seal I,6 and bend the arms 1 and 2, leaving a space of a mm between them at the crossing I,3. A metal shim is a good spacer to use for this purpose.[2]

(4) While holding the arms squeezed against the metal spacer (a spring clothes pin with crossed grooves filed in it is a suitable clamp), make a spot weld I,7 and II,3 joining the inner and outer tubes together at this point. When the work cools, squeeze the arms carefully toward one another at the crossing point. Diagonal cracks I,8 and II,4 will lead off from the straight one. As a final step one of the arms is softened *above* the bend and the spacing I,3 reduced to about 0.5 mm for the finished leak. A modified pinch clamp may be used as a regulator for varying the space I,3 of the finished leak and controlling the leak rate. Arm I,2 is on the low pressure side.

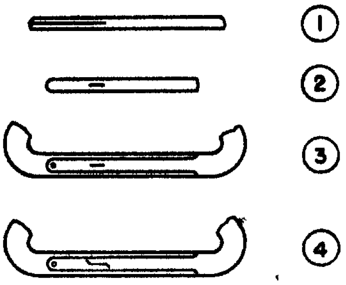

Fig. 2.

The above leak is satisfactory for work in which a tight shut-off is not essential. One can make it shut off more tightly when one springs the arms slightly apart at I,3. One then sees the diagonal crack close to optical contact and the "zero" leak is through the horizontal crack only. Too much spreading of the arms, however, is likely to start an opposite diagonal crack and spoil the leak.

Refinements.—(a) To obviate the above danger and still have the advantage of the lowered zero leak rate, one can proceed to *freeze* a *closing torque* into the finishing leak. This is done as follows: Put the finished leak with the metal spacer held in place by the spring clothes pin into a vise, using a split nut with the threads padded with asbestos to hold it, III. A helical spring attached to the arm I,2 and directly above the nut puts a slight twist in both inner and outer tubes. Now when one softens the spot weld I,7 with a blow pipe, the inner tube becomes relaxed, the left elbow softens, and the outer tube holds all the torque of the spring transmitted down arm 2. When the weld cools and the leak is unclamped, this torque is balanced by a counter torque in the inner tube, the diagonal cracks are found to be closed and can be opened by pressing the arms together as usual. In like manner one can freeze a compression in the inner tube by stretching the outer one.

(b) Another refinement is to fuse the horizontal crack and one of the diagonals permanently closed, leaving only one of the diagonals, subsequently extended if necessary, for regulation of the leak rate. To do this, one clamps the completed leak in the split nut as before, but omits the spring. The split nut is placed in position to cover the right-hand one of the diagonal cracks I,8 and to leave the rest of the crack uncovered. The spot weld is now softened with a fine pointed flame, and another not too hot flame is applied to the outer tube immediately over the crack. Because the edges of the crack in the inner tube are practically in optical contact they are fused together by this gentle heat even through the outer glass envelope. The protected diagonal remains unfused. Finally, after allowing the leak to cool, one reclamps it and freezes a closing torque in this remaining diagonal in the manner described under (a). Do not be discouraged by your first failure.

Microleaks of the last sort can be made to shut off completely and still have regulation up to their maximum rate of a few cc/hr.

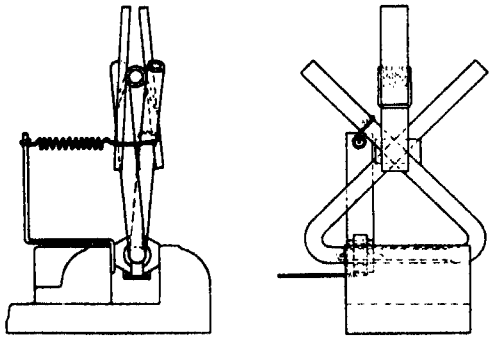

Fig. 3.

In such a leak, the closed crack is entirely invisible and when open it shows interference fringes. If left closed for a period, some of these leaks will freeze closed and refuse to open again. Therefore, it is usually preferable to leave a slight zero rate (about 0.02 cc/hr.) in the finished leak to prevent this freezing. The crack is stable and does not lengthen with use. Never flash a flame across the finished leak when fusing it to the apparatus; to do so may break it.

---

* Work finished under Navy Bureau of Ordnance Contract NOrd 7386.

[1] J. Opt. Soc. Am. and Rev. Sci., Inst. 12, 391 (1926). (The prototype of this leak was at one time commercially available. The present leak shuts off more nearly and is more stable than the prototype.)

[2] The spacing of the finished leak is half of this amount. The greater spacing gives room for initiating the diagonal cracks and overstraining the final crack about 30 percent so that it will be stable in the range of use.

Ultra-High Vacuum Ionization Manometer

J. J. Lander
Bell Telephone Laboratories, Murray Hill, New Jersey

April 20, 1950

THIS note describes an ionization manometer which indicates pressures more than two decades below the lower limit usually encountered at about 1×10^{-8} mm of Hg with other manometers.[1] This limit depends on the design of the gauge; however, values reported for various gauges do not differ much from that given above. Commonly the limit is observed as a lowest reading obtained despite recourse to more or less drastic methods of producing lower pressures, or a variety of changes in gauge design. The flash filament method of pressure measurement has been used to measure lower pressures and at the same time to indicate the lower limit of an ionization gauge.

The most generally accepted theory advanced to account for the lower limit assumes that soft x-rays, generated at the positive

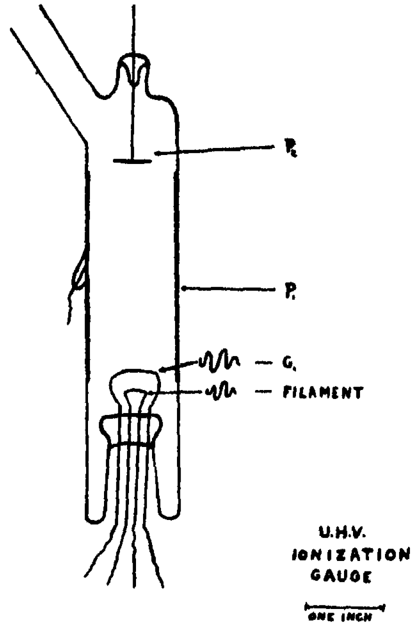

FIG. 1. Cross section of ultra high vacuum ionization gauge.

grid by electron bombardment, excite electron emission at the ion collector. At constant pressure the numbers of ions collected and photo-electrons emitted should be proportional to the ionizing electron current. The gauge fails when, with decreasing pressure, the number of ions collected becomes less than the number of photo-electrons emitted.

In a conventional gauge the positive ion collector surrounds, more or less completely, the filament and positive grid. This design is efficient and it reduces space charge effects to a minimum (ion current is proportional to ionizing electron current up to quite high currents). This design also guarantees that most of the soft x-ray radiation is intercepted by the ion collector and therefore that the lower limit of the gauge is high.

The gauge of Fig. 1 is designed with an ion collector P_2 which collects ions efficiently, but intercepts a relatively small amount of any direct radiation from G_1, which together with the filament is at the opposite end of the tube. P_1 is as efficient as the ion collector of conventional gauges and may be used in the upper pressure range or it may be omitted. The radius of P_2 is about 0.2 inch and it is about 2.7 inches from G_1. Thus P_2 intercepts about one part in 500 of the direct radiation from G_1, whereas P_1, intercepts about half of that radiation. But it has been observed experimentally that P_2, under normal operating conditions collects about ¼ of the total ion current. Thus the ratio of photo-current to ion current for P_2 should be depressed to about 1/50 of that for P_1. Furthermore, it was found that the wire support of P_2 alone is practically as sensitive as the support plus plate. Thus by removing the plate, a gain of more than two decades is to be expected.

Although current to P_1 shows little space charge effect up to ionizing currents of about 10 milliamperes, ion current to P_2 is effected by space charge. Ratios 1 $(P_1)/i(P_2)$ fall from 21 at very low current to about 3 at 10 milliamperes. The ratio has very little dependence on pressure. Data covering a wide pressure range are given in Fig. 2.

It was found that ion current to P_1 is not very sensitive to the potential on P_2 (between −48 and +24 volts) and conversely for P_1 less than −10 volt. Positive potential on P_1 increases ion current to P_2 to a maximum of about twice that obtained with P_1 at −24 volt.

The gauge was found to be about 75 percent as efficient as a D.P.I. gauge. Since it is very nearly as efficient as the D.P.I. gauge (which is relatively efficient), the estimated extension of more than two decades into the ultra high vacuum region should be realized if radiation from the electron collector is responsible for the normal lower limit.

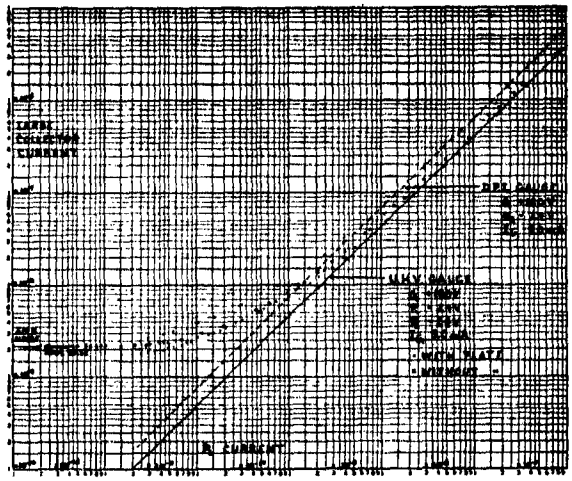

FIG. 2. Plot of ion current to collectors limited at about 2×10^{-8} amp. against current to collector P_2.

Since the wire support can be replaced by a hair-pin filament, the features of ultra high vacuum ionization manometer and flash-filament manometer can be combined in the gauge to produce a more versatile instrument.

The gauge was tested by sealing it, together with a D.P.I. gauge, to a pumping system believed capable of producing pressures well below 1×10^{-8} mm of Hg. Results are reproduced in Fig. 2. Currents to the large ion collectors are plotted against current to P_2. The lowest reading obtained from P_2 (with the plate off) is about 2×10^{-12} ampere, which should correspond to a current of about 1×10^{-11} ampere to P_1 or a pressure of about 1×10^{-10} mm of Hg if the residual gas is equivalent to air in ionization efficiency. Actually the current to P_1 reached a limit at about 2.2×10^{-9} ampere, which corresponds to a pressure of about 2×10^{-8} mm of Hg. The performance of the ion current in the D.P.I. gauge parallels that to P_1 but with a slightly higher limit.

It is to be noted that with the four lowest readings obtained with the U. H. V. gauge the base, containing filament and G_1 leads, was cooled. Either liquid air or dry ice was effective. It is concluded that the largest source of gas in the apparatus operating in the ultra high vacuum range is in the neighborhood of the hot filament.[2]

It is finally concluded that the ionization gauge described extends the useful range of pressure indication by such manometers by at least two orders of magnitude and that the success of the design may be accounted for by the soft x-ray theory for the lower limit of ionization manometers.

[1] While this note was in manuscript, a gauge of similar purpose but somewhat different design and due to R. T. Bayard, Westinghouse Manufacturing Company, was described at the M.I.T. Electronics Conference (April 1, 1950).

[2] Gettering action by the filament of a gauge has been observed by J. Blears, Proc. Roy. Soc. 188, 62 (1947).

An All-Metal Ionization Gauge

F. M. KELLY
McLennan Laboratory, University of Toronto, Toronto, Canada

April 21, 1950

THE construction of an all-metal ionization gauge for use as a rough pressure indicator in metallic vacuum systems was suggested by Kurie.[1] Such a gauge has been constructed and found to be satisfactory.

The design of the gauge is shown in Fig. 1. The outer jacket is a brass tube 2¼ in. in diameter and 4 in. long. It is cooled by water flowing in copper coils which are soldered on the outside of the jacket. The cylindrical anode is sheet monel and is mounted in a large metal-to-glass seal[2] in the side of the gauge. The nickel supports for the grid and filaments pass through and are soft soldered to Fusite terminals[3] mounted in a brass plate which covers the open end of the gauge. The grid consists of twenty turns of 15 mil tungsten wire in the form of a cylinder $\frac{5}{16}$ in. in diameter. The filament is a 2¾ in. length of 10 mil thoriated tungsten wire which is heated to operating temperatures by a potential of 4 to 6 volts across its ends. Only the lower filament support is shown in the diagram. The upper support is directly behind the filament and passes midway between the grid and the anode to a fourth Fusite terminal ¼ in. behind the central one shown in Fig. 1. The filament and grid mount is sealed in place with a Neoprene gasket and can be easily removed. Thus broken filaments can be readily replaced.

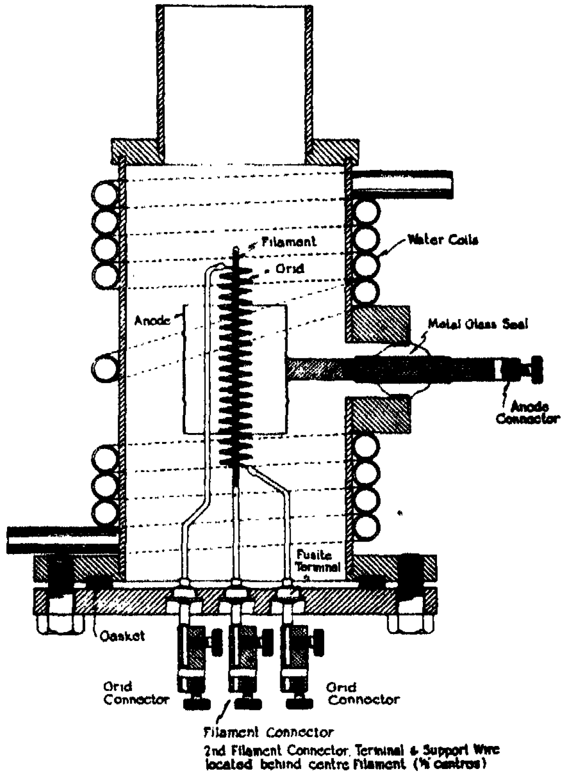

FIG. 1. Sectional elevation of metal ionization gauge.

The potentials used on the electrodes are the same as those for commercially available gauges. This gauge has been checked against the RCA ionization gauge 1949 and has been found to give comparable readings at pressures down to 10^{-5} mm of mercury. Ten to twenty minutes must be allowed for the gauge to reach a steady condition if it has been opened to the air.

The gauge is easily constructed and the parts are readily available. The ease with which filaments can be replaced makes safety devices for the protection of the gauge unnecessary. It is not suitable for accurate pressure determinations but is useful as a rough indicator and in leak hunting.

A Convenient Leak for Testing Helium Leak Detectors*

G. H. Jenks
Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

May 25, 1950

IN the use of helium leak detectors, it is frequently desirable to test the sensitivity of the instruments by admitting helium gas to the system at known slow rates. The methods commonly employed in admitting the gas make use of fine capillaries of different types. The capillary leaks, however, are troublesome to use because of the ease with which they are stopped or their calibrations changed.

It should be pointed out that a "leak" which is not of the capillary type but which makes use of the permeability of glasses to helium can also be used in testing helium detectors. Thus, the rate at which helium diffuses through silica glass at room temperature is known to be about 7×10^{-11} cc/sec./cm^2/mm/cm Hg[1]. A section of the glass having an area of 1 cm^2 and a thickness of 0.1 mm will then pass about 5×10^{-8} cc of helium per second when the pressure difference is one atmosphere. This rate is about 25 times greater than the minimum rate which the commercial instruments will detect. The diffusion constant of Pyrex glass is smaller than that of silica by a factor of ten, but the amount of helium passed by a section of Pyrex of moderate dimensions is still appreciable compared with the sensitivity of the detectors. Soft glass does not pass helium at appreciable rates.

The precise rates of diffusion of helium through glasses are strongly dependent upon the temperature of the glass, varying about 3 percent per degree for both silica and Pyrex at room temperature. However, if desired, corrections for temperature changes can be applied so that the relative rates at different temperatures should be known readily to within 3 percent.

A "leak" of the diffusion type has been in use at this Laboratory for several weeks and so far has operated very satisfactorily. The design of the leak is shown in the accompanying sketch. The silica glass bulb is approximately 1 cm in diameter and has an estimated minimum thickness of 0.1 mm. Helium gas under a pressure of 1 atmosphere is sealed in the Pyrex reservoir. The rate at which helium diffuses through the leak is such that a General Electric detector registers a steady deflection of one-tenth of the most sensitive full scale deflection. Momentary deflections of much greater magnitude can, of course, be obtained by allowing helium to collect in the Pyrex envelope for several minutes and then opening the envelope to the detector.

There is no apparent reason why the leakage through the above

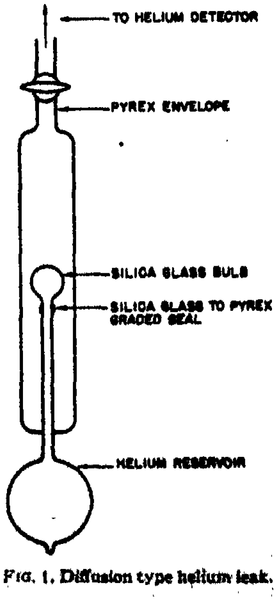

FIG. 1. Diffusion type helium leak.

leak when it is at constant temperature should change appreciably as long as the pressure of helium within the reservoir remains constant. The reservoir pressure will, of course, decrease as the helium diffuses through the silica, but the fractional decrease during a given period can be made small by choosing a sufficiently large reservoir volume. Thus, at a leakage rate of 5×10^{-8} cc/sec., about 1.5 cc/yr. will diffuse through the silica. If a reservoir having a volume of 100 cc is used, the yearly change in pressure will be 1.5 percent. Some additional leakage through the walls of the reservoir will occur, but this may be eliminated by substituting soft glass for the Pyrex.

* This document is based on work performed for the AEC at Oak Ridge National Laboratory.

Preparation of Unbacked Metallic Films

F. E. Carpenter and J. A. Curcio
Naval Research Laboratory, Washington, D. C.
May 11, 1950

A TECHNIQUE has been developed for the preparation of thin unsupported metallic films. The films are strong and usually free from pinholes. Aluminum films ranging in thickness from 1000 to 3000A have been prepared, the thickness determined from weight and area measurements. Usually, the films have been placed over slots 1 mm×10 mm for use in upper atmosphere x-ray investigations. A larger film of 3000A thickness with a surface area of 3 inches×4 inches has been prepared and used to cover an aperture 2 inches in diameter.

The aluminum film is evaporated in the usual way on glass slides which have previously been coated with a water soluble film. The slides are hand dipped in a sugar-aerosal solution and dried on edge in a dust free atmosphere before evaporation. The metallic film is stripped from the glass slide by immersion in water for 20 to 30 minutes. At the end of this time the film will be sufficiently detached so that it can be peeled off and placed over the area to be covered while still under water.

The water soluble film used to cover the slides is a dilute bubble solution as given by Kuehner.[1] In our application the solution is made up of 15 grams of ordinary cane sugar dissolved in 75 ml of a one percent aerosal-water solution.

Comments on "Velocity-Acceleration Response from a Seismic Pick-Up via Controlled Damping"*

A. J. Hermont
3737 Bellaire Boulevard, Houston, Texas
May 20, 1950

AS a corollary to Jeffries' paper, the following may be of interest. Since damping is an important parameter in determining the relationship between the response of an oscillatory system and displacement-, velocity-, and acceleration-input, and since the concept of damping is linked with the transient rather than the steady state, it was thought worth while to study the transient state of the systems discussed by Jeffries. The transient solutions for the underdamped (Fig. 1) and the overdamped (Fig. 2) cases were obtained by operational means, i.e., the response (S_a) of the relative motion to a unit-step ground acceleration for the underdamped, and the response (S_v) of the relative motion to a unit-step ground velocity for the overdamped cases were derived. For the numerical value $\omega_n=100$ radians per sec. (ω_n = natural circular frequency of the system) the relative indicial responses were computed and the results are indicated in the accompanying illustration. Consider first the underdamped case, Fig. 1. If the system were a perfect "acceleration reproducer," its relative motion to a unit-step acceleration would be a unit-step (ideal). Instead, the actual response for $\delta=0.5$ and $\delta=0.7$ (δ = damping factor) is as shown. For $\delta=0.7$, the system behaves as a near-perfect acceleration reproducer at low frequencies. For high frequencies, it is a poor acceleration reproducer. This is inherent in the fact that the transient starts with zero slope (as may at once be deduced from the equation given in Fig. 1) and is manifested by the pronounced "build-up" time.

New Instruments

W. A. Wildhack: Associate Editor
in Charge of this Section
National Bureau of Standards, Washington, D. C.

These descriptions are based on information supplied by the manufacturer and in some cases from independent sources. THE REVIEW *assumes no responsibility for their correctness.*

Principal Strain Computer

A new electronic computing instrument for automatically computing and indicating principal strains was developed and built for the National Advisory Committee for Aeronautics, and it is now in operation at Langley Field, Virginia.

This computer operates directly from strain gauge rosettes, indicating almost instantaneously the values of major principal strain, minor principal strain, and the principal angle.

Principal strains are determined experimentally by means of the strain gauge rosette which is an arrangement of 3 or 4 resistance strain gauges mounted on the surface under test at definite angles with each other. The voltage outputs of each gauge are translated into strain, and then these individual strain values are placed into equations or formulas which yield the desired values of principal strains and the principal angle. Equations differ for different arrangements of gauges in the rosette, but all equations involve

sums and differences and square roots of sums and/or differences squared.

The principal strain computer operates with equiangular rosettes, rectangular rosettes, and with TΔ rosettes. To convert from one equation to another, it is merely necessary to operate a single selector switch.

The sum and difference factors are obtained by networks, operating directly on the outputs of the individual gauges. The square root of the sum of several squares is obtained almost instantaneously by a self-balancing electrodynamometer.

The rosettes are powered by a 400-cycle carrier and all operations in the calculations are performed on this carrier without any modulation or demodulation, and wave form and frequency are not critical.

The computer contains all the oscillators, amplifiers, and power-supply equipment within one cabinet, for operation directly from a single source of 115-volt 60-cycle power. A total of 75 vacuum tubes is used.

A total of 48 rosettes, either of the 3-gauge or 4-gauge variety may be connected to the computer and each gauge properly balanced before strain determinations are made. After each increment of strain is applied, the operator can read and record the major and minor principal strains and the principal angle just as fast as he can operate the rosette selector switch and read and tabulate the results.

Built-in calibrating equipment is provided for quick and precise calibration for the rosette to the strain and angle indicators.—Hathaway Instrument Company, *1315 South Clarkson Street, Denver 10, Colorado.*

Chain Pulse Amplifier

The Model 214 Chain Pulse Amplifier has been specifically designed to amplify very fast pulses and transients. Employing fourteen 6AH6 vacuum tubes in a traveling wave circuit, it has a band width of 40 kc to 100 Mc and a gain of 30 db. The input impedance of 180 ohms is designed to match the output impedance of the Series 200 Wide-Band Chain Amplifiers for additional gain up to 60 db.

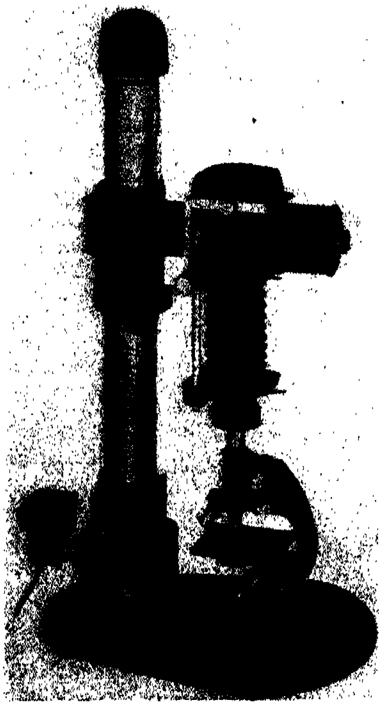
A special termination at the end of 15 inches of cable is provided for convenient use with a DuMont 5XP Cathode-Ray Tube for the viewing of high speed pulses. With an output voltage of 65 volts and a rise time of 6 millimicroseconds, 1 inch of deflection is obtained under the stiffest beam conditions. A second output is also provided for connection to high speed counters and other associated equipment. Standard connectors are used at the input and no special cable and fittings are required.

The Model 214 Chain Pulse Amplifier and power supply is housed in an aluminum chassis and can be supplied for either table or rack mounting. *This versatile amplifier finds many applications in nuclear physics, radar, high speed oscillography, television testing, and general laboratory measurements.*—Spencer-Kennedy Laboratories, Inc., *Department SI, 186 Massachusetts Avenue, Cambridge 39, Massachusetts.*

Versatile Photo-Micrographic Apparatus

This Photo-micrographic Apparatus, designed also to serve all other aspects of scientific photography, provides facilities for photo-micrography; photo-macrography; micro-projection; laboratory, clinical, and general photography; photo-copying; microfilming; x-ray photo-copying; and photo-enlarging.

The apparatus is named the Orthophot, and is used with any standard microscope. It comprises three basic units:



1. A base with permanently aligned built-in light source operating on the Koehler principle (balanced at 3200 K for color work) with intensity-control maintaining constant color temperature, and with built-in color filters for black-and-white photo-micrography. This unit is available separately as light source for exacting visual microscopy.
2. A self-aligning reflex camera with precision focusing device (for use with No. 120 roll film, $2\frac{1}{4}$ in.$\times 3\frac{1}{4}$ in. cut or pack film, and standard 35 mm film), automatic Rapax shutter (1 sec. to 1/200 sec., T and B); attached sensitive photoelectric exposure meter.
3. A vertical column assembly with counterbalanced elevating device for the camera, operated by rack and pinion.

These units are shown in the illustration assembled and with a microscope in position for photo-micrography. Accessories, not shown, convert the unit for photo-macrography, cine-photomicrography, general laboratory photography, photo-copying, of opaque and translucent objects, and photo-enlarging, by attaching lamp unit with double condenser which works through the basic camera unit.

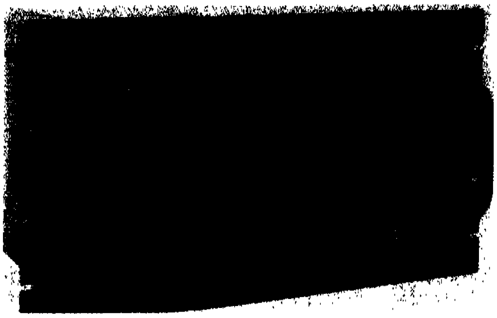
The reflex camera itself is detachable and can be used on a standard tripod or hand-held for all forms of scientific or general photography.

Light source, camera, or vertical column are available separately for combination with existing equipment in the user's laboratory. A simplified version of the column can be had with adjustable camera holder to permit use with a wide variety of standard still and motion-picture cameras. Price of the standard Orthophot is $825.00.—Silge and Kuhne, *Box E, 153 Kearny Street, San Francisco 8, California.*

Microwave Signal Sources

A series of Microwave Signal Sources covering the range of 634 Mc to 8340 Mc in four units, is now available.

These reflex klystron signal sources are controlled by one dial only and frequency is read directly from a linear indicator to accuracies of ½ percent. The reflector voltage is automatically tracked with the cavity tuner. There are no klystron modes to set, no voltage settings to be made and frequency can be read directly without resorting to charts or graphs. Non-contacting shorts are used to eliminate noise and reduce mechanical wear. Terminals are provided for applying modulation to either the grid or reflector.



The Model SSR Microwave Signal Source covers the range from 634 to 1174 Mc; Model SSL—1140 to 2184 Mc; Model SSS—2145 to 4310 Mc; and Model SSM—4290 to 8340 Mc. The signal sources are supplied complete with tube.

A Klystron Power Unit, Model KX-1, which has been designed to minimize klystron frequency modulation due to reflector voltage variations is also available.—Polarad Electronics Corporation, *100 Metropolitan Avenue, Brooklyn 11, New York.*

New Gamma-Ray Detector

The Model 939 Scintillometer (gamma-ray detector) employs the scintillation principle, and provides a detection sensitivity over 100 times that obtainable by conventional portable Geiger counters, the actual count rate being approximately 290 times that of three popular Geiger counters tested under identical conditions. This increased sensitivity, with negligible effects from cosmic rays, permits more rapid and accurate measurements of gamma-ray field intensity.

When used for radioactive ore survey, the Scintillometer will detect deposits through greater depths of over-burden and provides information which can be correlated with geological structure, to provide accurate information on distribution and concentration of the deposit. Through the use of a special gamma-ray spectrometer feature, the Scintillometer may be used to distinguish the difference between thorium and uranium ore deposits, and will indicate the uranium concentration in an ore containing both radioactive minerals.

The Scintillometer employs only high vacuum tubes in conservatively designed circuits, is protected against vibration, shock, temperature, and humidity; will operate continuously between −20°F and +110°F, with a relative humidity of 95 percent. A removable probe is contained in the lower section of the case proper, which need only be removed for laboratory research purposes.

The instrument is housed in a weather-proof aluminum alloy case, measuring 3½ in.×11 in.×13 in., and is supplied complete with batteries, canvas carrying case, and strap.—Halross Instruments Corporation, Limited, *171 Garry Street, Winnipeg, Canada.*

Ultra Low Frequency Oscillator

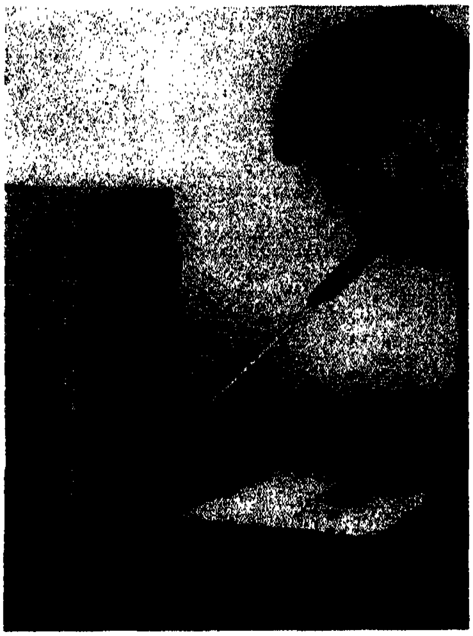
A new, wide range, ultra low frequency oscillator, Model 410-A, combines the sub-audio with the normal audiofrequencies and provides both sine and square wave outputs over the entire frequency range from 0.02 to 20,000 c.p.s. Six frequency bands are provided, each covering a full decade, with continuous control of frequency. A single, 11-in., illuminated, direct-reading logarithmic scale is used on all bands.

The sub-audio range of frequencies makes the unit especially useful for design and test of servomechanisms, geophysical instruments and feedback amplifiers, for vibration checks and medical research, and in conjunction with time and production controls. The square wave output is useful for low frequency switching and triggering operations, and for checking the frequency or transient response of audio circuits.

This instrument features low distortion and hum level, constant output impedance, excellent frequency stability, and amplitude constancy over the entire frequency range. An important feature of a sub-audio electronic oscillator is its ability to recover quickly from bandswitching and similar disturbances; the sine wave output of the 410-A recovers to 90 percent of its steady state amplitude in less than 2 cycles of the dial frequency.—Krohn-Hite Instrument Company, *580 Massachusetts Avenue, Cambridge 39, Massachusetts.*

Oscillo-Tracer

The Oscillo-Tracer is an optical super-positioning device, using a newly developed double-coated lens. The arm carrying the lens is adjustable in length to fit any standard oscilloscope, and looking down through it one sees a reflection of the cathode-ray trace superimposed on the paper directly below the lens. A small lamp is provided in the base of the Oscillo-Tracer to illuminate the pencil while you trace the oscillogram. The Oscillo-Tracer has been found useful for many applications, such as detecting small, slow changes of patterns, comparing traces by the super-position

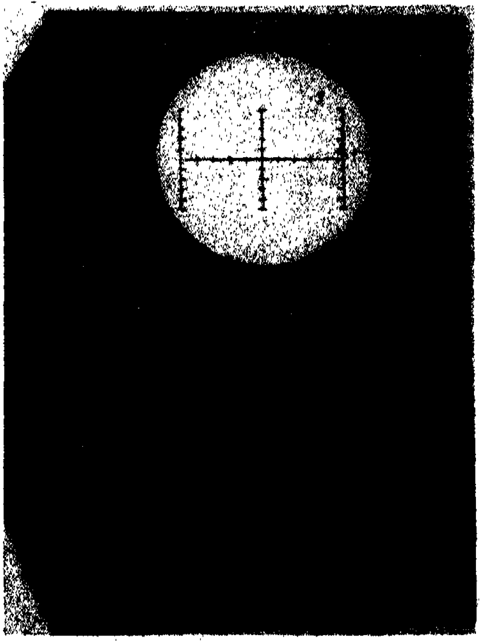


method, and so on. School and college laboratories find the Oscillo-Tracer invaluable for economical recording of experimental data in student notebooks. It is priced at $19.50.—Robert A. Waters, Inc., *4 Gordon Street, Waltham 54, Massachusetts.*

Model On-5 Oscillo-synchroscope

This new oscillosynchroscope, Model ON-5 is designed to provide wide band amplifier and versatile sweep facilities in single portable unit. It is particularly well adapted to the study of pulse and transient phenomena as well as being useful in all conventional oscillographic applications.

Vertical amplifier response is flat within 3 db from 5 cycles to 5 megacycles. Horizontal amplifier is direct-coupled with high frequency response extending to 500 kilocycles.

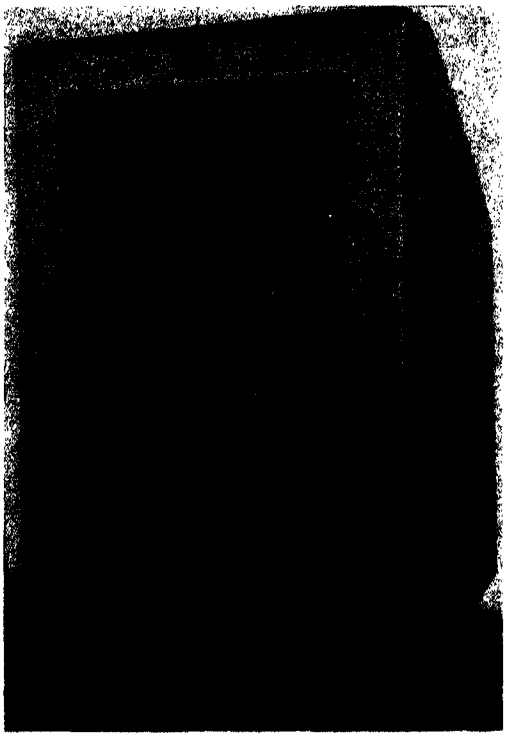


The sweep generator may be triggered or recurrent with direct reading-writing rate calibration for any internal sweep condition. Triggered sweep speeds from 1.0 microsecond per inch to 25,000 microseconds per inch and recurrent sweeps of 10 to 100 kilocycles are available.

An adjustable calibration voltage may be used for determination of vertical deflection voltage amplitudes. Either d.c. or a.c. connection may be made to all deflection electrodes. Also provided is a panel connection to the cathode-ray tube for external beam modulation. The ON-5 is housed in a steel cabinet. Dimensions: height 14¾ in., width 10 in., depth 16¾ in.; weight: 50 lbs.—Browning Laboratories, Inc., *Winchester, Massachusetts.*

Projection-Microphotometer

A double projection comparator and microphotometer, particularly applicable to rapid qualitative and quantitative spectrographic analysis, has been developed by Optica, Milan, Italy. The instrument, called "Evaluation Apparatus," serves three purposes: (1) a single plate or film projector combined with a micrometer for measuring line-to-line distance; (2) a double projector providing direct comparison of two plates or films with controls for rapid alignment of the images on a horizontal screen; and (3) a microphotometer capable of measuring the transmittances of very narrow spectral lines. The instrument ordinarily accommodates plates and films up to 9 by 24 cm but, if necessary, can be used for sizes as large as 24 by 30 cm.



The single plates, or the two plates to be compared when the unit is used as a double projector, are placed on a slightly inclined table and images are projected on a horizontal table arranged at a suitable level in the front part of the projector. The spectrograms are quickly leveled and aligned by the controls provided. When two spectra are to be compared the images can be projected either side by side or one slightly above the other. The light intensities of the two projection systems, each being equipped with its own 6-volt, 100-watt lamp, can be adjusted individually; this permits adjusting for density differences between the two plates. When the unit used as a single projector the second field can be shielded, and the one image extended to cover the full area of the screen.

When the apparatus is to be used as a microphotometer, the white table used for comparing plate images is removed to uncover a second gray table. In the center of this table is a slit adjustable in width to 0.002-mm divisions by a drum and behind the slit is mounted an RCA 931A photo-multiplier tube fed by a constant voltage circuit. The deflections of a mirror galvanometer are observed on either of two moving scales, one linear with 1000 divisions and the other logarithmic. The system is designed to be compact by employing a scale reduced photographically to a few centimeters in length and then projecting the scale full size on the screen. The projection lamp is run on battery power when photometric measurements are made.

The whole unit is enclosed in a large metal cabinet, in front of which the operator may sit comfortably. The cabinet also serves as a light shield and, when not in use, the cabinet can be closed tightly by a curtain to protect the instrument against dust. The linearity of the photoelectric system is reported to be better than one percent.—Optica S.p.A., *Via Calatafimi, 7–9, Milan, Italy.*

Teflon Applications

Teflon (tetrafluorethylene resin) is finding electrical applications in which its electrical properties at high frequencies, its heat resistance, or both are important. Its short-time dielectric strength is 1000 to 2000 v.p.m. in 5- to 12-mil thicknesses and 400 to 500 v.p.m. in 80-mil thickness. Volume resistivity is greater than 10^{15} and surface resistivity 3.6×10^{6} at 100 percent relative humidity. Dielectric constant is 2.0 and power factor is less than 0.0005 over a frequency range from 60 to 10^{8} c.p.s. Teflon insulated wire is being used as ignition cable and for transformer leads in high voltage electronic devices. It is proving particularly useful as coaxial spacers in TV in f-m transmission lines where its low dielectric constant minimizes reflections, and its low loss factor makes the line practically the equivalent of a line with air insulation. Where machined Teflon inserts are used as insulators in coaxial connectors, the advantages are the same, and in addition the heat resistance of the material permits soldering of connections during assembly without danger of injury to the insulation.

In addition to its unique electrical, chemical, and thermal properties, Teflon has another characteristic which leads to interesting applications. Nothing sticks to it with any appreciable strength and it may be used in processes where a non-sticky surface is required, such as the jaws of heat-sealing machines and on conveyors and rolls handling sticky materials. For example, its use on bakery rolls for handling dough eliminates the need for dusting flour and for roll scrapers. Its use is under evaluation in non-adhesive applications such as bread pans, mold release agents, and conveyors.—E. I. du Pont de Nemours and Company, *Polychemicals Department, 350 Fifth Avenue, New York 1, New York.*

Silicone Molding Compound

GE-12810, consisting of a silicone resin with a glass fiber filler, is the first commercially available silicone molding compound. Its outstanding characteristic is heat resistance, continuous operation at 392°F being possible. High impact strength and excellent arc resistance, as well as good flow in the mold, are also reported. It will not support combustion and has no toxicity when burned. Applications include circuit breakers, switchgear and other parts where resistance to extreme heat and impact is needed.—Chemical Department, General Electric Company, *Pittsfield, Massachusetts.*

Aluminum-Silicone Paint

Silicone Coating Aluminum is a new aluminum paint supplied in separate compartments containing the pigment and the silicone resin vehicle. They are mixed just prior to use. The paint may be applied by brush or spray on plain or galvanized metal surfaces and affords weather protection in temperatures ranging from below freezing to 750°F. The coating is also resistant to attack by fumes. Coverage is about 1000 square feet per gallon and drying takes place in from one-half to three hours.—Dampney Company of America, *1241 River Street, Boston 36, Massachusetts.*

Silicone Rubber Sponge and Shock Mounts

Chorlastic, silicone rubber sponge, made from recently developed silicone compounds, has a more uniform cell size than previous types. Tensile strength, elongation, abrasion resistance, and tear strength have also been improved. The sponge has a volume of 25 to 35 cu.in./lb. and will resist temperatures between −100 and +500°F. It is used as a vibration damper at extreme temperatures, and as fairing strips, seals, gaskets, etc. It is available in sheet stock $\frac{11}{16}$, $\frac{1}{8}$, and $\frac{1}{4}$ in., and can also be obtained in special extrusions and molded shapes on a custom basis.

Chorlastic mountings use silicone rubber to permit vibration damping at temperatures ranging from −100 to +500°F. They will protect instruments and other apparatus under conditions of extreme cold where ordinary rubber becomes hard and brittle, and in locations where high ambient temperatures would make ordinary rubber soft and gummy. They are designed for loadings and deflections required by *AN* specifications and are available in many sizes of the *AN* instrument series. They can be designed for most services where temperature resistance is required with the vibration characteristics of a shear-type mount.—Connecticut Hard Rubber Company, *407 East Street, New Haven 9, Connecticut.*

Aluminum Wire

Polyethylene-covered aluminum line wire, for use where weatherproof or insulated electrical conductors are required, is available in a full range of sizes of solid and stranded conductors, as well as in small sizes. This wire has advantages which include light weight (one-half the weight of equivalent weatherproof copper wire); free stripping (making it easy to clean for splices and taps); resistance to abrasion and fungi; and freedom from rotting and festooning as textile coverings do. Long lengths can be readily handled because of the light weight.—Kaiser Aluminum and Chemical Sales Company, *1924 Broadway, Oakland 12, California.*

Laboratory Aids

Varniton Stopcock Lubricant has been found useful as a liquid pouring aid for screw-cap bottles, beakers, flasks, metal containers, and carboys. A small amount of the lubricant spread around the lip edge of the container acts as a barrier to prevent the spread of liquid drops, permitting pouring in a steady controlled stream. No drops form over the lip when the pouring is terminated. The lubricant is non-volatile and remains effective for a long time. It is almost completely insoluble in aqueous solutions of acids, bases, and salts so that no contamination results from its use.

Var-Clean is a high foaming laboratory detergent, containing no soap, for cleaning laboratory glassware, as well as metals, porcelain, plastic cloth, and stone surfaces. It has excellent wetting and spreading properties and is effective on oil, grease, gums, culture media, etc. It contains no strong alkali salts and is easy on hands. After rinsing, laboratory ware drains dry without wiping. The detergent is supplied in powder form in a conical dispenser which facilitates its use in narrow-necked flasks and other apparatus with restricted openings. Addition of water to the detergent makes a powerful cleaning agent.

Powdex contains the same ingredients as *Var-Clean* with the addition of a mild abrasive to facilitate the removal of waxes, stains, and carbonized material.

Nitro-Seal is a quick-drying, thick sealing cement designed for application to cold surfaces. It seals leaks in vacuum apparatus, dries fast by solvent evaporation, and leaves a smooth transparent coating. It can be employed for cementing wood, cork, metal, cloth, glass, porcelain, paper, plastics, leather, etc., and is satisfactory for insulating electric wires and protecting them from corrosion. It is resistant to dilute acids and alkalis, petroleum oils and greases, and may be removed with acetone. By adding fine wood sawdust it can be converted into a plastic wood filler.—Varniton Company, *416 North Varney Street, Burbank, California.*

Degreaser

Barco Metal Degreaser Q-200 is designed for cold application. Metals and plastics are degreased by immersion, by dipping and brushing, or by wiping with the fluid. It is also useful in removing pitch or cementing resins from ground lenses. It has been approved by the Underwriters Laboratories. Further information may be obtained from the manufacturer.—Barco Chemical Products Company, *701 South LaSalle Street, Chicago 5, Illinois.*

High Speed Hacksaw Blade

Molyflex is a high speed steel hacksaw blade which can be twisted through more than 90° without breaking. It is shatter-proof and when used in a frame is unbreakable. It is available in all popular sizes and pitches for hand-sawing.—Victor Saw Works, Inc., *Middletown, New York.*

Solder Alloys

New solder alloys for use with silver-printed or silver-plated conducting mediums are stated to eliminate danger of dissolving silver. The solder is formulated in two melting ranges: *Divco No. 233,* for applications where abnormally high temperatures are not encountered; and *Divco 276,* for use in assemblies that operate above 350°F. Both can be applied in the same manner as ordinary solders, and may be used on ceramic, plastic, Bakelite, and other base materials coated with silver. They are available in bar, solid-wire, and rosin-core shapes.—Department B-34, Division Lead Company, *836 Kinzie Street, Chicago 22, Illinois.*

Flashlight Battery

Eveready No. 1050 industrial flashlight battery has a plastic-coated cardboard-covered container with a carbon lining and a zinc vane as the central element. Unlike older type units which have a central carbon rod and a zinc container, this type of construction provides a container that is inert to electrolytic action, and that will not perforate, leak, corrode, swell, or jam in the flashlight. A metal disk at the top provides a connection to the carbon element and one at the bottom is welded to the zinc vane. This arrangement keeps the polarity the same as that in the older type cell, and the battery is completely interchangeable with all *D*-size (standard flashlight size) units. In flashlight service the new battery has more than double the useful life of any previous type.—National Carbon Division, *30 East 42nd Street, New York 17, New York.*

Welding Glass

G-S Welding Plates are guaranteed to absorb at least 99.5 percent of infra-red and 99.75 percent of ultraviolet radiations. They are graded for density and thickness in accordance with Federal Specification GGG-H-211 for welding helmets and shields. The standard size is 2×4¼ in.—General Scientific Equipment Company, *2700 West Huntingdon Street, Philadelphia 32, Pennsylvania.*

Metal-Ceramic Materials

Metal-Ceramics are a mixture of metal and ceramic materials having useful characteristics at high temperatures including high strength, good abrasion resistance, and high thermal shock resistance. They have intermediate electrical and thermal conductivities and can be machined and electroplated. Dense metal at one end and a "metal-ceramic" at the other can be incorporated. Possible uses include dies for hot forming, containers for high temperature furnace work, flux-resistant brazing and welding fixtures, electrical contacts, and spark-plug electrodes. The manufacturer is accepting sample orders for these materials to evaluate major applications.—Special Metals Division, P. R. Mallory and Company, *3029 East Washington Street, Indianapolis 6, Indiana.*

The Measurement of Rates of Flow of Gases by Wet Test Meters*

ROBERT L. BURWELL, JR., MAX METLAY, AND FRANK W. PFOHL
Department of Chemistry, Northwestern University, Evanston, Illinois

(Received March 20, 1950)

Rates of flow of gases may be measured to an accuracy of better than 0.1 percent with properly modified and operated wet test meters. The period of a single rotation is measured by an electric stop clock. The instrument is not an absolute one but must be calibrated by a meter prover. A suitable prover is described. Within rather wide limits the calibration is independent of flow rate. The instrument may be used for direct measurement or for calibrating other types of flow meters.

RATES of flow of vapors may be measured with considerable accuracy by condensing and weighing the amount of vapor passing through a system in fixed time. However, measurement of the rate of flow of permanent gases such as oxygen or air to an accuracy of 0.1 percent or better is attended with considerable difficulty. To achieve this end, for example, Wacker, Cheney, and Scott,[1] in determining the heat capacity of oxygen, condensed oxygen at low temperatures in light weight pressure bottles and weighed it under pressure at room temperatures.

In experiments designed to measure the heat capacities of gases and vapors by a differential method in a dual flow calorimeter, it was necessary to measure the rate of flow of a reference diatomic gas (such as oxygen, nitrogen or air) to a high degree of accuracy as a routine operation. It has been possible to adapt the ordinary wet test meter to this purpose.

At first, it was planned to calibrate a capillary flow meter against a wet test meter as a secondary standard. The wet test meter was then to be calibrated against a fundamental standard.

The three-liter wet test meter manufactured by the Precision Scientific Company has been used. To obviate non-uniformity of the rotor,[2] it appeared essential to measure the time required for one rotation rather than the change in dial reading occurring in a fixed time. This instrument is provided with binding posts one of which is connected to the rotor needle and the other to a contact located at the top of the dial. A system of relays was arranged to start a Model S-1 precision timer of the Standard Electric Time Company of Springfield, Massachusetts, on the first contact between the rotor needle and the contact and to stop it on the second. The timer reads to 0.01 second. This arrangement eliminates possible observational error and preliminary experiments indicated a surprisingly high degree of reproducibility.

For the purpose in hand, dry gas had to be passed through the capillary flow meter. It was then passed directly into the wet test meter. Since it has been shown that gases are better than 98 percent saturated on passage through a wet test meter,[2] knowing the aqueous tension one could compute the corresponding rate of flow of the dry entering gas. However, the consequent evaporation of the water in the wet test meter, changes the calibration of the meter. Therefore, calibrations of the wet test meter were interspersed among the comparisons of pressure head in the capillary flow meter against time of rotation of the wet test meter. Thus, allowance could be made for the evaporation of the confining liquid in the meter.

However, since the calibration of a wet test meter may depend upon the rate of flow, it was necessary to calibrate the meter over the range of flows to be employed. A bulb of a capacity of somewhat less than three liters was provided at opposite ends with two coaxial tubes of a cross-sectional area of 2.35 sq. cm. The tubes were provided with centimeter scales 35 cm in length. Calibration enabled one to know the volume between any point on the upper scale and any on the

lower to 0.0005 liter. A little wetting agent was added to the water used in the bulb. A standard period of drainage, five minutes, was employed in all experiments.

In operation, the air contained in the calibrating bulb was displaced by water from a storage bottle connected to the lower tube of the calibrating bulb. Air from the compressed air line was employed for this purpose. The position of the rotor of the wet test meter was adjusted so that the needle would make contact when the water level was in the lower part of the scale of the lower tube. About 250 cc of air would flow before this would occur. The air flow was started and the scale reading taken visually when the clicking in the timer relay circuit was heard. The reading in the upper scale was similarly taken when the next clicking was heard.

Over rotation periods of 67 to 970 seconds, the calibration was constant to within the precision of measurement, about 0.001 liter save at times of less than 100 seconds in which case the precision is less owing to observational difficulties. Andersen and Friedman[3] with a one-quarter cubic foot meter have reported a constant calibration over the range of 0.1 to 0.8 c.f.m. to within 0.2 percent in mean deviation from the average.

Using the procedures outlined satisfactory calibration of capillary flow meters was achieved.

At this stage, the paper of Andersen and Friedman appeared in which they describe a device for controlling the water level of a wet test meter by the use of a depth micrometer with enlargement of the bore of the sight gauge tubing to 1.5 inches. A similar device was installed by removing the gas pressure gauge and inserting a Starrett one-inch micrometer head which was insulated from the meter body. The micrometer spindle was terminated with a tungsten rod of 1-mm diameter ground flat at its lower extremity.

In the technique of Andersen and Friedman, the end of the comparable part was dried and the water level raised until an electrical contact was indicated. In the present work, it was found that, if the rod was dipped into the liquid before use and then raised, the drop which was formed at the end of the rod was sufficiently constant to give results precise to 0.001 inch. Before this operation, gas was run through the meter for one revolution and the rotor brought to the zero position. It is important to fix the rotor needle permanently at half-way between uncupping points as otherwise serious errors enter.[2] By the use of the meter prover described above, it was found that the meter calibration changed by 25 parts in 100,000 per 0.001 inch change in water level. For their meter Andersen and Friedman reported 15 parts in 100,000 per 0.001 inch.

An enclosed plumb bob leveling device similar to that used by Andersen and Friedman was also fitted to our meters. However, it should be unnecessary where meters are mounted firmly in one place and subject to periodic recalibration.

Two meters have been found to give results equal to one another to within the experimental error of the meter prover. They have been further cross-checked by passing air from a constant pressure system through a water vapor saturator and then through the two meters connected in series. With meter I first, the following pairs of periods of rotation were determined: meter I, 161.68 sec., meter II, 161.76 sec.; 161.68, 161.58; 161.46, 161.39; 191.79, 191.64; 191.72, 191.66; and 191.81, 191.69. In another experiment, with the meters reversed, the following pairs of values were obtained: 200.05, 200.01; 200.03, 200.10; and 200.04, 200.12. It would thus appear that the flow rates are reproducible to ±0.05 percent.

In view of these developments, the wet test meters are being used directly for flow measurement and the capillary flow meters which precede them are used only for adjustment of approximate flow rates and to check upon constancy of flow. The porous ceramic biological filter thimbles manufactured by the Selas Company, Philadelphia, Pennsylvania, have advantages over conventional capillary tubes.[4] Effects due to turbulence and orifices are much reduced and the total flow follows Poiseuille's Law. Owing to the expansion of gas as it passes through the capillaries, π_0/V' should not be a constant as it would be for an incompressible fluid. Here, π_0 is the pressure drop through the capillary and V' is the volume per unit time read on the wet test meter. Rather

$$\pi_0/V'=2p/[k(2p+\pi_0)],$$

where p is the barometric pressure. Or if one feeds a stream of dry air to the capillary flow meter,

$$\pi_0/V'=2(p-a)/[k(2p+\pi_0)],$$

where a is the aqueous tension. These equations are valid for ideal gases only.

An accuracy of better than 0.1 percent may be obtained by the use of properly modified and operated wet test meters. An accuracy of 0.05 percent would require the temperature to be held constant to within 0.15°. Where location does not readily permit this, the meters would have to be thermostated. If one can afford several liters of gas for each flow determination, the modified wet test meter provides a convenient and accurate method of measurement of gas flow. Where smaller quantities of gas must be used, it provides an accurate method of calibrating capillary flow meters.

Solution of Simultaneous Equations through Use of the A.C. Network Calculator

L. M. HAUPT
Texas Engineering Experiment Station, Texas A. & M. College System, College Station, Texas

(Received December 27, 1949)

Kirchhoff's law equations may be written for any electrical network. Conversely, it is usually possible to find an electrical network whose Kirchhoff law equations are similar to the given set of simultaneous equations. The solution to the equations may then be found by measuring the corresponding quantities in this analogous network. The a.c. network calculator is adaptable to this method of solving equations. Presented here are the fundamentals of finding the correct electrical network for a given set of simultaneous equations.

INTRODUCTION

An alternating current network calculator[1] may be used to solve simultaneous linear equations. This method, where applicable, offers certain advantages over other methods. However, certain limitations prevent the general application of this method to all problems. These advantages and limitations are discussed below.

The alternating current network calculator is an adjustable electric system made up of generators, transformers, resistors, inductance coils, and condensers so arranged that any electric network, within the limitations of the calculator, may be set up for study. There are now (1949) 22 large calculators in operation or on order in the United States, a number of which are located on college campuses. They are used mostly by electric utility companies in the study of their operating and design problems. They have also proved useful in the studies of mechanical, hydraulic, thermal, and other systems for which electrical analogies have been determined.

Fundamentally, Kirchhoff's law equations may be written for any electrical network. These equations may then be solved simultaneously for the unknown quantities. Conversely, it is usually possible to find an electrical network whose Kirchhoff law equations are similar to the given set of simultaneous equations. The solution to the equations may then be found by measuring the corresponding quantities in this analogous network.

GENERAL NETWORK

The coefficients of the equations derived from physical systems often lead to determinants that are symmetrical about the principal diagonal. Analogous networks may be found on either a "loop basis" or a "node basis."[2] The general form for a set of symmetrical equations written so that an analogous electrical network may be found on the "loop basis" is

$$\begin{array}{l}
Z_{11}I_1+Z_{12}I_2+Z_{13}I_3+\cdots Z_{1n}I_n=E_1\\
Z_{21}I_1+Z_{22}I_2+Z_{23}I_3+\cdots Z_{2n}I_n=E_2\\
Z_{31}I_1+Z_{32}I_2+Z_{33}I_3+\cdots Z_{3n}I_n=E_3\\
\cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\\
\cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\\
Z_{n1}I_1+Z_{n2}I_2+Z_{n3}I_3+\cdots Z_{nn}I_n=E_n,
\end{array}$$

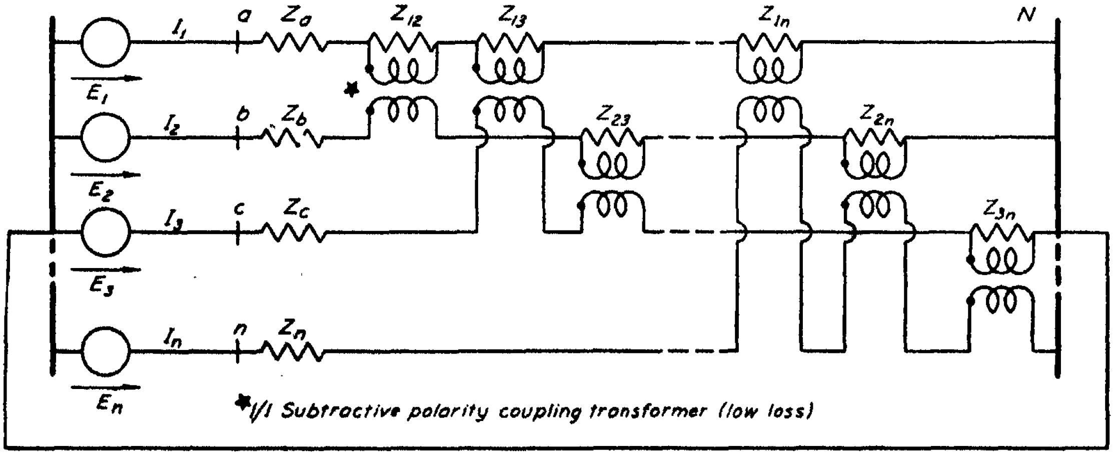

FIG. 1. General network used in the solution of simultaneous equations.

$$\begin{array}{l}
Z_a=Z_{11}-(Z_{12}+Z_{13}+\cdots Z_{1n})\\
Z_b=Z_{22}-(Z_{21}+Z_{23}+\cdots Z_{2n})\\
Z_c=Z_{33}-(Z_{31}+Z_{32}+\cdots Z_{3n})\\
\cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\\
Z_n=Z_{nn}-(Z_{n1}+Z_{n2}+Z_{n3}+\cdots)
\end{array}$$

---

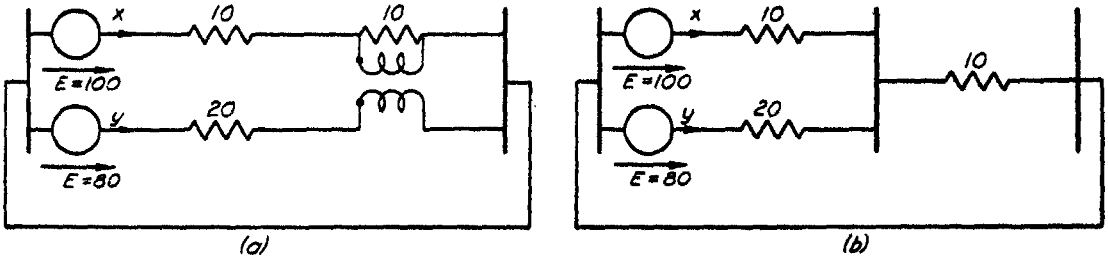

FIG. 2. Elimination of coupling transformers in a two-circuit network.

$$\begin{aligned} 20x+10y &= 100 \\ 10x+30y &= 80 \end{aligned}$$

where

$$Z_{12}=Z_{21},\ Z_{13}=Z_{31},\ \text{etc.}$$

In the above set of equations, $Z_{11}, Z_{22}, Z_{33}, \cdots, Z_{nn}$ represent the self-impedances to $I_1, I_2, I_3, \cdots, I_n$, respectively; and $Z_{12}=Z_{21}$, $Z_{13}=Z_{31}$, etc., represent the mutual impedances (coupling) between the circuits carrying I_1 and I_2, I_1 and I_3, etc., respectively. Both the currents, $I_1, I_2, I_3, \cdots, I_n$, and/or electromotive forces, $E_1, E_2, E_3, \cdots, E_n$, are adjustable in magnitude and phase relation to an arbitrary reference. This makes it possible to represent real, imaginary, or complex quantities.

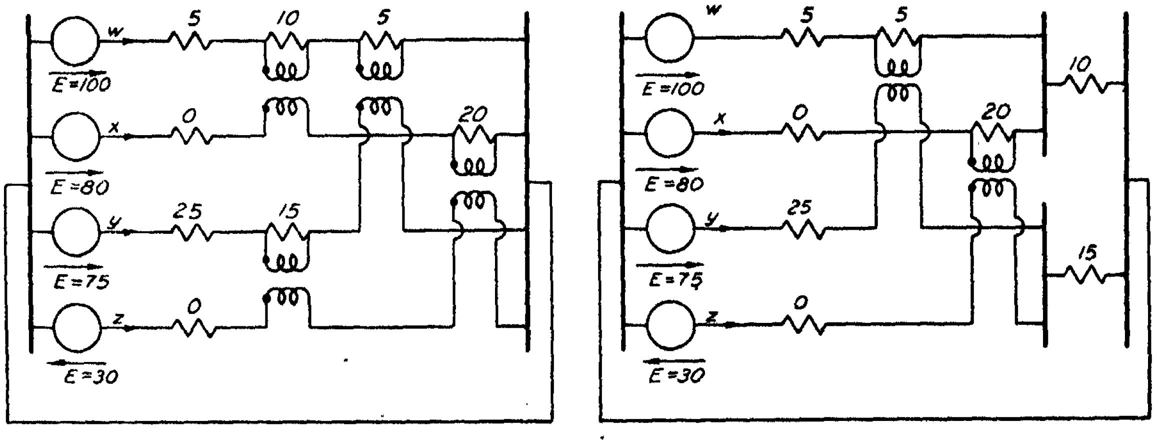
The above simultaneous equations may be obtained from the network, Fig. 1.

The number of low loss coupling transformers needed to couple the circuits inductively in the general network is given by the expression

$$n=[N(N-1)/2],$$

where n is the number of coupling transformers (1/1 ratio) needed and N is the number of simultaneous equations represented by the network. However, a limited number of circuits may be conductively coupled.[3] Coefficients that are zero (or negligible) also decrease the number of coupling transformers needed in the network.

In each of the examples, Figs. 2, 3, and 4, the original set of simultaneous equations may be found from the



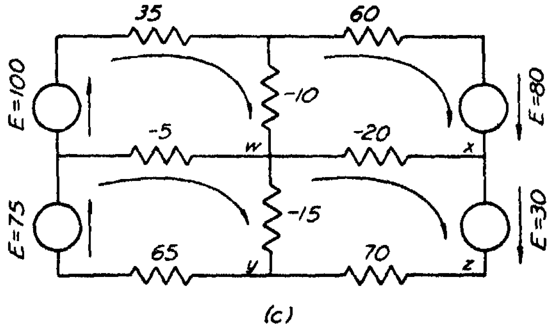


FIG. 3. Elimination of coupling transformers in a four-circuit network having a limited number of negligible coefficients.

$$\begin{aligned} 20w+10x+5y \qquad &= 100 \\ 10w+30x \qquad +20z &= 80 \\ 5w \qquad +45y+15z &= 75 \\ 20x+15y+35z &= -30 \end{aligned}$$

Note: For the general network, six coupling transformers would be needed. For this particular set of equations, the coupling transformers could be eliminated entirely, but this would necessitate the use of negative impedances (Fig. 3c) in a "mesh" network.

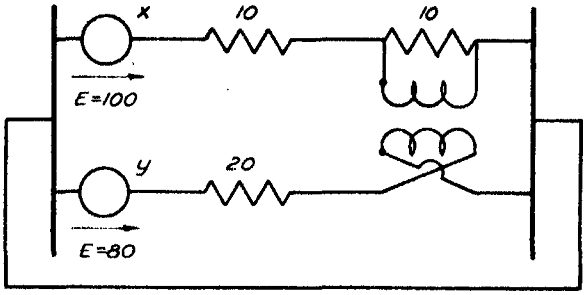

FIG. 4. Use of coupling transformers to obtain the equivalent of negative impedance. One winding of the coupling transformer is reversed.

$$20x-10y=100$$
$$-10x+30y=80$$

Kirchhoff second law equations written between the two busses from either figure.

NEGATIVE AND COMPLEX IMPEDANCES

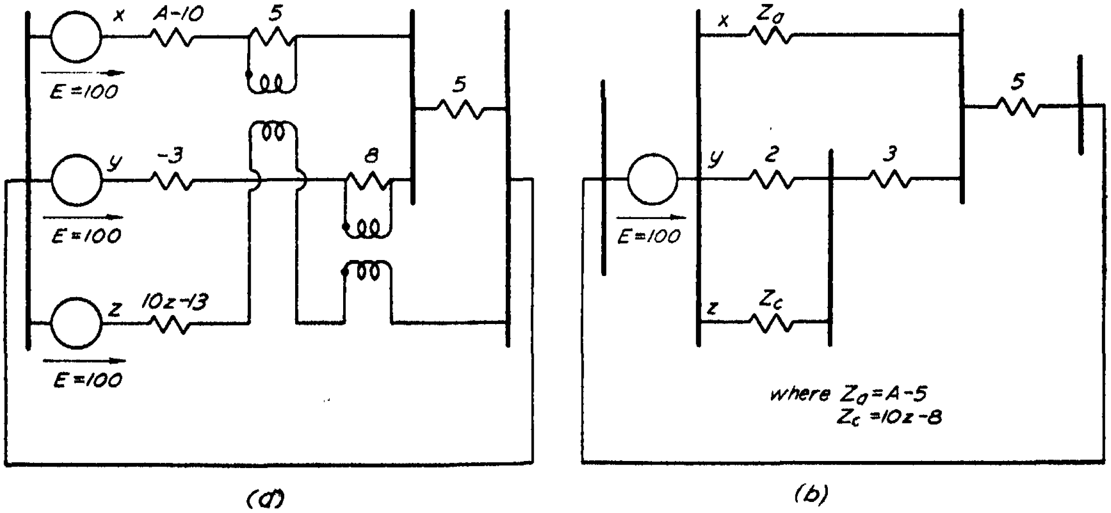
In the solution of simultaneous equations by this method, it is often necessary to deal with negative coefficients. This involves no difficulty so long as the real component of a coefficient is positive. Resistance is used for the positive real component, inductive reactance is used for the positive imaginary component, and capacitive reactance is used for the negative imaginary component.

If the coefficients of the equations are real numbers only, inductive reactance may be used for positive values and capacitive reactances may be used for negative values. The currents that flow will, of course, lag the voltages by 90°.

It is possible to simulate negative resistance by introducing a series electromotive force in the circuit. This electromotive force is then adjusted until it is in phase with the current and equal to the product of the absolute values of resistance and current.

NONLINEAR EQUATIONS

Equations whose coefficients are not constant and equations where one or more of the unknowns are of a degree higher than one may also be solved by this method. The procedure is similar to that used for linear equations except that adjustments of the impedances in



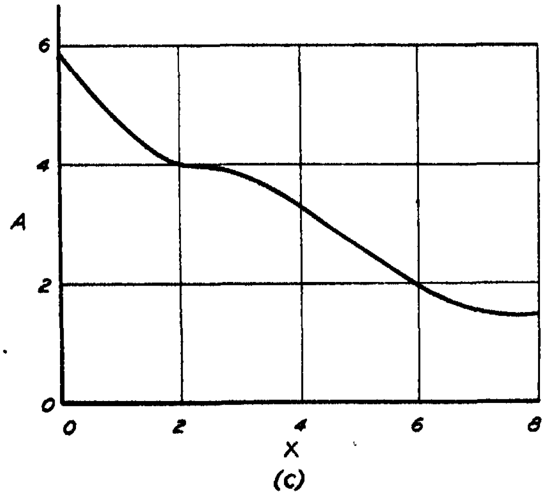


FIG. 5. Network for the solution of equations whose coefficients are not constant. The relation between A and x is given by the accompanying graph, and the network has been reduced so as to use only one generator, no coupling transformers, and no negative resistance.

$$Ax+5y+5z=100$$
$$5x+10y+8z=100$$
$5x+8y+10$[illegible]$=100$

question must be made until the conditions of the equations are satisfied. This is demonstrated in Fig. 5.

The circuit is "balanced" by adjusting Z_a and Z_c, respectively, until the given conditions are satisfied. This may be done easily by first plotting the two graphs (Z_a *vs.* x) and (Z_c *vs.* y) as a guide to the adjustments that must be made.

NONSYMMETRICAL EQUATIONS

The use of this method is not limited to simultaneous equations that are symmetrical about their principal diagonal. This is demonstrated by Fig. 6. However, the analogous network is not so easily found and sometimes may be quite complicated. Where possible, the equations should be converted into a symmetrical system.

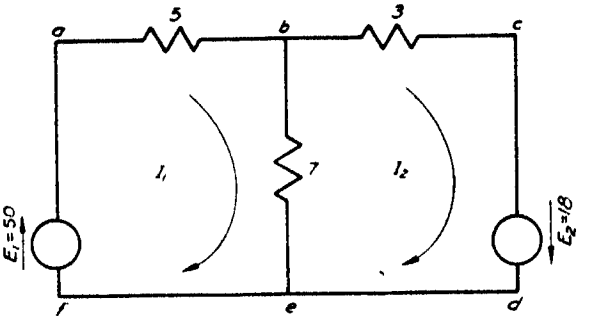

FIG. 6. Network for the solution of equations that are not symmetrical about their principal diagonal.

$$12I_1-7I_2=50$$
$$5I_1+3I_2=68$$

Note: Kirchhoff voltage equations are written around the loop *abef* and *abcdef* respectively.

APPLICATION

This method is particularly applicable where it is permissible to have a possible error of several percent in the solution and where it is necessary to find solutions of similar sets of equations which differ only in the values of one or more coefficients. This method has value in that the resulting electrical network may be considered an electrical analogy to the original physical system from which the equations were derived. This sometimes permits analysis that would otherwise be improbable. It is also possible to show clearly and easily the sensitivity of the solution to the accuracy of any coefficient by noting the effect of variation of the analogous circuit parameter.

Personal errors, i.e., error due to wrong connections, missetting of impedances, misreading instruments, etc., are reduced to a minimum through a careful systematic check. For example, the first equations of the general form could be checked from the general network, Fig. 1, by adjusting I_1 to one ampere after the other circuits have been opened at $b, c, d, \cdots, n$. The voltages from a to N, b to N, c to N, $\cdots$, n to N, should be the coefficients $Z_{11}, Z_{12}, \cdots, Z_{1n}$, respectively. The second equation could be checked by adjusting I_2 to one ampere after the other circuits have been opened at $a, c, d, \cdots, n$. The voltages from a to N, b to N, $\cdots$, n to N are now the coefficients $Z_{21}, Z_{22}, Z_{23}, \cdots, Z_{2n}$, respectively. This is repeated until all of the coefficients have been checked. The solution may be checked, of course, by substitution into the proper Kirchhoff law equation.

SUMMARY

The a.c. network calculator has been used on various occasions to solve equations involving complex numbers for zero sequence impedances,[4] for a study of intrasystem transmission loss,[5] and other problems, some purely theoretical. As a rule, the solution may be obtained in less time, with less personal error, and with greater accuracy than by other methods in which slide rule calculations are involved. For example, it required approximately four hours to set up and find a solution to simultaneous equations involving ten unknowns. After the initial solution was found, solutions to 28 similar problems (which differed only in the values of one or two of the coefficients) were found in less than one hour additional time. Only a few minutes was required to balance and find the solution of nonlinear simultaneous equations involving four unknowns.

The a.c. network calculator is a tool of many uses. It is felt that this is another application that will prove valuable to those who find it necessary to solve many simultaneous equations and who must obtain the solutions in a minimum of time.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 8 AUGUST, 1950

Arithmetic Operations in a Binary Computer

ROBERT F. SHAW
Eckert-Mauchly Computer Corporation, 3747 Ridge Avenue, Philadelphia, Pennsylvania

(Received February 13, 1950)

The application of binary arithmetic in the computing circuits of a high speed digital computer is discussed in detail. The discussion covers, with numerous examples, the use of complements to represent negative numbers, the corrections necessary in the multiplication process as a result of the use of complements, and additional modifications of the process to simplify mechanization. A special division method well-adapted to automatic computer use is described, and round-off procedures are noted briefly. The article is concluded with a discussion of the storage of negative numbers as absolute values with a sign rather than in complement form.

INTRODUCTION

THE extensive development of large-scale digital computers in the past few years has naturally been accompanied by a corresponding development of the mathematical techniques required for the most efficient use of these tools of research. Probably the outstanding feature of electronic circuits, insofar as their application to digital computers is concerned, is their binary nature. It is possible, by relatively simple means, to use these essentially binary circuits for operation in the decimal system, provided the decimal digits are represented in binary coded form. There is little doubt that all significant future development of general purpose computers, particularly for use in the commercial and industrial field, will be concerned with decimal operation. Nevertheless, it is also true that many of the large-scale computers now under development both in this country and abroad are purely binary, at least in their arithmetic operations. The greater simplicity of this type of device and its slightly more efficient use of memory capacity will probably assure it a position of continuing importance in the field of small special-purpose computers such as those contemplated for industrial control applications.

While the present discussion is concerned chiefly with the arithmetic operations of the Binac, a general purpose binary computer recently completed by the Eckert-Mauchly Computer Corporation, they apply to a large degree to most of the other binary computers now under construction. The mathematical developments presented are not intended to be rigorous, but are intended more to convey as simply and clearly as possible the principles underlying the operation of the Binac's arithmetic circuits. For a more thorough and rigorous analysis of these principles, the reader is referred to the report of Burks, Goldstine, and von Neumann, on the computer being built at the Institute for Advanced Study.[1] The arithmetic operations in this computer are similar to those in the Binac, although the latter is serial in nature, while the Institute's computer is of the parallel type.

I. RANGE OF NUMBERS

The arithmetic circuits and memory of a computer are designed to handle data in units, each consisting of a fixed number of binary digits; since these units may represent either numbers or instructions,[2] they are commonly referred to as "words." The choice of word length must be a compromise among a number of factors, such as available memory capacity, operating speed, required accuracy of numerical data, and other considerations. A word length of 30 binary digits, equivalent numerically to slightly less than 10 decimal digits, was chosen for the Binac; other binary computers now in the process of construction use word lengths varying from 16 to 44 binary digits.

Placement of the binary point must next be determined. Multiplication will be simplified if the point is placed to the left of the first significant digit, since it will then be possible to form the product of two factors, each having the maximum of 30 significant digits, without exceeding the capacity of the computer, and without resorting to "floating point" methods which require the keeping of a separate record of the binary point position. Placing of the point in this position also leads to a convenient method of handling negative numbers, as will be seen later. The absolute values of numbers which the computer can represent will lie in the range $0\leqq x<1$, and, since 30 binary digits can be stored, the smallest increment which the computer can represent is 2^{-30}.

Both positive and negative numbers can be represented if one additional digit, to the left of the binary point, is used. This digit will be a 0 for positive numbers and a 1 for negative numbers; and the absolute value of the latter will actually be replaced by its complement with respect to 1; for example: $+\frac{3}{16}$ will be written 0.0011, but $-\frac{3}{16}$ will be written 1.1101. (It will be noted that if the sign is treated as if it were simply another digit, negative numbers are represented by

---

[2] Instructions and numerical quantities are handled interchangeably in both the memory and arithmetic circuits, instructions being modified in the latter circuits by addition or subtraction of constants where necessary. However, an instruction differs from a quantity in that it can be interpreted by the control circuits of the computer and through those circuits can cause predetermined operations to be performed.

TABLE I.

Addends	Sum	Carryover
0 and 0	0	0
0 and 1	1	0
1 and 1	0	1

their complements with respect to 2. This statement will be further amplified in the discussion of addition and subtraction.) The total range of numbers which the computer can represent is then $-1 \leqq x < 1$.

II. ADDITION

It will next be shown that the correct algebraic sum of two quantities can be formed by an adder which will form the correct sum of two positive numbers. The basic rules of binary addition are illustrated in Table I. Since the adder must be capable of forming the correct sum even if two ones from the two addends coincide with a carryover from the preceding digit, Table II, which is developed from the basic principles in Table I, summarizes the results which the adder must produce. An adder satisfying these requirements, then, will form the correct sum of two positive numbers. Since it is not the purpose of this paper to discuss circuit details, it is sufficient to state here that these requirements can be met electronically by relatively simple means.

The significance of the statement, previously made, that negative numbers are represented by their complements with respect to 2, must now be examined. This implies that if $-1 \leqq x < 0$, x is actually written $2+x$, which obviously lies in the range between 1 and 2. Thus, in the example previously given, $-\frac{3}{16}$ (in binary form -0.0011) is written 1.1101. If the digits to the left of the sign position are ignored, any positive number $0 \leqq x < 1$ is indistinguishable from $2+x$; for example, $\frac{3}{16}$ in binary form is 0.0011; $\frac{3}{16}+2$ is 10.0011, which becomes 0.0011 again if the 1 to the left of the sign digit is ignored.

Thus, if an adder is constructed which discards carries beyond the sign digit, it should work equally well for positive or negative numbers. The following examples will illustrate this.

$$\begin{array}{rr} 0.0011 & \frac{3}{16} \\ 0.0111 & \frac{7}{16} \\ \hline 0.1010 & \frac{5}{8} \end{array}$$

$$\begin{array}{rr} 0.0011 & \frac{3}{16} \\ 1.1001 & -\frac{7}{16} \\ \hline 1.1100 & -\frac{1}{4} \end{array}$$

$$\begin{array}{rr} 1.1101 & -\frac{3}{16} \\ 1.1001 & -\frac{7}{16} \\ \hline (1)\ 1.0110 & -\frac{5}{8} \end{array}$$

TABLE II.

Addends	Sum	Carryover
0, 0, and 0	0	0
0, 0, and 1	1	0
0, 1, and 1	0	1
1, 1, and 1	1	1

(The carryover, shown in parentheses, is discarded.)

$$\begin{array}{rr} 1.1101 & -\frac{3}{16} \\ 0.0111 & \frac{7}{16} \\ \hline (1)\ 0.0100 & \frac{1}{4} \end{array}$$

(Again, the carryover is discarded.)

To summarize these results, then, it is possible to use a simple binary adder to add positive or negative numbers, provided (a) each quantity is confined to the range $-1 \leqq x < 1$ and a 2 is added to the quantity before it is sent into the machine, and (b) any digits to the left of the 2^0 position, called the sign position, are discarded, whether they result from the original addition of 2 to the number or from an addition in the course of subsequent computation.

III. SUBTRACTION

Since the addition process just described works equally well for positive and negative quantities, subtraction can be accomplished by changing the sign of the subtrahend and adding. Since the sign reversal is accomplished by determining the complement of the quantity with respect to 2, a procedure for complementing is required.

First, consider the result obtained by selecting a quantity, changing all its zeros to ones and its ones to zeros, then adding the result to the original number.

$$\begin{array}{r} 0.1101001 \\ 1.0010110 \\ \hline 1.1111111. \end{array}$$

It is evident that the result will always be a series of ones. For n digits to the right of the binary point, the result will be $2-2^{-n}$. The quantity obtained by interchanging zeros and ones is therefore the complement of the original quantity with respect to $2-2^{-n}$; that is, the new quantity $m' = 2-2^{-n}-m$. Since the result required is $2-m$, it is only necessary to add 2^{-n} to the result obtained by interchanging ones and zeros:

$$m = 0.110100$$
$$-m = 1.001011 + 0.000001 = 1.001100.$$

Complementing is thus accomplished by interchanging ones and zeros in the quantity to be complemented, and adding a one to the result in the least significant digit position.

A somewhat different subtraction method is discussed in the section dealing with storage of absolute values.

IV. MULTIPLICATION

Multiplication in the binary system is simplified by the fact that any multiplier digit can be only a one or a zero. This fact results in a process easy to mechanize, since additions and shifts alternate, whereas in the decimal and other number systems, the number of additions between shifts varies in accordance with the multiplier digits. (Of course, the case of no addition can be treated as equivalent to the addition of zero.) Multiplication of two positive binary quantities, then, consists of examining the multiplier digits in succession, starting with the least significant, adding the multiplicand into the partial product if the corresponding multiplier digit is a one, but adding zero if the multiplier digit is zero. After every such addition, the partial product is shifted one place to the right. The following example illustrates the procedure:

$$\begin{array}{rll}
0.1\,1\,0\,1 & x & \frac{13}{16} \\
0.1\,0\,1\,1 & y & \frac{11}{16} \\
\hline
0.1\,1\,0\,1 & x\cdot 1 & \\
0.1\,1\,0\,1 & x\cdot 1 & \\
0.0\,0\,0\,0 & x\cdot 0 & \\
0.1\,1\,0\,1 & x\cdot 1 & \\
0.0\,0\,0\,0 & x\cdot 0 & \\
\hline
0.1\,0\,0\,0\,1\,1\,1\,1 & xy & 143/256.
\end{array}$$

Note that a shift takes place after every addition except the last. Although the above example is written as if the multiplicand were shifted to the left, obviously this is equivalent to shifting the partial product to the right; the latter process is better adapted to computer operation.

Now suppose that the multiplicand, x, is positive and the multiplier, y, is negative. As usual, y is written $2-|y|=2+y$. Multiplying gives $x(2+y)=2x+xy$, which can be corrected to equal the product xy by subtracting $2x$. Although $2x$ is obtainable by a simple shift, nevertheless it would be more convenient if this shift could be avoided, and this turns out to be easily possible. Let x be multiplied by all digits of y except the sign digit. Since y is negative, this sign digit is 1; the result, therefore, is to multiply x by one less than before. This means the formation of the product $x(1+y)=x+xy$ instead of $x(2+y)=2x+xy$. Now, a correction of $-x$ is sufficient, and furthermore, the process is more systematic, since every addition is followed by a shift.

Thus, to take care of the cases of x positive and y either positive or negative, it is only necessary to follow the procedure outlined for both x and y positive, and, if y is negative, correct the result by subtracting x from it. The following example illustrates the procedure:

$$\begin{array}{rll}
0.1\,1\,0\,1 & x & \frac{13}{16} \\
1.0\,1\,0\,1 & y & -\frac{11}{16} \\
\hline
0.1\,1\,0\,1 & & \\
0.0\,0\,0\,0 & & \\
0.1\,1\,0\,1 & & \\
0.0\,0\,0\,0 & & \\
\hline
0.0\,1\,0\,0\,0\,0\,0\,1 & xy+x & \\
1.0\,0\,1\,1 & -x & \\
\hline
1.0\,1\,1\,1\,0\,0\,0\,1 & xy & -143/256.
\end{array}$$

From symmetry it is apparent that if x is negative and y positive, a correction of $-y$ will give the true product. As a preliminary assumption, let the sign digit of x be ignored until the correction at the end is made. This leaves only the question of how to add in the $-y$. It turns out to be convenient, as far as computer design is concerned, to examine successive digits of y by shifting y to the right a digit at a time, dropping off each digit after it has been examined. This means that by the end of the process y has been lost and is not available for use in correcting the product. Therefore, the possibility of making the correction digit by digit as the product is built up must be examined.

Suppose the numbers being used have 30 digits and a sign. Referring back to the basic multiplication process, it is noted that 30 shifts are made in building up the product; therefore, the sign digit of x during the first addition finally becomes the 30th or least significant digit of the product. Similarly, the sign digit of x on the second addition becomes the 29th digit of the product, and so on. It therefore becomes apparent that the sign digit of x during any addition occupies in the final product a position equivalent to that of the digit of y which controlled its addition into the product.

Next, note that the correction needed is the complement of y. Thus, for every 1 in y a 0 is needed in the correction term, but for every 0 in y a 1 should appear in the correction term. As usual, the complement must be corrected by adding a unit in the last place. Note further that the correction is needed only if x is negative —that is, if its sign digit is 1.

Putting together the above facts, the required procedure may be defined. If a digit of y is 1, x (without its sign digit) is added into the partial product. If a digit of y is 0, its complement, 1, must be added into the partial product, but a 1 is available, in the correct position, in the form of the sign digit of x. Thus, if a digit of y is 0, the sign digit only of x is added. Of course, this sign digit might be 0, but that would imply that x was positive and no correction was required; thus no harm is done by adding the zero. Since the additions are terminated before examining the sign digit of y, the correction term, if any, still lacks a 1 in the sign position and a 1 in the units position. Hence, if x is negative, these digits must be added to the product, as shown in the following:

$$\begin{array}{rll}
1.0011 & x & -\tfrac{13}{16}\\
0.1011 & y & \tfrac{11}{16}\\
\hline
0.0011 & (x \text{ without sign}) & \\
0.0011 & & \\
1.0000 & (\text{sign only of } x) & \\
0.0011 & & \\
\hline
0.01100001 & & \\
1.0001 & (\text{correction term}) & \\
\hline
1.01110001 & xy & -143/256.
\end{array}$$

Taking the third term of the partial product (that is, 1.0000 shifted twice to become 0.0100) and the correction term, and adding, the result 0.0100+1.0001 = 1.0101 is obtained. Thus, it is shown that the complement of y has in fact been added to the product.

Finally, the case of x and y both negative will be considered. Starting with the numerical example, and following the procedure outlined for the preceding cases:

$$\begin{array}{rll}
1.0011 & x & -\tfrac{13}{16}\\
1.0101 & y & -\tfrac{11}{16}\\
\hline
0.0011 & (x \text{ without sign}) & \\
1.0000 & (\text{sign only of } x) & \\
0.0011 & & \\
1.0000 & & \\
\hline
0.10101111 & & \\
1.0001 & (\text{correction for sign of } x) & \\
\hline
1.10111111 & xy+x & \\
0.1101 & -x\ (\text{correction for sign of } y) & \\
\hline
0.10001111 & xy & 143/256.
\end{array}$$

The correction terms added on account of the sign of x are (1) 1.0000, shifted three times to become 0.0010; (2) 1.0000, shifted once to become 0.1000; (3) 1.0001, added after all shifts are completed.

Again adding these various corrections, the result is 1.1011, which appears to be wrong, because the complement of y is 0.1011. Recalling that, up to the correction steps, signs were disregarded, and that therefore the factors behaved like $x+1$ and $y+1$, the uncorrected product obtained must be $(x+1)(y+1)=xy+x+y+1$. Hence, it is necessary to subtract 1 as well as x and y to get the true product. Since all carryovers beyond the sign are disregarded, subtracting 1 is the same as adding 1. Thus, the extra 1 which appeared in the complement of y is necessary.

The foregoing discussion covers all possible cases and shows that a single generalized multiplication process can be used to produce results which are correct regardless of the signs of the factors.

V. DIVISION

The division process used in the binary computer is the non-restoring method, analogous to that used in desk computing machines. This method has two important advantages—it eliminates time-consuming comparison operations which are necessary in the restoring method, and it requires no extra correction operations if either dividend or divisor is negative.

In the non-restoring method of division, the signs of the dividend and divisor are first examined. If they are alike, the divisor is subtracted from the dividend repeatedly until the signs become different, a unit being added into the corresponding quotient digit for each subtraction. If the signs are different, the divisor is added to the dividend repeatedly until the signs become the same, a unit being subtracted from the corresponding quotient digit each time. Thus, in the decimal system, if the signs were alike and the divisor had to be subtracted three times to cause a sign reversal, the corresponding quotient digit would be 3; if the signs were different and the divisor had to be added seven times to cause a sign reversal, the corresponding quotient digit would be −7. As soon as a sign reversal occurs, the remainder is shifted one place to the left and computation of the next quotient digit begins.

If the above process is carried out exactly as described, any quotient digit may be $\pm n$, where n is an integer in the range 1 to 10 inclusive. It is obvious, however, that if a sign reversal has not occurred after nine additions or subtractions (in the decimal system), it must surely occur on the tenth operation.[3] Thus, it is sufficient to terminate the computation of each digit of the quotient after nine operations and shift the remainder without waiting for a sign reversal. The quotient digits then may be $\pm 1, \pm 2, \cdots, \pm 9$. Suppose the quotient obtained is the sequence 1, −3, 9, 5, −4, 6. To obtain the quotient in usable form, the aggregate of the negative digits must be subtracted from the aggregate of the positive digits: 109,506−30,040=79,466. If the quotient was built up in an accumulator (i.e., a register containing an adder so arranged that after entry of a new quantity the register contains the sum of the latter and the previous contents), this process was carried out stepwise as the quotient was built up.

An accumulator must be used to hold the dividend (which becomes the remainder, of course, after the process has started), in order to provide means for adding in the divisor or its complement. It is more convenient to store the quotient digits in a simple register, which cannot add or subtract, thus avoiding the necessity of providing an additional accumulator. Returning for a moment to the decimal example, it is noted that there are 18 possible quotient digit values

---

[3] An exception to this rule occurs in the case of an improper division, i.e., one in which the dividend is larger than the divisor. In this case, no sign reversal would occur on the tenth operation in the computation of the first quotient digit; it may, in fact, be desirable to perform the tenth operation and institute an automatic corrective procedure if no sign reversal occurs.

($\pm 1, \pm 2, \cdots, \pm 9$). By the same reasoning, it follows that in the binary system there are only two values (± 1) and that only one operation (addition or subtraction, as the case may be) is necessary for each quotient digit. Thus, as in multiplication, additions (or subtractions) can alternate with shifts, and the result is a process easy to mechanize. There is still the difficulty, however, that the quotient register has no way of distinguishing -1 from $+1$. An investigation of the possibility of entering a 0 in the quotient wherever a -1 is called for immediately suggests itself, in order to see if the pseudo-quotient so obtained bears some simple relationship to the true quotient, x/y, of two binary quantities. If such a simple relationship exists, it will be reasonable to compute the pseudo-quotient and make any necessary corrections to the latter to obtain the true quotient.

Recalling that -1 should be entered in the quotient if y is added to the remainder, and $+1$ if y is subtracted, 0 is used for each addition and $+1$ for each subtraction. An expression can now be written for the new remainder, r_k, in terms of the old remainder r_{k-1}, the quotient digit p_k, and y:

$$r_k = 2r_{k-1} + (1 - 2p_k)y$$

which reduces to $2r_{k-1}+y$ if p_k is 0 and $2r_{k-1}-y$ if p_k is 1. The factor of 2 results from the fact that the old remainder was shifted to the left before the addition or subtraction of y. Multiplying through by 2^{-k}

$$2^{-k}r_k = 2^{-(k-1)}r_{k-1} + (2^{-k} - 2^{-(k-1)}p_k)y$$

gives a more convenient recursion formula. Noting that the "zeroth" remainder is actually x itself,

$$\begin{aligned} 2^{-1}r_1 &= x + (2^{-1} - 2^0 p_1)y \\ 2^{-2}r_2 &= 2^{-1}r_1 + (2^{-2} - 2^{-1}p_2)y \\ &= x + [(2^{-1}+2^{-2}) - (2^0 p_1 + 2^{-1}p_2)]y \quad \text{etc.,} \end{aligned}$$

or, in general,

$$2^{-n}r_n = x + \left(\sum_1^n 2^{-k} - \sum_1^n 2^{-(k-1)}p_k\right)y.$$

Now

$$\sum_1^n 2^{-k} = 0.1 + 0.01 + \cdots = 0.111\cdots$$

which is evidently equal to $1-2^{-n}$. Thus, making this substitution and transposing,

$$x = \left[-1 + 2^{-n} + \sum_1^n 2^{-(k-1)}p_k\right]y + 2^{-n}r_n$$

and, dividing by y,

$$x/y = \left[-1 + 2^{-n} + \sum_1^n 2^{-(k-1)}p_k\right] + 2^{-n}r_n/y.$$

The expression in square brackets, then, is the desired quotient. Now if $n=30$, the first 30 quotient digits computed by the method outlined above correspond to the sign and the first 29 digits of the pseudo-quotient. (The first digit, p_1, corresponds to the sign rather than the most significant digit because it is in the 2^0 position; ($2^{-(k-1)} = 2^0$ for $k=1$.) To convert the pseudo-quotient into the true quotient, it is necessary to add 2^{-30} and subtract one. The first of these corrections corresponds to putting a unit in the least significant digit position, a step which also coincides with the round-off procedure to be adopted. As for subtracting 1 from the result, since carries beyond the sign position are disregarded, subtracting 1 is the same as adding 1; the two corrections can therefore be taken care of by bringing the pseudo-quotient from the register where it was built up into the accumulator, simultaneously clearing out the last remainder and adding units into the sign and the least significant digits. (It may be noted that the latter position is still unfilled, since p_{31} was not computed; the correction in this position could therefore have been made in the register, but an adder is required for the sign correction.)

The reader may have been troubled by the fact that in doubling the remainder the sign digit will be lost. Actually, this does no harm. The addition or subtraction of the divisor is always such as to decrease the absolute value of the remainder; since $x<y$ to begin with, $2x-y<y$ and in general $2r-y<y$. Since $y<1$, $2r-y<1$, and therefore the result of the operation is always within the range of the machine; although the sign digit of r was shifted out of range, it could not have affected the result in any case. It should be noted that the sign of r is used to determine whether y is to be added or subtracted, however; therefore, since this sign is lost by the shift, it must be examined and compared with the sign of y before the shift takes place.

The example below illustrates the division process just described:

1.0111	$x(r_0)$	$-\frac{9}{16}$
0.1011	y	$\frac{11}{16}$
0.1110	$2r_0$	
0.1011	$+y$	
1.1001	r_1	$(p_1=0)$
1.0010	$2r_1$	
0.1011	$+y$	
1.1101	r_2	$(p_2=0)$
1.1010	$2r_2$	
0.1011	$+y$	
0.0101	r_3	$(p_3=0)$
0.1010	$2r_3$	
1.0101	$-y$	
1.1111	r_4	$(p_4=1)$
0.0010	$x/y+1-2^{-4}$	
1.0001	$1+2^{-4}$	
1.0011	$x/y+2=x/y$	$-\frac{13}{16}$

TABLE III.

Minuend	Subtrahend	Difference	Borrow
0	0	0	0
1	0	1	0
1	1	0	0
0	1	1	1

which is the exact quotient, $-9/11$, rounded off to four binary places. r_4 is discarded; the pseudo-quotient ($p_1+p_2+p_3+p_4=0.001$) and the correction term 1.0001 are added together and the result left in the accumulator.

VI. ROUND-OFF PROCEDURES

Both multiplication and division give results having more significant figures than the original numbers entering into these processes; in general, multiplication of two n-digit factors yields a product of $2n$ digits, and division yields a quotient having an infinite number of digits. Since only n digits are required for most computational processes, some round-off procedure must be followed in order to avoid the bias which would result if the remaining digits were simply dropped. The round-off procedure should fulfill two requirements: the approximation should lie as close to the true product or quotient as practical, and it should be unbiased, i.e., its mean should equal the true result.

Of the various possible round-off schemes, two are of interest here. The first and most familiar consists of adding a unit to the $n+1$st digit, allowing any resulting carries to take place, and then keeping only the first n digits. The other consists of replacing the nth digit with a 1, regardless of whether that digit was originally a 1 or a 0. It can be shown that both schemes produce results which are sufficiently unbiased in view of the fact that products and quotients themselves are not entirely unbiased.[4] The latter situation is due to the fact that the original quantities themselves are, in general, rounded-off approximations of other quantities. On the other hand, the variance of the second method is twice as great as that of the first, being 0.58 times the last digit as compared to 0.29 times the last digit for the more familiar scheme.

In spite of the larger variance, however, the second round-off scheme is used. It has the advantage of being usable even after the $n+1$st digit has been lost as the result of a right shift; thus, it is unnecessary to interrupt the multiplication process before the last step to add in the unit for round-off. Furthermore, no carries are produced; thus, the unit pulse can be put in after the adder, and the process carried out concurrently with the last complement correction. In the case of division, as has already been seen, the result obtained already conforms to this round-off procedure without further modifications; it therefore becomes unnecessary to compute the 31st quotient digit.

0	0	1	1	1
0	1	1	0	1

When it is necessary during computation to round off to less than 30 digits, the more precise method can be used; in most cases the procedure will be to shift right until all but one of the unwanted digits are lost, add a unit in the lowest position, and then shift right one more place.

VII. STORAGE OF ABSOLUTE VALUES

While negative quantities are stored in complement form in the Binac and most other binary computers now under construction, it is of interest to examine briefly the possibility of storing the absolute values of negative quantities, distinguishing them from positive quantities only by the difference in the sign digit; in this case it is immaterial whether 0 and 1 are used for + and −, respectively, or vice versa. There are two principal advantages to such a procedure; first, the preparation of input data and the interpretation of output data are simplified; and second, the visual interpretation of data in registers and memory is made easier, thus expediting trouble-shooting.

The effect on multiplication and division is that of simplification, since in these operations the signs can be disregarded and the operations performed on absolute values with no corrections necessary. A preliminary comparison of the signs of the operands discloses immediately the sign of the result; this is stored until the operation is complete and then appended to the product or quotient.

In the case of addition, however, the operations become more complex. Before addition can take place, the signs of the addends must be compared; if they are alike, an addition is performed; otherwise subtraction is necessary, with some provision for assuring the subtraction of the operand having the smaller absolute value from that having the larger, or for making a suitable correction which will produce the same effect. The subtraction can be accomplished in a regular adder by complementing negative quantities before sending them to the adder, but it is possible to avoid complements completely, even in the arithmetic circuits, by using a subtractor rather than an adder when such operation is indicated. The subtractor proves to be as simple electronically as an adder, since it must fulfill a set of conditions differing only slightly from those satisfied by the adder.

---

[4] See reference 1, p. 20.

For two binary digits, the rules for subtraction can be summarized as in Table III. To complete the subtraction, provision must be made for taking the "borrow" pulse and subtracting it from the next minuend digit. This is equivalent, however, to adding it to the next subtrahend digit; and the latter procedure proves to be more advantageous electronically. The full set of conditions can now be written down as in Table IV.

The preceding discussion of the storage of absolute values has been included here partly to illustrate the difficulties to be encountered in such a system, and partly because of the importance of the system in computers of the decimal type, even though the latter are not otherwise considered in this paper. Because of the complications involved, storage of absolute values is not ordinarily employed in binary computers, probably because it is felt that the inconvenience of representing quantities in binary form is not materially increased by the necessity of representing negative quantities in complement form. In decimal computers such as the Univac, however, where convenience in handling of input and output data is of great importance, the storage of complements is avoided.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 8 AUGUST, 1950

A Recording Polarimeter

GABOR B. LEVY, PHILIP SCHWED,* AND DAVID FERGUS
Research Department, Schenley Laboratories, Inc., Lawrenceburg, Indiana

(Received March 23, 1950)

A recording polarimeter has been constructed. The principle of operation is essentially the replacement of an operator in conventional visual polarimetry by a photoelectric servo system. A photo-multiplier tube is used which, in conjunction with a mechanical chopping system, delivers an alternating current signal proportional to the unbalance. The latter is filtered and amplified and actuates a servo mechanism. The precision of the system is ±0.005° for static balance and the speed about 0.5° per minute. Hence the arrangement compares favorably with ordinary visual operation. The construction of the instrument is discussed briefly and its performance is illustrated by examples.

INTRODUCTION

IN the study of chemical or biochemical reactions, it is of great advantage to select a method of analysis that is non-destructive and which does not involve sampling. Potentially, polarimetric measurements are suitable, particularly in the biochemical field, since the optical activity is frequently subject to change in the course of the reaction. However, the measurement of changing optical rotation by visual methods is tedious and of limited precision. For such applications, a recording polarimeter would be of great value.

Instruments of this type are not available, and furthermore, the existing literature gives no encouragement for success of such a scheme. For example, W. Heller[1] states: "Persons with particularly sensitive, specially trained, and well-adapted eyes can be expected, however, to surpass any photoelectric registration. . . ."

Considering the fact that measurement of fast changing rotation is far from an ideal condition for visual observation, we felt encouraged to construct a photoelectric instrument despite the statement cited. In addition, the potential value of such an instrument appeared to warrant the effort.

We have chosen the most direct approach, i.e., converting a visual instrument to photoelectric operation. The performance of the resultant instrument and its potential value in the study of optical activity seems to justify its description in some detail.

PRINCIPLES OF OPERATION

Essentially monochromatic light is passed through a conventional polarimeter. The "half-shade" image from its Lippich analyzer (with two fields) is projected onto a photo-multiplier photo-cell. Interposed is a semicircular sector which is driven by a synchronous motor. Thus the output of the photo-cell, at unbalance, is a sinusoidal alternating current whose phase is shifted by 180° when the direction of the unbalance reverses. This signal is amplified by a battery operated untuned preamplifier and further amplified by an amplifier tuned to the fixed frequency of the sector and signal. The signal, which is thus freed from noise, is fed after further amplification to one of the two coils of a differential relay, the coil energized depending on the position of the sector. This arrangement provides phase discrimination and rectification as well as further filtering. The relay actuates a reversible 60-cycle motor which is mechanically linked to the analyzer of the

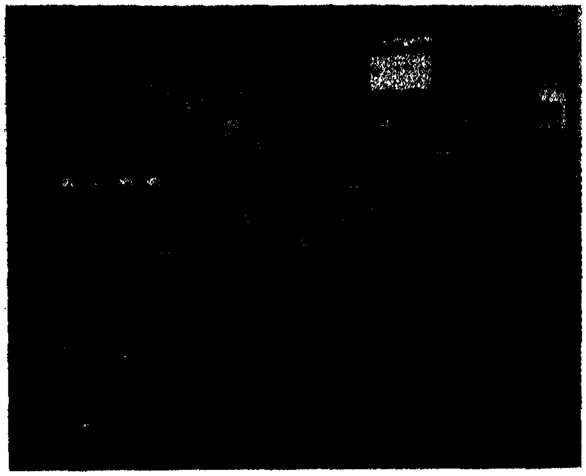

FIG. 1. The recording polarimeter.

polarimeter. An electrical link is also provided to a fast strip chart recorder.

The operation can be summarized as follows: Whenever the polarimeter analyzer deviates from zero position the two halves of the half-shade field differ in intensity. Therefore, as the semicircular chopping disk is rotated, a periodic variation of light intensity occurs which appears as alternating current in the photo-cell circuit. This alternating current, after suitable amplification, is rectified and fed into one of the coils of a differential relay, depending upon which of the two fields is the brighter. The relay switches the line voltage accordingly into a motor which drives the analyzer in the proper direction to optical balance. A recorder indicates the angular travel of the analyzer.

DETAILS OF CONSTRUCTION AND OPERATION

In constructing the instrument it was found that the design of the electrical components is not critical. The circuits used are conventional and therefore are only indicated and discussed briefly. The most important factors for successful operation proved to be the proper design and arrangement of mechanical parts and a number of small details aiding operations which are discussed in the following.

The general appearance of the assembly is shown in Fig. 1 and a schematic plan in Fig. 2. The light source (1) is a General Electric mercury vapor lamp (S-4) which is operated at about 150 watts from 250 v d.c. line voltage by use of a rheostat. The lamp housing is connected to an exhaust fan (2) and the lamp thus cooled has a life of several months. The light passes through two Corning filters (Nos. 3484 and 5120) which isolate the mercury line of 5460A. In a housing (3) together with the filters may be placed a ground glass plate so that a beam of more uniform intensity enters the polarimeter (4). The polarimeter is the research type of O. C. Rudolph and Sons which was modified slightly by providing weights to enhance its stability and leveling screws in three planes (5). The half-shade image emerging from the polarimeter enters box (6) and can be observed by means of a 45° plane mirror through a port (7). Alternately by means of a knob (8), the mirror can be swung out of the optical path thus closing the port and opening an interlocked window. This is the normal mirror position; and the light passes through a brass tube which is equipped at its exit with an adjustable knife edge blocking exactly half of the tube. The tube is mounted between two ball bearings and can be rotated by means of an external

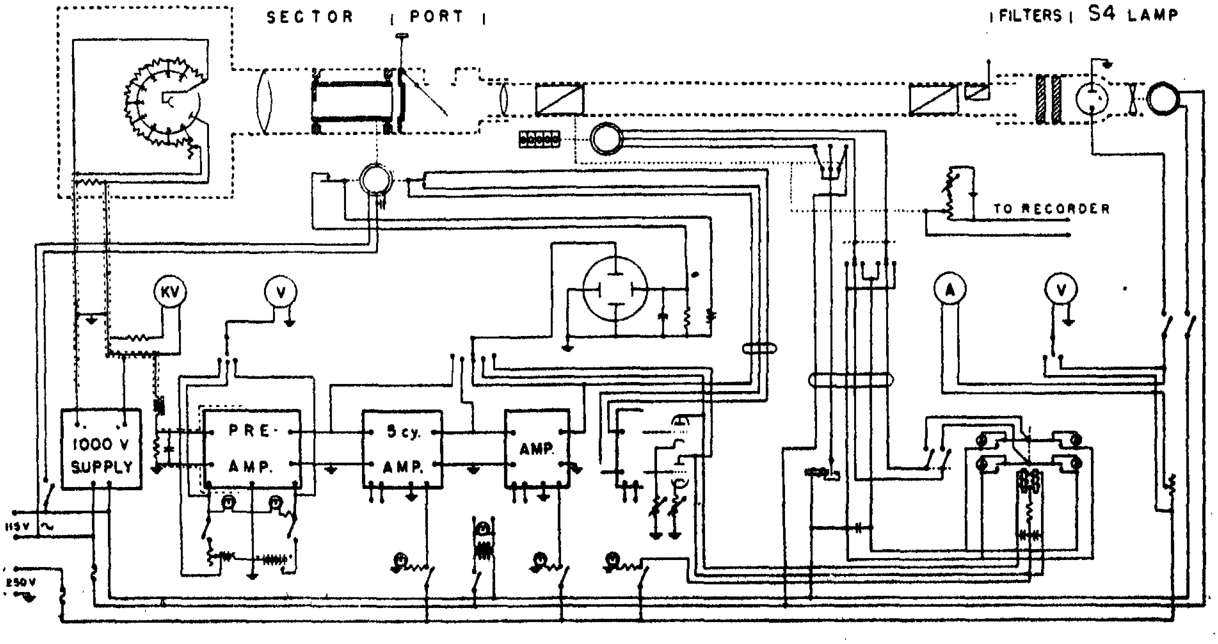

FIG. 2. Schematic diagram of polarimeter.

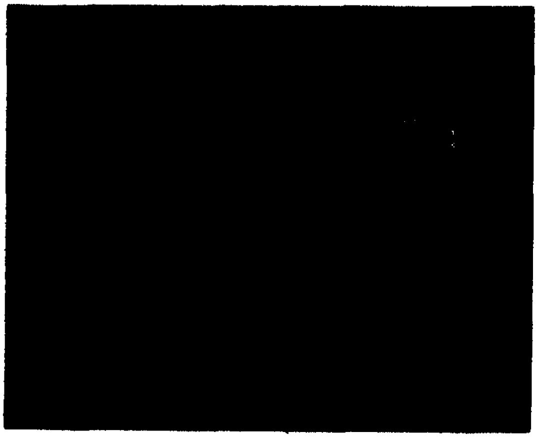

FIG. 3. Oscillogram (preamplifier circuit).

gear, gear train, and synchronous motor (9). There is also a screw mounted on the periphery of the tube which actuates a microswitch. This switch in conjunction with a dry cell, resistor, and condenser serves as a synchronized saw tooth voltage generator for the horizontal sweep of the oscilloscope (10). The tube is rotated at 5 cycles/second and serves as a chopping shutter.

The chopped light is focused by a small lens on a photo-multiplier tube which is mounted on an adjustable, well-insulated bracket at the end of box (6). Tube 1P21 is preferred although No. 931A can also serve (with some loss in over-all sensitivity). The fixed dynode resistors and a potentiometer, for a variable output, are arranged inside the box. The electrical components are contained in the console (11). The services used are: 110 v a.c. for the filament transformer and the synchronous motors, 250 v d.c. for the plate voltages and the mercury vapor lamp, 12 v d.c. from two storage batteries for the preamplifier filament (variable 6–7 v), and inside the console a tapped 45-v dry-cell for variable plate voltage for the preamplifier. The various chassis in the console contain the following units:

(1) The bottom chassis contains the power supply of 1000 v for the photo-multiplier. This is of conventional design using a 2×2 rectifier tube. It supplies approximately 100 v per dynode stage of the photo-tube while the output can be regulated, as mentioned.

(2) The next chassis contains the rheostat for the light, fuses, a filament transformer and the differential relay assembly. Four neon bulbs are wired in parallel with the four contact points of the relay. This arrangement is beneficial for the stability of the unit and at the same time provides a visual guide to the performance of each contact.

(3) The third chassis contains the preamplifier which is electrostatically shielded and shock mounted. It is a direct coupled amplifier of conventional design using two No. 5693 tubes. The tuned amplifier is of the parallel *T* type.[2] Controls are provided for both the total amplification and the sharpness of tuning of this amplifier. An untuned amplifier stage follows this unit. It

FIG. 4. Oscillogram (tuned amplifier circuit at balance ±0.015°).

provides additional amplification and is set to clip the signal to some extent (Fig. 5).

The filtered and amplified signal is fed to the pair of microswitches (12). These are mounted on alternate sides of a brass plate which also contains a bearing for a gear. The face of the gear carries a raised sector of 40° which actuates the switches. This assembly slides on the box and by withdrawing it, the gear can be made to engage the synchronized gear train in any position. Once locked in, the scanning sector, sawtooth voltage and the phase discriminator (i.e., the switches discussed) are in permanent synchronization. Each switch is associated with a No. 5692 tube, connecting the voltage passed by it to the grid of the proper tube. These tubes are biased by variable cathode resistors to deliver less than 2 milliamperes, at 0 v grid signal, which is the release point for the differential relay contained in the plate circuit.

(4) The next chassis contains the toggle switches for the multipurpose instruments, the resistor by which the filament voltage of the preamplifier is varied and the selector switches for the oscilloscope.

(5) The instrument panel permits the reading of the following: a. High voltage (photo-tube circuit). b. D.c. voltages, both of plate circuits and mercury vapor lamp. c. Current through mercury vapor lamp. d. Voltages of batteries, preamplifier plate, and filament circuits.

The line voltage switched into two branches by the differential relay drives the small motor in either

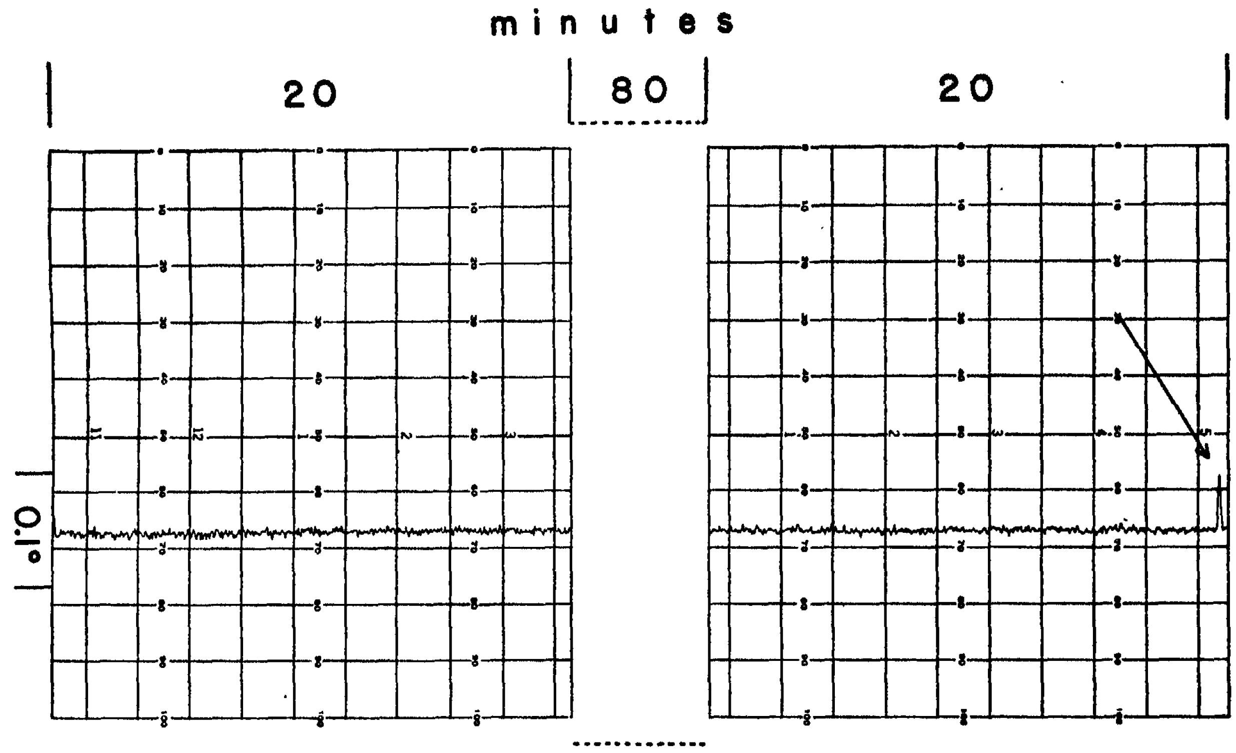

FIG. 6.

direction. This motion is transmitted to a counter (13) and also through a gear train to the fine adjustment of the polarimeter analyzer and hence to a Beckman 360° potentiometer (14). This potentiometer provides a variable voltage (0–50 mv) to the Brown Electronik recorder. The gear arrangement is such that each count of the counter corresponds to 1/1000° rotation of the analyzer† while the full rotation of the potentiometer and hence 100 divisions of the strip chart correspond to 0.5°. This arrangement provides a convenient scale expansion. A double throw switch (15) is provided by means of which the motor driving the analyzer may be controlled independently of the signal of the servo. Outside the console is the detachable oscilloscope whose function is discussed below.

In setting up the instrument for operation the procedure is as follows: The 250-v d.c. line is switched on and the mercury vapor lamp started, including the fan. After a few minutes the lamp is adjusted to about 150 watts and the filters are inserted. The half-shade angle is set between 3° and 10° and a cell containing water is inserted in the polarimeter. The position of the lamp is adjusted for proper illumination of the tube. The mirror is swung into place and the analyzer is set near the balance. Then the front panel is removed from the box and the mirror removed from the light path. The knife edge is now set to coincide with exactly half of the half-shade image. For observation of this and subsequent steps a piece of paper is held in front of the photo-cell assembly. The polarimeter is leveled to approximately the right height, and laterally so that the rotation of the shutter intersects the center of the field. Simultaneously the analyzer is focused. Then the lens is inserted and the photo-cell adjusted so that the light spot hits the center of the cathode surface. The front panel is replaced and the ground glass diffuser inserted.

It should be mentioned that alignment, as described, is only made once when setting up or after very severe mechanical shock. In daily operation only fine adjustment is made as described in the following.

The power is switched on including the synchronous motor driving the scanning sector. With the relay circuit switched off, the analyzer (with fine adjustment locked) is moved off balance and the preamplified signal observed in the oscilloscope. If properly aligned, a sinusoidal curve is observed (Figs. 3, 4). In conjunction with observing the travel of the analyzer (by means of the counter) the operation of the instrument can be gaged. Lack of sensitivity indicates improper focusing or improper operation of the amplifiers. After the suitable adjustments have been made the operation of the phase discriminator may be observed with the oscilloscope switched into the coupling amplifier circuit (Fig. 5). The drop in voltage coincides with the operation of the switches. (When setting up the instrument the gear is made to engage in such a manner that the switch operation coincides with the maxima.) The

---

† The drive is actually proportional to the tangent of the angles but no correction is necessary at the small angles in question.

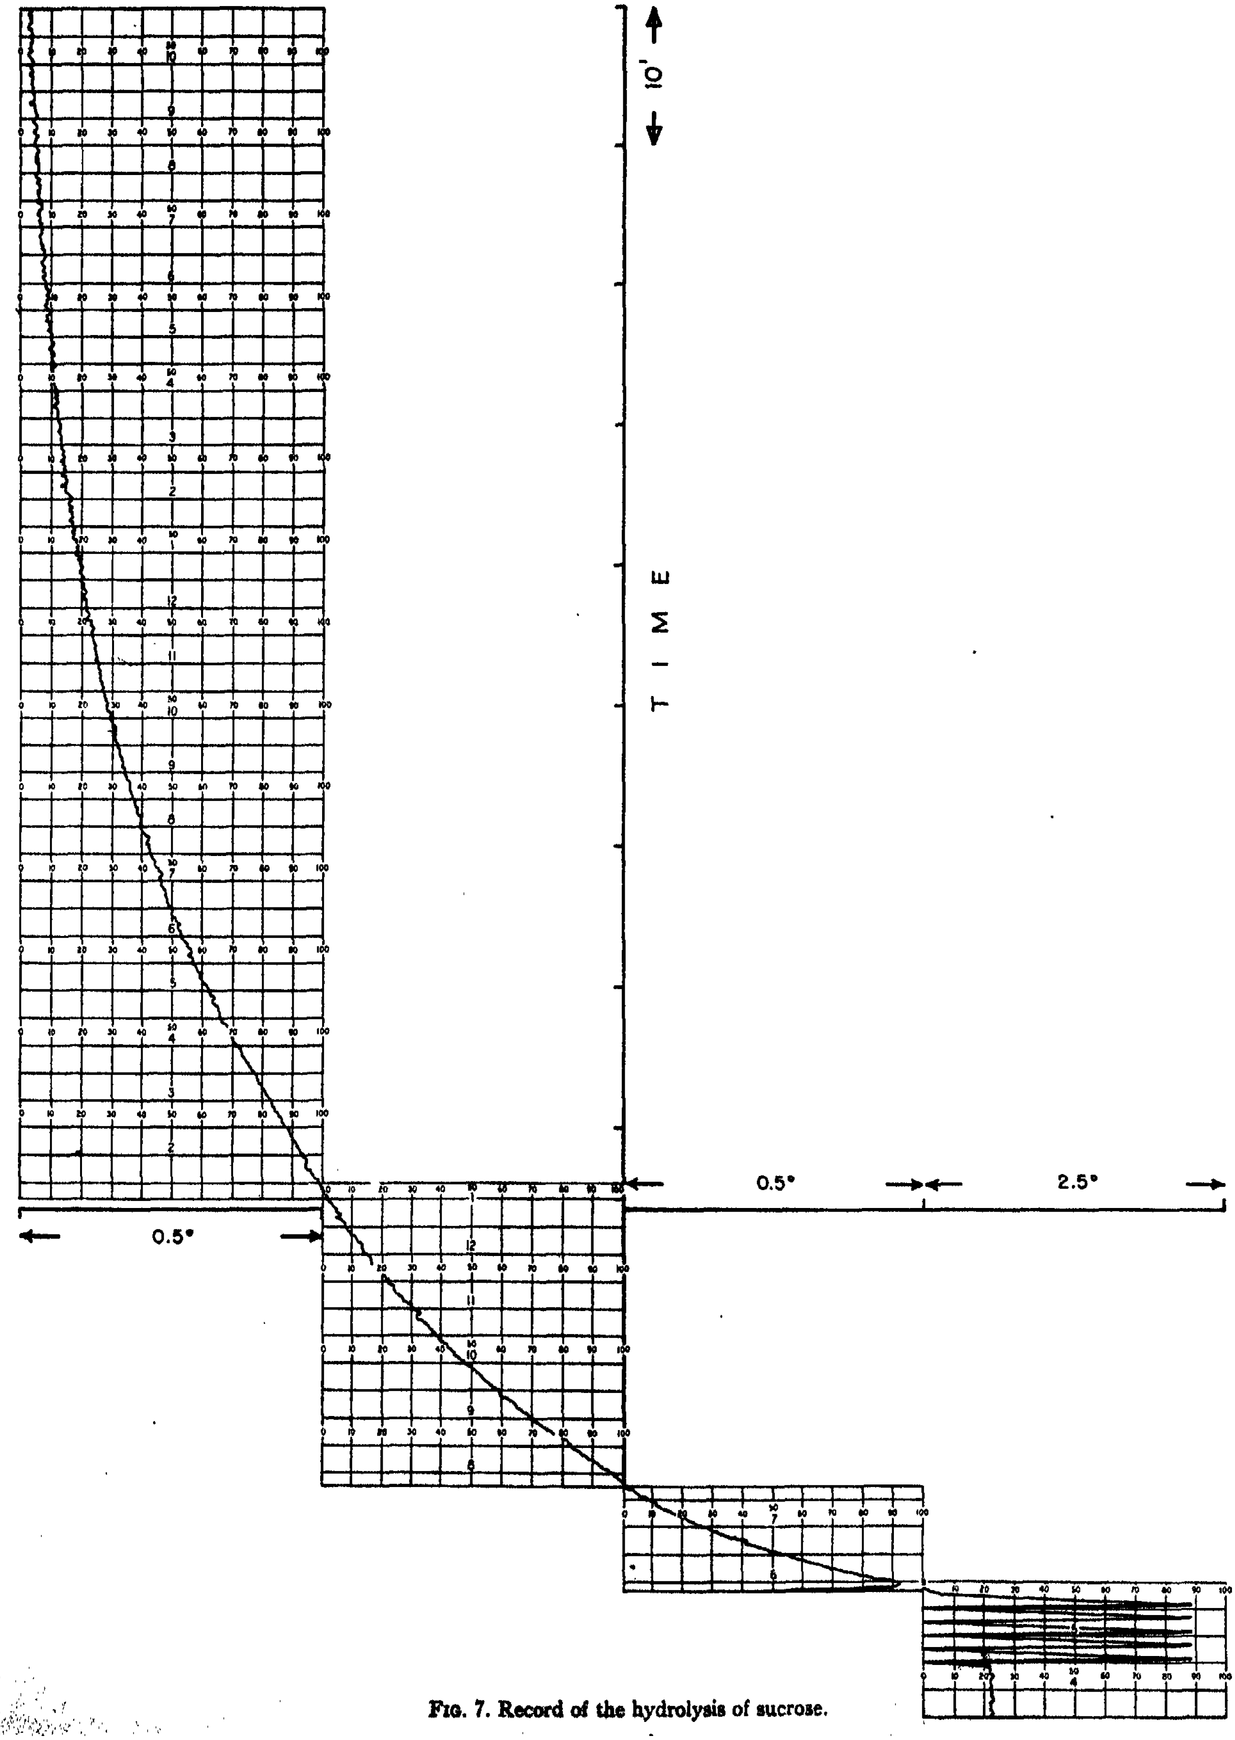

FIG. 7. Record of the hydrolysis of sucrose.

proper operation of the relay may be observed in the oscilloscope by switching to either plate circuit of the last tube. The only remaining step is to adjust the voltage in the recorder circuit so that the pen travels 100 divisions per revolution of the polarimeter fine adjustment screw.

PERFORMANCE

The performance of the instrument is shown graphically in Fig. 6. This is a record of a two-hour test run showing a scatter of less than ±0.005°. There is no measurable shift of rotation during the run. The amplification was set, as usual, so that a response commensurate with the speed of the balancing motor was achieved. This can be seen on the chart where, at the end of the run, the position of the analyzer was changed by overriding the signal; immediately the instrument readjusted itself. The slopes indicate that the travel was at maximum speed of about 0.5° minute in the reverse direction also. The ultimate limit in precision is determined by the period of the amplifier and the motor speed, which in the present arrangement is about 1/5 second and 1/120°/second, respectively, and so the limit is about ±0.002°/second.

Extensive tests were also made to determine the effect of alignment. It was found that the shift most frequently encountered was in the height of the instrument. This does not generally cause a shift in values of rotation although it does affect the sensitivity adversely. The position of the sample tube was found to cause considerable shift in values of rotation due to asymmetries in construction. This was minimized by marking the tube and by placing it always in the same angular position. The resultant reduced scatter of values was found to be of the order of 0.01°.

DISCUSSION

In planning for the construction of the recording polarimeter the preceding literature on photometric polarimetry was considered.[3] Particularly with a view toward adapting an existing design to include recording features. Previous schemes of photoelectric polarimetry were reviewed, e.g., that of Landt and Hirschmüller,[4] Ebert and Kortüm,[5] Bruhat *et al.*,[6] and Schönrock and Einsporn.[7] None of these seemed easily adaptable and therefore the more direct approach was chosen of substituting a photoelectric-servo system for the observer in the visual system of polarimetry. An advantage of this scheme was that it permitted the use of available component parts which proved expedient. The system described could probably be improved in precision by more careful mechanical design, since mechanical deficiency was found to be the limiting factor in the present arrangement. However, the present operation is adequate for most applications.

The main use of the instrument was found in the study of enzyme reactions. This work is being reported elsewhere. However, as an illustration a tracing is included Fig. 7, which represents the hydrolysis of sucrose, catalyzed by the enzyme invertase. The typical logarithmic course of the reaction is apparent.

Other possible uses include measurement of optical activity on changing product streams. In this application a careful design of the sample cell is important, as was found in exploratory experiments. The reason for this is that the appearance of schlieren materially impedes the measurement of optical activity.

In view of the precision of the instrument which compares favorably with visual observation under ordinary conditions, the use for routine determination of optical activity may also be considered. In this application the counter suffices and the use of the recorder is unnecessary.

ACKNOWLEDGMENT

The authors wish to express their appreciation of James H. Hocker for many valuable suggestions concerning the circuits used and to various members of the shops who helped in construction, particularly, C. Miller and H. Giffin. They thank Dr. G. E. Ward for his advice and encouragement, and Schenley Industries, Inc. and Dr. E. C. Williams for permission to publish this material.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 8 AUGUST, 1950

High Pressure Ionization Chamber Counters and Their Use

R. Wilson, L. Beghian, C. H. Collie, H. Halban, and G. R. Bishop
Clarendon Laboratory, Parks Road, Oxford, England

(Received March 6, 1950)

Certain new developments in ionization chamber technique are described. Ionization chamber counters have been designed to operate with fillings of H_2, D_2, or CH_4 to pressures of 35 atmos. with simple filling techniques. The design, characteristics, and uses of these counters are described.

ELECTRON collection makes it possible to use ionization chamber counters with fast amplifiers. We have used these counters for several experiments and therefore feel that a summary of our experimental techniques may be useful. We have used counters filled with hydrogen and methane for the detection of neutrons by proton recoil,[1] and deuterium-filled counters for investigation of the photo-disintegration of deuterium.[2] For both of these applications it is necessary to use a high gas pressure to obtain a sufficiently high counting rate and to reduce the number of protons which lose most of their energy in the walls and are not counted ("wall effect").

GAS PURITY

In order to obtain electron collection it is important to use a gas in which the formation of negative ions by electron attachment to neutral molecules is negligible; H_2, D_2, N_2, CH_4, and the inert gases do not form negative ions. But the electron attachment coefficient for such molecules as O_2, CO, H_2S, Cl_2, H_2O is so large that the presence of even small impurities can cause a considerable fraction of the electrons to form ions before collection. The electron attachment coefficients have been measured at low pressures (10 cm) (e.g. Massey)[3] and usually under different conditions from those prevailing in ionization chamber experiments, so that comparison between theory and experiment is difficult. Rough estimates, however, indicate that one part in 10^7 of oxygen, the most difficult impurity to avoid, will prevent electron collection in a counter filled to ten atmospheres pressure.

It has been the practice to mix 10 percent CO_2 with a gas such as argon in order to increase the electron mobility[4] and therefore to make the effects of impurities less serious. But above pressures of three atmospheres, this leads to loss of pulse height,[5] probably due to columnar recombination, which is high in CO_2.[6] This columnar recombination is discussed more fully later. The introduction of CO_2 reduces the average electron energy by inelastic collisions to a value where the mean free path of electrons in argon is large. (The variation of mean free path with electron energy is often called the Townsend-Ramsauer effect.)

PREPARATION OF GASES

Hydrogen, deuterium, and methane were purified by different methods. The hydrogen is obtained at 180 atmos. pressure from a large hydrogen liquefier,[7] the supply being taken after the charcoal cleaning stage.

The deuterium is prepared by electrolysis of heavy caustic soda* solution in a simple bell type cell. The electrolytic cell is run with a current of 6 amp., giving a current density at the anode of about 0.2 amp. per sq. cm. The electrodes are made of nickel and the nickel leads are welded to tungsten seals; the weld is guarded with glass so that the tungsten is not unduly corroded. The oxygen passes through two liquid air traps to the open air, one to trap heavy water vapor, the other to prevent entry of light water vapor. The hydrogen passes through a metal pressure controlling reducing valve[8] and a capillary to the catalyst tube which is normally at some pressure below atmospheric. Here any residual oxygen is recombined over a red-hot platinum spiral about 2 cm long and 1 cm diameter. Water vapor is condensed out in a liquid air trap, and the deuterium passes through 10 cm of capillary tube before it is adsorbed on charcoal immersed in liquid air. The filling continues until sufficient gas has been produced or until the pressure in the charcoal bottle rises to atmospheric pressure. The only impurity in a large concentration to be expected from this system is CD_4 from CO_2 dissolved in the caustic soda.

A second evacuated charcoal bottle equally immersed in liquid air is then connected to the first until equilibrium has been established. It is hoped that any residual impurity will not desorb from the first charcoal bottle. On removing the liquid air the pressure in the charcoal bottle rises from 1 atmos. to 60 atmos. and the gas is available for filling counters. It is important to use a material for the charcoal bottle that does not

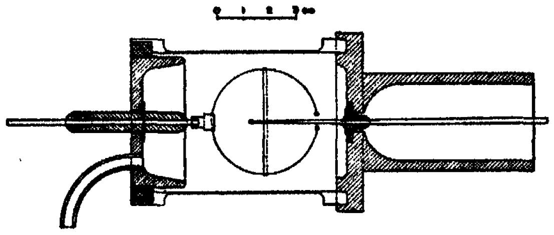

FIG. 1. Ionization chamber counter with well-defined counting volume.

become brittle at liquid air temperature. Stainless or Vibrac steel or Phosphor Bronze are satisfactory, but not mild steel.

Dr. London and Dr. Kronberger, AERE Harwell, supplied the methane, which was distilled by a fractionating column of 30 plates.[1]

We have found that when we add one part in 2×10^5 of oxygen to a deuterium gas filling there is no electron collection at 6 atmos. It is estimated that not more than one part in 10^7 of oxygen is normally present. In some preliminary experiments using impure methane, there was no electron collection. But after two months without use, electron collection was achieved, without any loss of pressure. This we attribute to adsorption of the electronegative impurity—presumably oxygen—on the counter walls. This adsorption may be hastened by operating the counter in a high gamma-ray flux with a reverse voltage. The impurities then form negative ions which drift to the outer cylinder and hence have a chance of being adsorbed. The adsorption effect has also been noticed with deuterium.

The gas purity has been sufficient to achieve electron collection at 35 atmos. for each gas.

COUNTER CONSTRUCTION

The counters we have used are all made of metal' The first were made of brass, but this was sometimes found to be porous. Subsequently we have used copper —which is reputed to act as a good "getter" for oxygen. More recently, stainless steel, and a high tensile strength aluminium alloy (No. 66E, T.I. Aluminium Ltd., Birmingham) have been used. The metal surfaces are well cleaned, before assembly, in chromic acid and then acetone; the assembly is carried out in a workshop where the risk of radioactive contamination has been kept low.

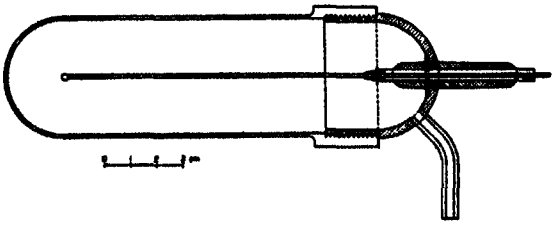

FIG. 2. Ionization chamber counter with low neutron scattering by the walls.

In order to minimize the charge induced on the collecting electrodes by heavy ions in the counter, cylindrical or spherical geometry has been used. The counters have been made in several shapes and sizes, according to the purpose to which they are to be put, but they are of two general types. The first type (Fig. 1) consists of an earthed metal vessel designed for the pressure limits required (made of stainless steel with mild steel ends) with a collecting electrode connected through a Kovar-to-glass seal coming out at one end, and a cylindrical or spherical electrode of aluminium connected through a seal at the other end. It is possible to make the sensitive volume equal to the geometrical volume of this sphere by making only a very small hole for the entry of the collecting electrode, and shielding the collecting electrode till it is inside the sphere. The uncertainty in this volume is then about 0.1 percent. The metal parts are joined with hard solder; the metal-to-glass seals are soldered in with a silver-tin alloy solder of melting point 300°C (Johnson-Matthey LM 10) and the final assembly of the counters is completed by screwing in the end cap (on which the high voltage electrode is usually mounted) and sealing with soft solder. This final seal is made without flux on previously tinned surfaces. It is not, however, easy to soft-solder to aluminium or stainless steel. In these cases the seal is made by running Cenco-Sealstix in the thread and screwing up the joint when the wax is warm.

The second type of counter (Fig. 2) uses a "guard ring" type of seal. This enables the outer pressure vessel to be also the high voltage electrode. Because the diameter is only that of the collecting electrode, the walls of the pressure vessel may then be made thinner. The disadvantages are that the counting volume is less well defined, and there is a likelihood of spurious discharges from the outside of the counter. It is often necessary to reduce the amounts of material in the immediate vicinity of the counter as much as possible to reduce neutron or gamma-ray scattering. Stainless steel or aluminium counters are then the most convenient because less massive walls may be used to withstand the same pressure. All equipment except the first valve of the subsequent amplifier is placed at a distance.

Most of the Kovar-to-glass seals used are made by Cathodeon Ltd., Cambridge, England; the guard ring type seal was made specially for us. For the counter in Fig. 1 a special low capacity seal for the collecting-electrode was made for us by B.T.H. Ltd. The small hollow seals for the proportional counter (Fig. 5) were made by Stupakoff Ceramic and Manufacturing Company, Latrobe, Pennsylvania. After assembly of the counter we usually took an x-ray photograph. This verified the alignment of the electrodes. We use x-rays from a tungsten target, and we can observe a 0.001-in. tungsten wire inside a counter.

The counters are sealed with a specially developed

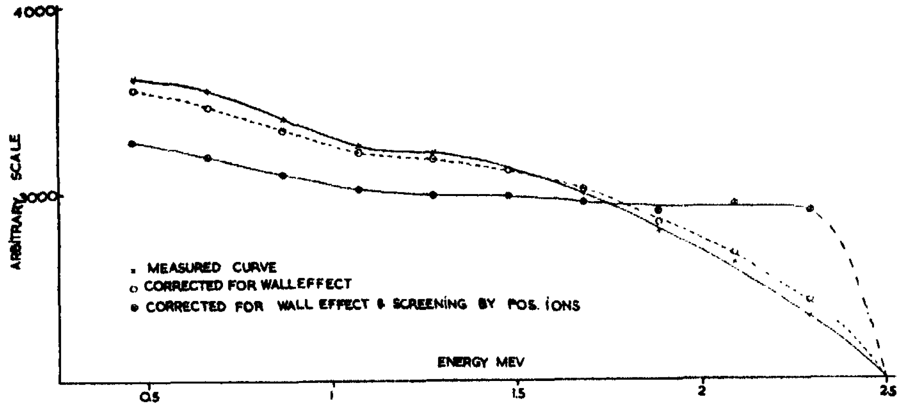

FIG. 3. Pulse-height distribution for recoil protons from 2½-Mev neutrons in the counter of Fig. 2 filled with CH_4 to a pressure of 20 atmos.

vacuum and pressure tap[8] which is also used in the filling system. The counters are joined to the filling system by a metal cone and socket join which is screwed tight and covered with Cavendish wax. The counters are outgassed by pumping for several days at a pressure of 10^{-6} mm of mercury until the pressure does not rise when the pump is disconnected. Slight heating (up to 100°C for a soft-soldered join or 50°C for a waxed join) hastens this process. For the H_2 fillings, the counters and filling tubes are washed out well with pure H_2, so that the filling tube need not be evacuated. In order to avoid wastage of D_2 or CH_4 the filling tube is carefully evacuated when using these gases. The gas pressure is measured when the counter is filled with a Bourdon gauge connected to the filling system. After use the pressure in the counter may be measured by expanding the gas into a known volume and measuring the resulting pressure accurately on a mercury manometer. An accuracy of two percent is attainable with a gauge; 0.1 percent with the expansion method.

POSITIVE ION EFFECTS

In order to make full use of a counter it is necessary to calculate the theoretical pulse height. The positive ions and electrons move in opposite directions, and as they move they induce currents on the collecting electrode. The electrons are all collected within a few microseconds, but the positive ions take longer. For many experiments it is desirable to reduce the gamma-ray background. It is then necessary to shorten the amplifier time so that secondary electron pulses do not pile up. For coincidence work it is also necessary to shorten the amplifier time constants. The amplifier will not then respond to the slowly moving positive ions. If an appreciable part of the pulse is caused by the positive ions, this will result in a loss of pulse height, and this loss will depend on the position of the initial ionization in the counter. This is especially the case for the parallel plate counters of Scherr and Petersen.[9] In the cylindrical and spherical geometry which we used this effect is considerably reduced.

It is possible to calculate how much of the pulse is caused by collection of the electrons and how much by collection of the positive ions as a function of the distance of the initial ionization from the central electrode. This calculation can be readily performed for any geometry by using a theorem due to Shockley[10] that the current induced on a conductor by a moving charge q is given by $i=qvE_v$, where v is the velocity of the charge and E_v is the component of the electric field in the direction of the velocity that would exist if the collecting electrode were at unit potential, all other electrodes earthed, and the charge removed. Calculations made in this way agree with the results of Nicodemus[11] for the special case of a cylindrical counter. The correction to be applied to a spectrum of proton recoils from monokinetic neutrons has been evaluated for the case where the positive ion contribution may be neglected (e.g., using CH_4 as a counter gas where the positive ion mobility is low). If N' are the measured number of pulses per second in an energy interval dE,

then the number corrected for positive ion effect is given by the relation

$$N'=N\left\{1+\int_y^1 \frac{p^{(z-1)}}{z^2}dz-\frac{p^{y-1}}{y}\right\},$$

where $y=E/E_{\max}$ and $p=b/a=$ radius of outer electrode/radius of collecting electrode. An uncorrected and a corrected curve for 2½-Mev D−D neutrons are shown (Fig. 3) for the cylindrical counter of Fig. 2.

The wall effect was calculated from simple geometrical considerations using the known range energy relationship and is seen to be small in comparison with the positive ion effect. The divergence from the isotropic distribution at low energies may be caused by a small (three percent) group of inelastically scattered neutrons, or to the effect of carbon recoil atoms. It is not, however, known whether the counter voltage is sufficient to saturate the counter for the intensely localized ionization produced by the carbon recoils.

The counter shown in Fig. 2 is partly spherical and partly cylindrical. The positive ion correction is then difficult to evaluate. The correction is small for pure H_2 or D_2 at moderate pressures, where the positive ion mobility is high, because the positive ions move sufficiently quickly to contribute to the pulse. This is especially true for high fields. Figure 4 shows a typical pulse-height distribution for photo-protons, with the counter filled to 8 atmos. D_2, and with a counter voltage of 4 kv. The asymmetry in the peak is due to the positive ions and electron loss. The wall effect correction is here easy to apply and is shown dotted. This correction can be avoided altogether by using a gridded counter.[12]

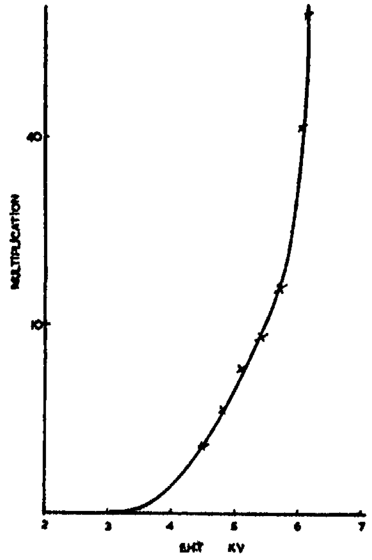

FIG. 6. Proportional counter filled with hydrogen to 20 atmos. pressure. Variation of multiplication with voltage.

PROPORTIONAL COUNTERS

For some purposes a high pressure proportional counter may be required. The design shown in Fig. 5 has been developed, but for various reasons has not yet been used for experiments. The counter wire (made of 0.001-in. tungsten) must be cleaned well before assembly, and flashed to 2000°C during the outgassing. The temperature of the wire is measured during flashing by the change in resistance. This flashing was not always found adequate to reduce spurious pulses. In these circumstances we flashed the wire to 2000°C with the counter filled and with the voltage on, a procedure which appeared to remove any points from the wire very effectively.

There is no variation of pulse height with position of the initial ionization in a proportional counter.[13] This is due to the fact that the pulse is caused by the movement of the positive ions formed in the avalanche away from the central wire, and is independent of the initial ionization. The total length of the pulse is great (10 μsec.) but the initial rise is short (0.05 μsec.) and the pulse may be sharpened in the amplifier without affecting proportionality of pulse height. This is fully discussed by Corson and Wilson.[14]

The characteristics of the proportional counter are given in Figs. 6 and 7. It was necessary to use a large amplifier band width to amplify the short pulse (0.08 μsec.), and a large amount of shot noise was introduced. The proportional multiplication was sufficient to make

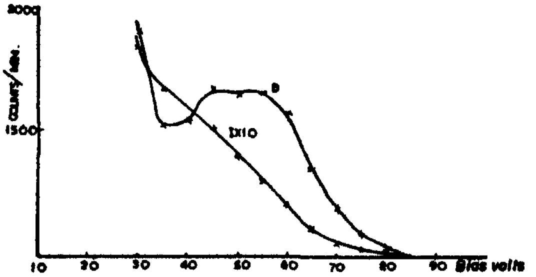

FIG. 7. Proportional counter filled with deuterium to 20 atmos. pressure. Pulse-height distribution of photo-protons from RdTh 2.62-Mev γ-ray line. Curve *I* is the integral count, Curve *D* the differential count.

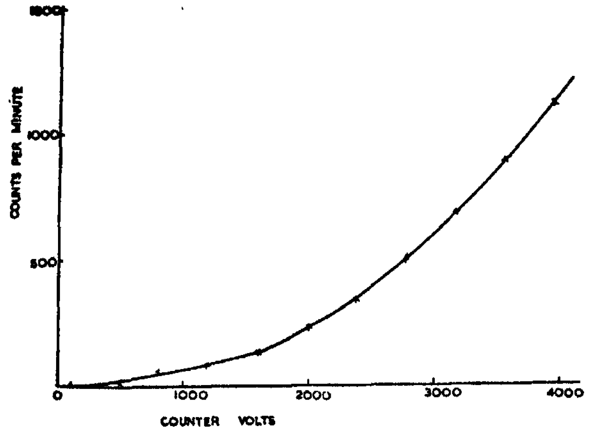

FIG. 9. Saturation curve of γ-ray background in photo-chamber of counts above a fixed bias voltage.

the effect of the shot noise small. In order to obtain the high photo-proton counting rate (20,000/min.) there was an intense γ-ray source and an intense background of secondary electrons. It was possible to discriminate against this background by using a short pulse width. This would not have been possible with an ordinary ionization chamber counter, because the increase in amplifier noise would have been too great.

COLLECTION TIME

The collection time is measured by observing the rise time of the pulses on a triggered oscilloscope. A delay line is used to delay the signal until the sweep is under way. It was noticed that the pulse rise time depends upon the type of event causing the pulse. If the ionization is localized the rise time will be the short time taken for the electrons to cross the high field region near the center wire. If, however, the ionization is along a long track crossing the counter, the pulse rise time is equal to the electron collection time.

Different cases arise. For instance, with a filling of 10 atmos. D_2 a photo-proton track from RdTh gives localized ionization, whereas some of the recoil protons from a PoBe neutron source (which have up to 9.5 Mev) will give a long track.

On the other hand, a counter filled to 30 atmos. CH_4 has a high stopping power so that all the recoil protons from a PoBe source give localized ionization. Because of the high stopping power, Compton recoil electrons will now lose sufficient energy in the counter to produce a count. Some of these electrons will have long tracks.

The pulses from events with a long track are used to measure the electron collection time. They may also be used to measure positive ion collection time by reversing the counter potential. When a slight impurity prevents electron collection, the rise time of the pulses is due to negative ion collection. A routine check of the counter filling is to observe the collection time of the negative ions in this way, with the amplifier time constants set to accept all pulses between 0.1 μsec. and 3 millisec. and to check that no pulses of rise time greater than the electron collection time occur.

With some counter fillings the collection time may be measured more accurately by measuring coincidences between the neutrons and γ-rays of a Po-Be source detected by proton recoil and scintillations, respectively. The coincidences will decrease if the coincidence resolving time is reduced below the counter collection time. The analysis is simple because the photo-multiplier has a much faster response than the ionization chamber counter.

The collection time of electrons in CH_4, at 35 atmos. pressure in the counter of Fig. 2 with 15 kv on the electrode, is found to be 1 μsec. in fair agreement with the formula of Snyder.[15] The electron collection time in D_2 at 10 atmos. found by observation of pulses in the counter of Fig. 1 and with four kv collecting potential is found to be 1 μsec. The positive ion collection time in D_2 at three atmos. at three kv is found to be 40

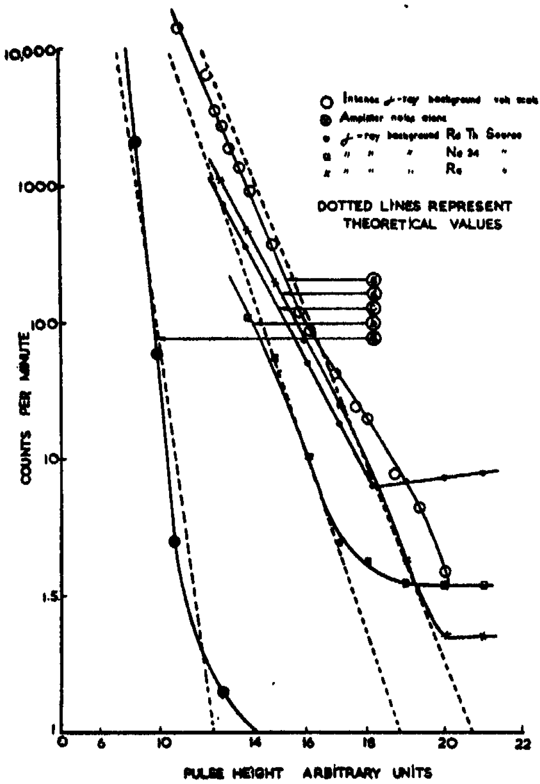

FIG. 13. Plot of $\log_e$ (counts/min.) against the square of the bias voltage V^2, for various types of background and noise.

μsec.; this suggests a positive ion mobility of 60 cm/sec./volt/cm at one atmosphere pressure which is higher than the value 10.6 recently reported.[16] This is presumably due to the different conditions of the measurements.

It is possible to take advantage of the difference in collection time for localized ionization and extended ionization to discriminate against gamma-ray background. The amplifier time constants may be adjusted so that the pulse from the desired localized ionization is just accepted, whereas a pulse from the background extended ionization, being longer, is heavily attenuated. This is the case for the proportional counter adjustment in Fig. 7.

SATURATION CURVES AND PULSE-HEIGHT LOSS

We have plotted in Figs. 8 to 12 saturation curves for a counter taken under various conditions.

Figure 8 shows that ordinary saturation takes place at 100 volts, but there is still a considerable increase in pulse height above this value. This is shown in Fig. 9; the rise in γ-ray background count is between linear and logarithmic with *HT* voltage; this is equivalent to an increase in pulse height which is less than linear at the high voltages showing approximate saturation of pulse height.

Figure 12 shows complete saturation of the counting rate of photo-protons under actual experimental conditions. Figure 11 also shows that at low *HT* voltages, the pulse height is reduced and confirms that saturation is effective for the experimental conditions of Fig. 12. Confirmation of this is also given by the distribution curve of Fig. 4, which shows that pulse height losses, if they exist, are proportional. Figure 10 shows that saturation is less easily attained for recoil deuterons than for photo-protons.

With one counter filling (20 atmos. H_2 in a counter two cm diameter, one mm inner electrode diameter, and four kv on the electrodes) the pressure was slowly reduced. It was found that there was three percent pulse height loss at 20 atmos., due presumably to initial recombination. This effect is reported to be smaller in D_2 and CH_4 and should not therefore affect most of our measurements.[17]

AMPLIFIER EQUIPMENT

We have used for this work standard amplifiers, and have found the AERE amplifier Type 1008 particularly reliable. The preamplifier used has, however, been one of especially low noise discussed elsewhere.[18] In order to test the amplifier, pulses from a pulse generator are fed through the high voltage condenser and counter. The rate of counting of noise peaks has been measured for different types of background (using a counter filled to 10 atmos. D_2) and compared with the formula of Rice.[19]

C = rate of counting of noise peaks $= \frac{1}{2}\exp(-v^2/2V_0^2)$ (expected number of zeros of the noise wave form per second) $\simeq (1/T)\exp(-v^2/2V_0^2)$, where T is the amplifier pulse width.

In Fig. 13 $\log C$ is plotted against v^2. It may be seen that the extrapolation of the curves to zero does not give the constant $1/T$ (in this case 10^6/sec.). In curve (a) of amplifier noise alone, this is attributed to some 50-cycle background of about two volts amplitude, which is difficult to observe in the presence of the noise. The existence of this 50-cycle background was verified by the change in the rate of counting of noise peaks at different parts of the 50-cycle wave form, the other parts being suppressed with a gating circuit. Once discovered, this 50-cycle background was eliminated. The failure of the law for curves (b), (c), and (d) at high counting rates is largely due to the small number of events which constitute the gamma-ray background. At low counting rates, curve (b) shows recoil protons from background neutrons, and curves (c) and (d), the wall effect from disintegration protons. The curve (e) for an intense gamma-ray background is slightly distorted at low counting rates by the presence of an unresolved group of photo-protons.

[19] S. O. Rice, Bell Sys. Tech. J. 23, 282 (1944); 24, 146 (1945).

The gain constancy of the whole equipment, as determined by the change in counting rate on the side of a photo-proton peak, is better than one percent over a period of a week. Tests over longer times than this have not been made.

COUNTER BACKGROUND

The spurious pulses from the amplifier are below noise level; there are some pulses from the counter which are due to breakdown in a bad seal, or high voltage condenser breakdown; we cannot distinguish between these two types of breakdown which together give detectable pulses at a rate of about 2/min., but they are of the opposite sign to the genuine pulses from the counter and can, therefore, be readily separated. Polonium contamination on the counter electrodes has led to a background as high as 5/min. But the background of a good counter filled to 10 atmos. D_2 varies from less than 1 in 20 min. at 30,000 ion pairs to 0.7/min. at 6000 ion pairs. We attribute this to cosmic rays. At higher pressures (35 atmos. CH_4) pulses due to individual secondary electrons produce a background of 100/min. at 10,000 ion pairs and 0.2/min. at 100,000 ion pairs.

ACKNOWLEDGMENTS

We gratefully acknowledge the assistance given to us by Mr. V. Round who assembled many of the counters and by Mr. Larsen in the design of the deuterium production plant. We are also grateful to Dr. J. Tuck for suggesting the use of methane, to Dr. London and Dr. Kronberger of AERE Harwell for its purification, and to Professor F. E. Simon for the use of pure hydrogen from his liquefier. We would also like to thank Lord Cherwell for extending to us the facilities of his laboratory and for his interest and encouragement.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 8 AUGUST, 1950

The Chalk River Single Crystal Neutron Spectrometer

D. G. Hurst, A. J. Pressesky, and P. R. Tunnicliffe*
Atomic Energy Project, National Research Council, Chalk River, Ontario, Canada

(Received November 1, 1949)

A single crystal neutron spectrometer has been constructed which shows improvement in resolution and intensity over previously described instruments. This has been made possible by the high flux available from the Chalk River heavy water reactor. The instrument can be operated automatically.

Mechanical design, crystals, resolution and the contamination of the spectrum by higher orders are discussed.

I. INTRODUCTION

Monochromatic neutrons in the energy range from zero to several kilovolts are used for studying nuclear energy levels, absorption and scattering cross sections, nuclear reactions, and the structure of matter. Various methods have been described for producing such neutrons. The modulated cyclotron method originated by Alvarez[1] and developed by the Columbia[2] and Cornell[3] groups permits measurements up to ten kilovolts. The mechanical velocity selector developed by Dunning *et al.*[4] and by later workers has been most useful at thermal energies. Crystal diffraction spectrometers have been described by Zinn,[5] Sturm[6] and Borst.[7] An instrument designed specifically for the study of crystal structures has been described by Wollan and Shull.[8]

The lower limit of energy of the crystal spectrometers is determined by crystal spacing and is in the neighborhood of 0.001 electron volt; the upper limit, due to loss of resolution is less definite and is approximately 50 electron volts. Such a wide range can be achieved only with extreme precautions and the intensity is low at both ends. For normal use the range is roughly from 0.02 to 10 electron volts.

The Chalk River heavy water reactor provides an intense neutron flux and is an excellent source for a crystal diffraction spectrometer. Two instruments have been built; the first is described in this paper and is a single axis spectrometer similar in principle to the spectrometer at the Argonne Laboratory described by Zinn;[5] the second, to be described in a later paper, is a double axis instrument.

II. MECHANICAL DESIGN

The instrument is large and strongly constructed to carry the massive shielding required for adequate re-

duction of background intensity. Also, to obtain reasonable intensities from the extended neutron source, a beam of relatively large cross section is necessary and, therefore, the distance between the crystal and counter must be large for work at small angles.

The general arrangement is shown in Figs. 1 and 1A and details are shown in Figs. 2 and 2A. The spectrometer is anchored to the floor, its axis of rotation being accurately vertical and intersecting the center line of a horizontal steel collimator inserted into one of the experimental holes of the reactor.

The main bearing of the spectrometer (Fig. 2, item 2a) is the azimuth bearing from a Bofors antiaircraft gun. Preliminary tests had shown that this bearing could support a load of 500 pounds at six feet radius with a deflection at that distance of less than 1/16 of an inch. The bearing is mounted on a structural steel platform. The arm (2b) which carries the counter and its shielding is made of two eight inch structural steel channels, welded to form a rigid beam and bolted to the upper face of the Bofors bearing. Machined ways are provided on the arm for accurate positioning of the counter.

The crystal table (2c) is fifteen inches in diameter and is machined from a rib-reinforced brass casting. It is mounted on a spindle which is centered by a precision 3-ball cone bearing (2d), the balls being equally spaced by balls of smaller diameter. The spindle is maintained vertical by a ground and lapped journal bearing at its lower end. A spring and cam actuated collet (2e) is provided to grip the lower end of the spindle to lock it to the base if required. The edge of the crystal table is graduated in 1/4 degree divisions and a vernier (2f) allows the angle to be read to 0.01 degree.

A second circle (2g), graduated as above and provided with a similar vernier, turns with the arm. This circle is mounted on the same type of bearing as the crystal table. Connection between the arm and the divided circle is made through a link which permits vertical and radial freedom of motion and embodies a tangent screw for zero adjustment.

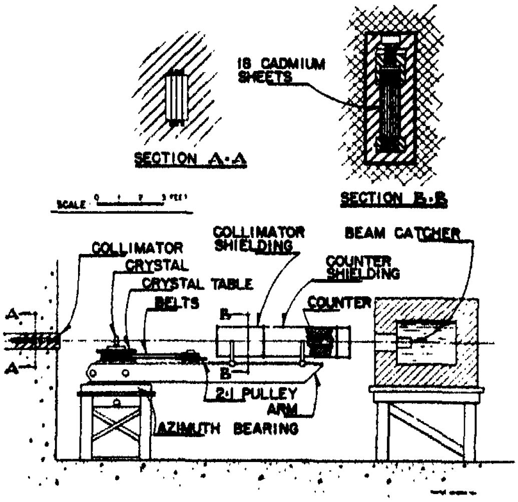

FIG. 1. General arrangement of the neutron spectrometer.

To keep the counter on the line of the diffracted beam, a 2:1 angular relationship between the rotation of the counter arm and the crystal rotation must be maintained. This is accomplished by means of steel pulleys driven by spring-tensioned steel belts (2h). A step pulley (2j) mounted on the arm is held in fixed azimuth by an equal stationary pulley (2i) with its center on the spectrometer axis. The smaller step of pulley (2j) is in 2:1 ratio with the crystal table pulley (2k) and causes it to turn at half the rate of the arm. The crystal table is connected to the pulley (2k) by a clamp and tangent screw. The pulleys are carefully machined and hardened, the edges being chromium plated and ground to a tolerance of ±0.0002 inch. The steel belts are 0.010 inch by 1/2 inch in cross section and are under a tension of 20 pounds. To allow for the effect of belt thickness, the effective pulley radius was taken as the actual radius plus 40 percent of the belt thickness. In practice the angular relationship between the arm and crystal table is held to better than 0.01 degree in a 90 degree rotation of the arm.

To take advantage of the continuous operation of the reactor means are provided for automatic operation of the spectrometer (see Section VIb). Because the belts and pulleys maintain the correct angular relationship between the crystal and counter, it is only necessary to rotate the arm to change the energy setting and a motor drive is provided to move the instrument in discrete steps (Fig. 3). The final pulley of the drive (Fig. 3, item 3a) is connected to the main bearing by crossed belts (3b). The ends of the belts are anchored, thus limiting the rotation by the automatic drive to slightly less than 90 degrees but this is more than is required in practice. Limit stops and switches prevent damage to the belts.

The pulley (3a) is mounted co-axially with the final worm wheel (3c) of the drive gear train and may be connected to it through a clutch plate (3d) which has a circle of 72 equally spaced holes drilled in it. Four equally spaced holes are drilled in the pulley on a circle matching that of the 72 holes, and to engage the clutch steel pins are inserted through a diametral pair of the holes in the pulley into a pair of holes in the clutch

FIG. 1A. A photograph of the neutron spectrometer with the counter rotated almost into line with the main neutron beam. The exit hole from the pile is on the left. A sample cell for gases can be seen mounted in front of the counter collimator both here and in Fig. 2A.

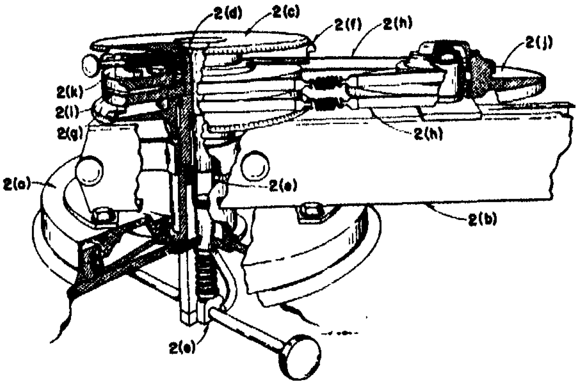

FIG. 2. Details of spindle assemblies and belt linkage.

plate. This provides preliminary arm settings at intervals of five degrees.

The shaft of the final worm carries a circular cam (3e) which operates the controlling microswitch (3f) by means of notches cut in its periphery. The gear ratio has been chosen so that one revolution of this shaft provides one degree of rotation of the arm to better than one part in a thousand. Cams with one, two, four, eight or sixteen notches provide the corresponding fractions of one degree down to 1/16 degree for each step.

For transmission measurements it is necessary to move the sample into and out of the neutron beam at each energy setting. A motor driven sample carriage, which can be seen in Fig. 2A, is attached to the front of the counter collimator shielding. The carriage runs on ballraces and the limits of its travel are determined by microswitches connected into the control system as described in Section VIb. To and fro motion is achieved by a rack and pinion drive from a reversible shaded-pole motor. A boron carbide defining aperture may be placed in front of small samples to reduce the beam to an appropriate area.

III. THE COLLIMATION SYSTEM

The angular spread of the neutron beam emerging from the reactor is limited by a steel plug 81 inches long inserted in a hole through the concrete shield. A rectangular channel (Section AA, Fig. 1) one-inch high by half an inch wide is cut along the axis of the plug. Three equally spaced vertical septa of 0.020 inch steel shim stock along the channel improve the collimation further and the resulting beam has a horizontal divergence of eight minutes of arc and a vertical divergence of about one degree. The beam is very sharply defined and has a total flux of about 4×10^7 thermal neutrons per second. The steel septa are readily removable and four times the intensity can be obtained at a sacrifice of energy resolution.

The hole extends all the way through the shielding and reflector to the walls of the reacting core. The source of neutrons is thus the flux at the outside of the heavy water. Between the inner end of the collimator and the core there is a cast iron gate which may be closed, thereby cutting off the thermal neutron beam and markedly reducing the fast neutron and gamma-radiation. This means of shutting off the beam during operation is a very useful feature of the experimental facilities of the reactor.

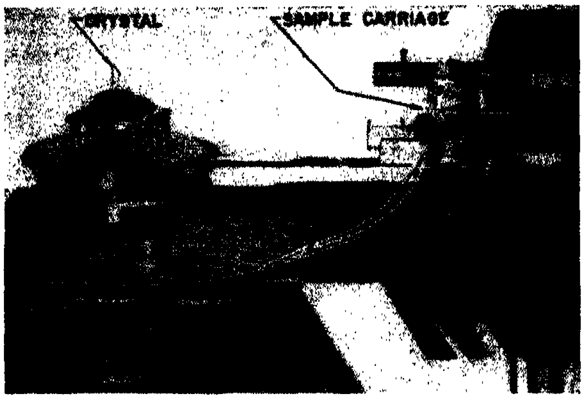

FIG. 2A. A close-up of the crystal table, belt linkage and sample carriage. Entrance to the counter is at the right.

The undeflected beam is received by a catcher (Fig. 1) consisting of a 15 gallon drum containing a saturated aqueous solution of potassium tetraborate. The drum is shielded by one layer of nine inch thick laminated steel and masonite blocks. The radiation from this beam catcher is negligible from the health point of view. It is also worth noting that although the intense beam of neutrons is accompanied by an equally intense flux of gamma radiation, it is possible to work within a foot of the axis of the beam for reasonable lengths of time.

IV. DETECTION SYSTEM

The detector is a proportional counter containing boron trifluoride enriched to 96 percent in the B^{10} isotope. The cathode, which is also the outer shell, is made from copper tubing $2\frac{1}{2}$ inches in diameter and

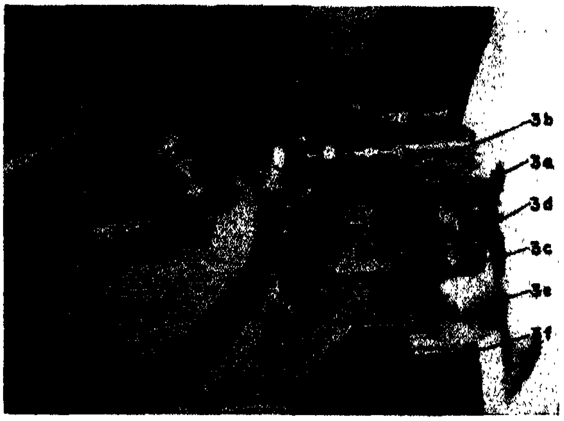

FIG. 3. The motor drive for automatic operations. The motor turns the main arm of the spectrometer by belts (b) the control being through cam (e) which operates switch (f). The pulley (a) is connected to gear (c) by a clutch plate (d).

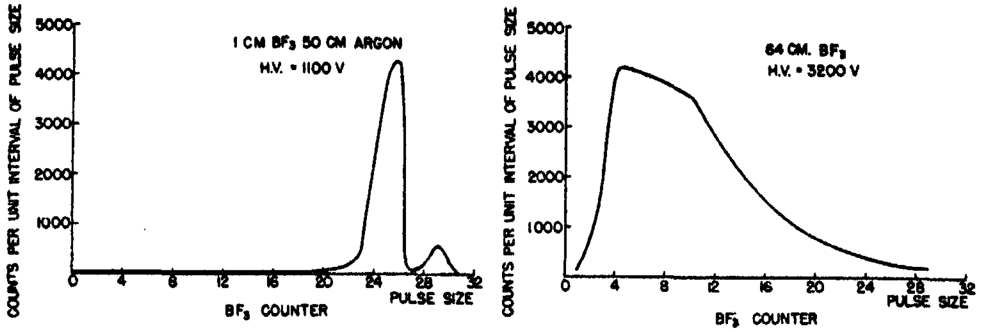

FIGS. 4 AND 5. Pulse size distributions for two pressures of BF_3 in the proportional counters. The distribution of Fig. 4 is characteristic of the boron disintegration, but Fig. 5 shows considerable deterioration of the pulses because of electron attachment in the gas.

25 inches long. The anode is a tungsten wire 0.002 inch in diameter. Neutrons enter through an end window of copper 0.010 inch thick, and pass axially along the counter.

Early studies of the distributions of pulse sizes led to results typified by Figs. 4 and 5. It was assumed that (after allowance for end effects) all disintegrations occurring in the sensitive volume of the low pressure counters could be detected, but that this might not be true for the high pressure counters. Accordingly the low pressure type was used where a knowledge of the absolute neutron flux was required, the efficiency being calculated from the BF_3 pressure, the boron cross section and the length of the anode; the high pressure type was used where maximum sensitivity was required. More recent work has yielded counters with pressures of BF_3 up to 60 cm having the "ideal" characteristic of Fig. 4. These are suitable for absolute measurements and, compared to the low pressure type, have the advantage that the efficiency is much less sensitive to errors in pressure or boron cross section over the important thermal neutron energy range. Figure 6 shows typical efficiency curves. The maximum efficiency for the high pressure type is determined by the length of the inactive region preceding the counting volume. These counters will be discussed in detail in a forhtcoming paper by Mr. I. L. Fowler and one of us (PRT).

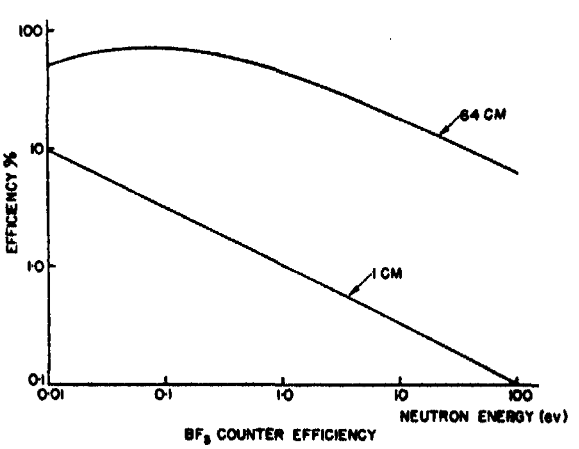

FIG. 6. Efficiency as a function of energy for the two counters of Figs. 4 and 5. The efficiency was calculated using the pressures and the known boron cross section.

The counter and its preamplifier fit inside a cylindrical shield containing a layer of one inch of boron carbide surrounded by four inches of paraffin wax. Mounted in front of the counter and inside similar shielding is a slit system, referred to as a "collimator" (Section BB, Fig. 1), the function of which is to reduce the neutron background by limiting the field of view of the counter to a small area around the crystal. This collimator consists of a steel box divided into narrow vertical apertures by eighteen flat parallel cadmium sheets 0.004 inch thick, 18 inches long and 2¾ inches high. The long edges of the cadmium strips are clamped firmly between steel spacers 1/32 inch thick, and the assembly is stretched vertically by bolts like that shown in Section BB, Fig. 1. The horizontal angular divergence is 12 minutes of arc and this does not affect the resolution of the spectrometer.

The background counting rate, with the entrance of the counter collimator closed and using the more efficient counter, ranges from one to ten counts per minute, depending on the state of neighboring experiments. With the entrance open but the crystal rotated several degrees from the Bragg position, the background is approximately one hundred counts per minute.

For the study of neutron induced nuclear reactions a sample together with the necessary counters and preamplifier may be inserted between the counter and its collimator.

V. CRYSTALS

The crystal holder (seen in Fig. 2A) permits rotation of the crystal about two orthogonal axes through a fixed point which is arranged to be the center of the neutron beam. Thus the crystal planes may be aligned with respect to the beam. All parts of the holder are below the beam and introduce no scattering.

In general the crystals are used in transmission with the advantage that they cover the full area of the beam at small Bragg angles. In some cases, e.g. lithium

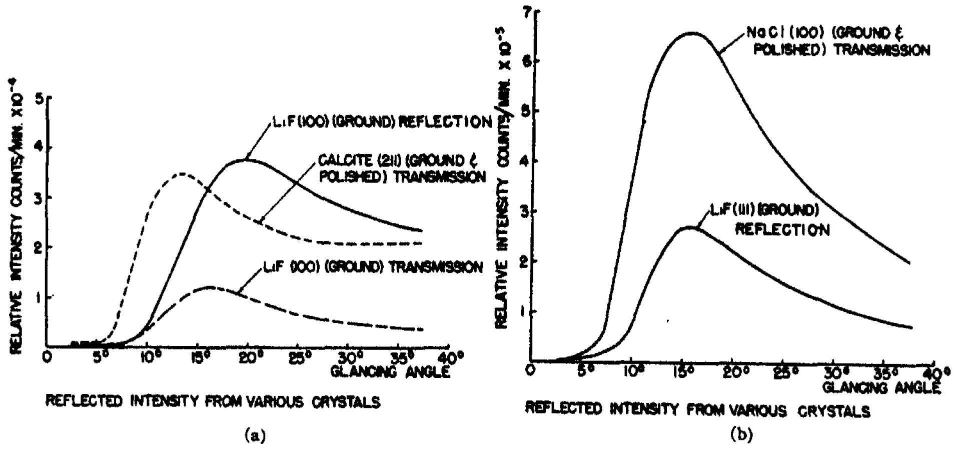

FIG. 7. Reflected intensity from various crystals.

fluoride, large absorption offsets the gain of intensity resulting from this arrangement.

A number of crystals have been prepared, e.g., NaCl, (100) and LiF, (100) (111) cut from samples grown synthetically,* and calcite (211) cut from natural calcite. Counting rates as a function of glancing angle for transmission and reflection by these crystals are plotted in Figs. 7a and 7b.

In a particular experiment choice of crystal depends on a number of factors: (a) Upper and lower energy limits, (b) intensity, (c) resolution, (d) permissible contamination by higher orders. We may group these factors in relation to the following properties of the crystal: (i) Plane spacing with reference to (a). (ii) Crystal structure, chosen planes and relative phases of neutron scattering with reference to (b) and (d). (iii) Mosaic structure with reference to (b) and (c).[9]

In general NaCl has been found to yield a much larger intensity than most crystals and is used for the majority of work at energies below a few electron volts. However, LiF (111) yields less order contamination since even orders are almost entirely absent owing to the opposite sign of scattering from successive planes. LiF (100) has the smallest crystalline plane spacing and yields the highest energy for a given angle but owing to the low reflectivity per plane the intensity is low. For high resolution calcite is used because of its negligible mosaic structure but it yields poor intensities.

We have investigated the mosaic structure of the crystals with a simple double crystal x-ray spectrometer.† The instrument is illustrated in Fig. 8 and is designed for the parallel position only. Two crystal tables, *A* and *A'*, are mounted on ball bearing shafts in dural blocks, *B* and *B'*, which rest on a heavy steel base plate. The first block, *B*, is mounted in a fixed position on levelling screws. The second block, *B'*, can slide on ways perpendicular to the incident x-ray beam. The diffracted beam is detected by an argon filled ion-chamber, *C*, mounted on the second block and connected to a vibrating reed electrometer, *D*. Micrometer heads, *E* and *E'*, serve as tangent screws for the crystal tables. The crystals, mounted on holders similar to that seen in Fig. 2A, are used in the reflection position. The output of the electrometer is connected to an Esterline-Angus recording milliammeter and the chart drive of the recorder turns the second crystal tangent screw *E'*. The instrument plots the rocking curve automatically, a typical curve being shown in Fig. 9.

We have found that most of our samples of synthetically grown NaCl and LiF have mosaic structure of about four minutes of arc width at half maximum but some samples of LiF have large areas of the crystal tilted by an appreciable fraction of a degree to each other and are therefore unsuitable for neutron diffraction work. Ground and polished calcite crystals have widths of 30 seconds which can be reduced to about 5 seconds by etching.[10]

VI. ELECTRONIC EQUIPMENT

The electronic equipment can be divided into two main sections: (a) counting section (b) control and recording section. Figure 10 is a block diagram of the equipment.

(a) Counting Equipment

Two channels of counting equipment are provided, each consisting of its own high voltage supply, linear amplifier with pulse discriminator, and scaling circuits. One channel is connected to the neutron counter and the second is available for use in the nuclear reaction studies referred to at the end of Section IV.

The scaling units are of British manufacture** with

† The use of the double crystal x-ray spectrometer for investigating the diffraction pattern of crystals is discussed by Compton and Allison, *X-Rays in Theory and Experiment* (D. Van Nostrand Company, Inc., New York, 1935), Chapter IX.

[10] K. V. Manning, Rev. Sci. Inst. 5, 316 (1934).

** Type 200 manufactured by Dynatron Radio, Maidenhead, England.

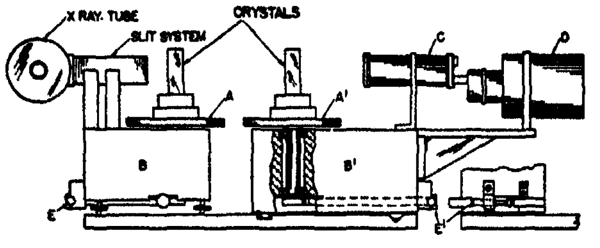

FIG. 8. Double crystal x-ray spectrometer built for checking the quality of the crystals used on the neutron spectrometer.

two scales of ten in series and a mechanical register. Connections are provided for remote control and for remote indication of the information supplied by the units and for these reasons they are eminently suitable for our purpose. By arranging units in series any decimal number of counts is available for recording or automatic control.

(b) Control and Recording System

Automatic operation of the spectrometer is controlled by a relay system connected to the scaling units. The operations are in the following sequences:

(a) Transmission measurements

- (I) sample in
- (II) count
- (III) sample out
- (IV) count
- (V) spectrometer shift and repeat

(b) Reaction rates, etc.

- (I) count
- (II) spectrometer shift and repeat

Backgrounds are determined separately.

The accumulation of a preset number of counts in one of the alternative counting channels results in operation of the register circuit of the last scaler; this energizes the control system and the appropriate motor in the sequence begins to operate. During operation of the motor the relay system automatically stops the scalers and clears any spurious counts. When the operation is completed as indicated by the cam of the main drive or by the limit switches of the sample holder, the motor stops and the scalers are brought into operation again. Overrun of the main drive induction motor is prevented by passing direct current through the motor for about one second immediately after the alternating current is switched off.

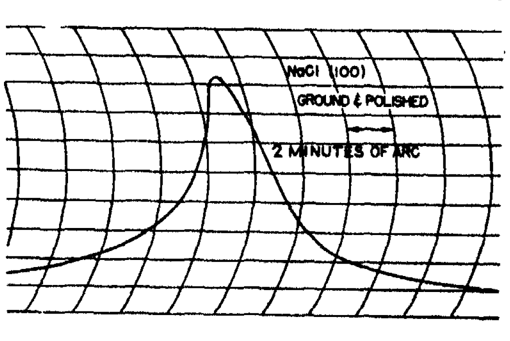

FIG. 9. Rocking curve obtained with the instrument shown in Fig. 8. This corresponds to adjusting the crystal on table *A* (Fig. 8) for Bragg reflection of the x-ray line and table *A'* so that the diffracted beam falls on the face of the second crystal. The second crystal is then turned slowly through the position of parallelism with the first crystal. The above curve is the reflected intensity as a function of angle of the second crystal. The shape of the curve is determined by the characteristics of the two crystals.

Data are fed into a ten-pen Esterline-Angus operation recorder as follows: Two pens mark the times during which each of the motors is operating; a third pen marks the position of the sample; pens are connected to the scalers to record the number of counts at convenient increments; another pen indicates when the reactor is operating at steady power and is connected to the reactor control system; a further pen can, if necessary, be used to record time intervals from a clock, but in general the chart is sufficiently accurate; several pens remain which are available for special purposes.

A record* of deviations up to 25 percent from the normal operating level of the reactor is used for conversion of counting rates to a common basis of power, the detecting instrument being a boron-coated ion-chamber placed in the thermal column of the reactor.

VII. ALIGNMENT

After the spectrometer had been adjusted so that the arm moved accurately in a horizontal plane, the axis of rotation was made to intersect the center of the beam with the aid of photographs taken on x-ray film backed by cadmium. A cadmium pointer was set up on the axis of rotation and its shadow on the photographs served as an index for alignment.

The counter and its collimator are aligned with adjusting screws which carry the supporting frame on the arm. Mechanical alignment of the height and level of this system is sufficient, but to ensure that the counter collimator points at the crystal a maximum counting rate is obtained by alternately adjusting the system and the crystal about vertical axes through their centers.

The zero of the instrument can be found in two ways. A relatively inaccurate method (±0.05°) is to reduce the main neutron beam intensity with absorbers so that the counter can be moved into the beam and a maximum counting rate found. Accuracy to the precision of the angular scale can be had by finding the position of the indium resonance absorption on both sides of zero and taking the mid point.

VIII. PERFORMANCE

(a) Intensities

The counting rates noted in Figs. 7a and 7b are representative of those obtainable with the instrument using the high efficiency counter.

(b) Resolution

When the instrument is set for diffraction at a certain angle, the diffracted beam contains a band of energies, the width of this band depending principally on the horizontal divergence of the primary beam, and to some extent on the mosaic structure of the crystal. Recalling the Bragg equation $n\lambda = 2d\sin\theta$ and that the energy E is proportional to λ^{-2}, we get

---

* The current for this is available to us through the courtesy of Dr. R. E. Bell.

$$-\delta E/E = 2\delta\lambda/\lambda = 2\cot\theta\delta\theta,$$

where $\delta\theta$, measured in radians, may be associated with the horizontal divergence and then $\delta E/E$ is the fractional spread in energy and its reciprocal is a measure of the energy resolution.

The intensity of the diffracted beam is small at high energies and a compromise must be reached between the needs for intensity and resolution. In fact, with the type of spectrometer described here, the resolution is poor above a few volts. For these energies simple differentiation is inadequate and one has to consider the two limits $\theta+\delta\theta$ and $\theta-\delta\theta$. The narrowest collimation available in the present instrument is 0.110 inch in 80 inches, i.e., $\delta\theta = 1.4\times10^{-3}$. Table I contains some examples of the energy ranges involved with this collimation. The composition of the diffracted beam has been calculated for various conditions of collimator and crystal. The case of reflection from a set of crystal planes parallel to the crystal surface is the simplest, the transmission case is complicated by uncertainty as to the behavior of the beam inside the crystal. Only an outline of the calculations and results for reflection is given.

Referring to Fig. 11, we assume a parallel sided collimator and a crystal set for reflection of the central ray at an angle θ_0. The corresponding wave-length is determined by $\lambda_0 = 2d\sin\theta_0$.

The effect of vertical divergence of the beam on the angle of incidence is small and we limit ourselves to the horizontal plane. A ray from any point P in the entrance plane YY' of the collimator meets the crystal at an angle θ. Because the source emits a continuous spectrum comprising neutrons of all relevant wave-lengths, there will be a diffracted ray BQ of wave-length λ satisfying the Bragg equation. If the crystal were perfect the wave-length λ could be diffracted only for directions extremely close to PB. However, we are interested in mosaic crystals for most of our work and this means that the crystal planes are broken up into small areas tilted at small angles about the mean direction. In other words diffraction of the wave-length λ is possible over a much wider range of direction of PB than for a perfect crystal. The diffracted intensity as a function of direction of PB is known as the "rocking curve" of the crystal. If $\pm\alpha$ is the angular range in which the intensity is appreciable then the rays within $\pm\alpha$ of PB will be diffracted, and furthermore they will be focused at Q on the plane XX', where XX' and YY' are equidistant from the crystal. This focusing action is known for powdered crystals and the mosaic is like a powdered crystal with limits $\pm\alpha$ on the orientation.

Table I. Energy spread of the diffracted neutrons.[a]

θ Degrees	E_0 Electron volts	$\frac{E_0-E}{E_0}$ %	$\frac{E-E_0}{E}$ %	$E_{\min}$ Electron volts	$E_{\max}$ Electron volts
20	0.019	0.8	0.8		
10	0.073	1.6	1.6		
5	0.29	3.1	3.3		
2	1.8	7.5	8.5	1.66	1.95
1	7.3	14	18	6.3	8.6
0.5	29	26	42	21.4	41

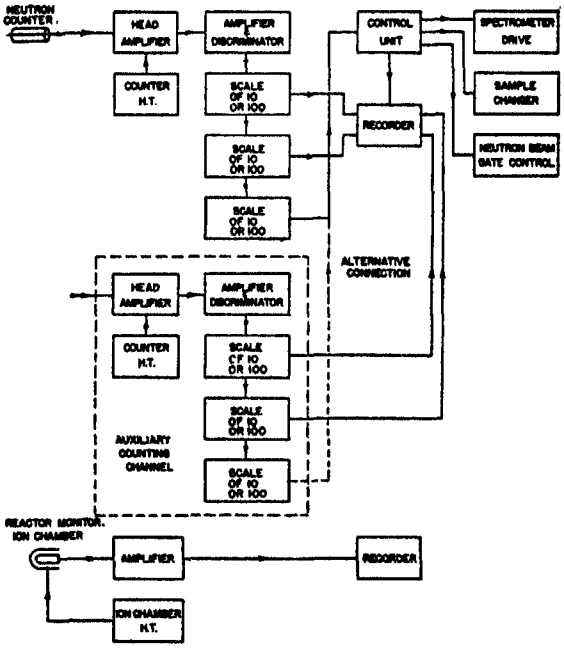

Fig. 10. A block diagram of the arrangement of the spectrometer electronic equipment.

As P is moved across the entrance of the collimator the foci Q for a chosen wave-length trace an image of the collimator entrance on XX', the extent of the image being limited by the collimator channel. The λ_0 image has maximum intensity and due to the variation of θ with λ the images for different wave-lengths are displaced along XX'. It is now clear how the structure of the diffracted beam may be calculated, and that an aperture of width $2a$, equal to the width of the collimator, placed on XX' to coincide with the λ_0 image will pass all diffracted neutrons of wave-length λ_0 but reduce the intensity and limit the range of other wave-lengths.

Using $\delta\theta = \theta-\theta_0$ as the variable which expresses deviation of wave-length (or energy) from the chosen value, the curves of intensity against $\delta\theta$ were drawn for several values of β/α, assuming a rectangular rocking curve (β being the collimator semi-angle). They are nearly triangular and are symmetrical about $\delta\theta = 0$. The effect of an aperture of width $2a$ at XX' is to narrow the triangles without reducing the peaks.

[a] θ = Bragg angle. E_0 = energy corresponding to θ for calcite (211). E = energy corresponding to $\theta\pm\delta\theta$ for calcite (211). $\delta\theta$ = 4.8 minutes of arc.

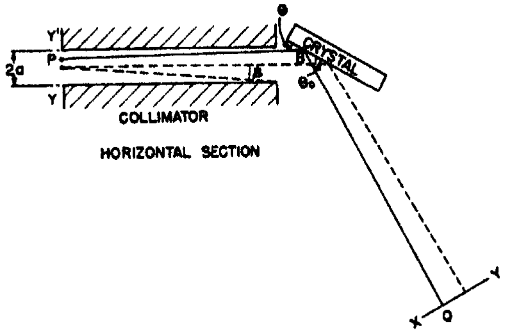

FIG. 11.

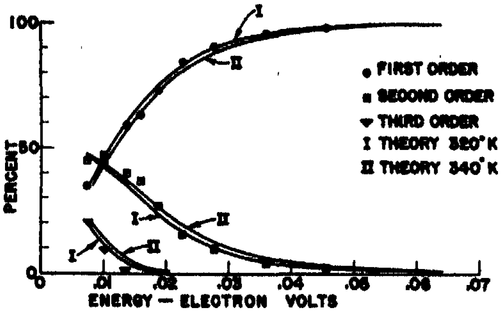

FIG. 12. Comparison of experimentally measured order contamination with the theory of Goldberger and Seitz.

The experimental measurement of such resolution functions would be very difficult. They are however directly related to what we may call the geometrical resolution function, that is, the intensity as a function of angle within the diffracted beam neglecting the effect of the width of the crystal rocking curve. This we have measured by the following method. Calcite crystals free from mosaic structure were mounted on the main axis and on an auxiliary axis behind the exit of the counter collimator. The counter and its shielding were carried on an arm rotating about the auxiliary axis thus forming a two-crystal spectrometer. In the antiparallel position the variation of intensity obtained by rocking the second calcite crystal is the geometrical resolution function and was found to be very nearly triangular in reasonable agreement with that expected.

(c) Orders

In dealing with resolution we are concerned with contamination of the chosen neutron wave-length by an undesirable spread about the chosen value. A second type of contamination arises because a series of wavelengths λ'/n satisfies the Bragg equation where λ' is the chosen wave-length and n is the integer known as the order. The higher orders are always present because of the continuous nature of the neutron spectrum from the reactor.

Sturm[6] has given a discussion of measurement of orders. He found agreement with the theory of Goldberger and Seitz[11] at 0.025 ev. Using the boron absorption method discussed by Sturm, we have measured the orders from a sodium chloride crystal [(100) planes]. The absorbers were sheets of Pyrex glass of thickness 3/16 inch, 1/4 inch and 3/8 inch. Because the same measurements have to serve to calibrate the Pyrex plates, the accuracy at low energies is poor as the calculations involve extrapolating the transmissions from the higher energies.

The results are shown in Fig. 12 together with theoretical curves based on the formula of Goldberger and Seitz. It will be seen that there is fair agreement with the 320°K curve except that the third order is too weak and the second order correspondingly too strong. This could be due to small errors in the calibrations.

The formula assumes a Maxwell distribution of neutron velocities and a perfect crystal. For energies above 0.2 ev the Maxwell distribution is negligible compared to a component of the spectrum which is proportional to E^{-1}. Using resonance absorbers 5 percent second order was found at 2 ev and this quantity does not vary rapidly with energy.

IX. ACKNOWLEDGMENTS

Credit is due Mr. Neilson of the Chalk River design section for the mechanical design of much of the instrument. Various parts were made by the NRC Workshops both at Chalk River and Ottawa and by Messrs. MacLanders and Dean in the Technical Physics Branch workshop. Thanks are due the Electronics Section for design, construction, and maintenance of electronic equipment, and to Mr. I. L. Fowler for construction and filling of our BF_3 counters.

Ring Focus in a Thin Magnetic-Lens Beta-Ray Spectrometer*

JOSEPH M. KELLER, ERNEST KOENIGSBERG, AND ARTHUR PASKIN
Institute for Atomic Research and Department of Physics,† Iowa State College, Ames, Iowa

(Received March 28, 1950)

The paths of electrons in a thin magnetic-lens type of spectrometer are described by a non-linear differential equation. The equation was numerically integrated to obtain a set of electron trajectories originating from a point source on the axis of the instrument. Trajectories for off-axis sources were approximated. On the basis of these trajectories, the location and some properties of ring focus were studied. Theoretically calculated line shapes are compared for axial and ring focus. For reasonable values of resolution, the transmission of the spectrometer would be roughly doubled by performing the momentum discrimination by a ring focus baffle instead of by a small counter on the axis.

SEVERAL authors[1–3] have suggested the possibility of using "ring focus" in a magnetic-lens spectrometer to obtain increased intensity for a given resolution. DuMond[4] and Persico[5] have recently studied the case of ring focus in a solenoid spectrometer, which lends itself to straight-forward calculations. Our paper presents a theoretical study of the electron trajectories in a thin-lens spectrometer of the type now in use at Iowa State College.[6] Unlike the case of the solenoid, trajectories in a thin-lens spectrometer cannot readily be described by analytic expressions and must be obtained by numerically integrating a differential equation.

Ring focus may be described in several ways. If the focusing action of a thin magnetic-lens is examined, it is found that electrons with a larger initial slope cross the axis closer to the lens than electrons with the same momentum and with a smaller slope. Therefore, the trajectories of two electrons with the same momentum and slightly different initial slope intersect. The family of electron trajectories will form an envelope, which in space is an axially symmetric surface. Any point on the envelope constitutes "ring focus" for some small range in initial slopes. The envelope is clearly shown in Fig. 3, below, which is a plot of radial distance *versus* axial distance for a set of trajectories of different initial slopes and a given momentum.

There is another way of considering ring focus, which brings out its possible advantages. If we choose a point at random beyond the lens, electrons of varying momentum will pass through this point, providing they are suitably directed initially. Figure 1 shows the qualitative relation between initial slope and momentum for electrons passing through some such point. Electrons of enormously high momentum are not appreciably affected by the magnetic field. If they are aimed geometrically for the point in question, they will pass through it. All the electrons of lower momentum require a larger initial slope in order that after deflection by the magnetic field they will still pass through the point. The gradual increase of initial slope, as electron momentum is decreased, is shown by the lower branch of the curve, Fig. 1. But there must be some minimum momentum, since sufficiently slow electrons will be deflected too much ever to reach the point. That there must be another branch to the curve is implied in the crossing of trajectories, already mentioned. For every trajectory (of electron momentum greater than the minimum) that passes through the point, there must be another trajectory passing through the same point corresponding to the same momentum, but with a different initial slope. As the momentum is decreased, the two initial slopes must both approach the initial slope of the trajectory for the minimum momentum.

Suppose we consider placing a discriminating baffle at this point, so as to transmit only electrons which pass

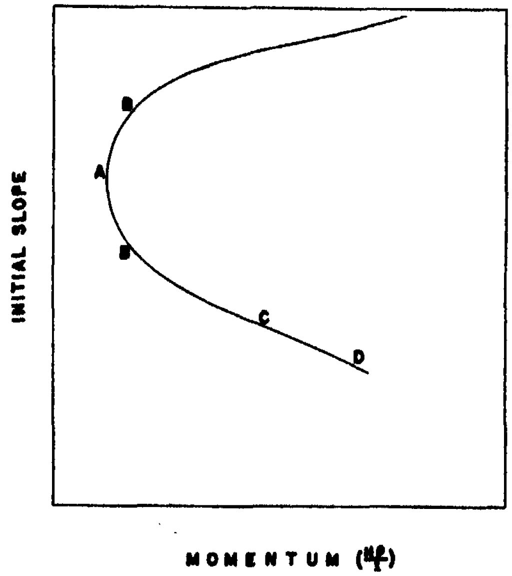

FIG. 1. A set of electrons pass through any point beyond the lens. This figure shows the relationship between initial slope and momentum for these electrons. The existence of a minimum momentum (at *A*) is essential for ring focus.

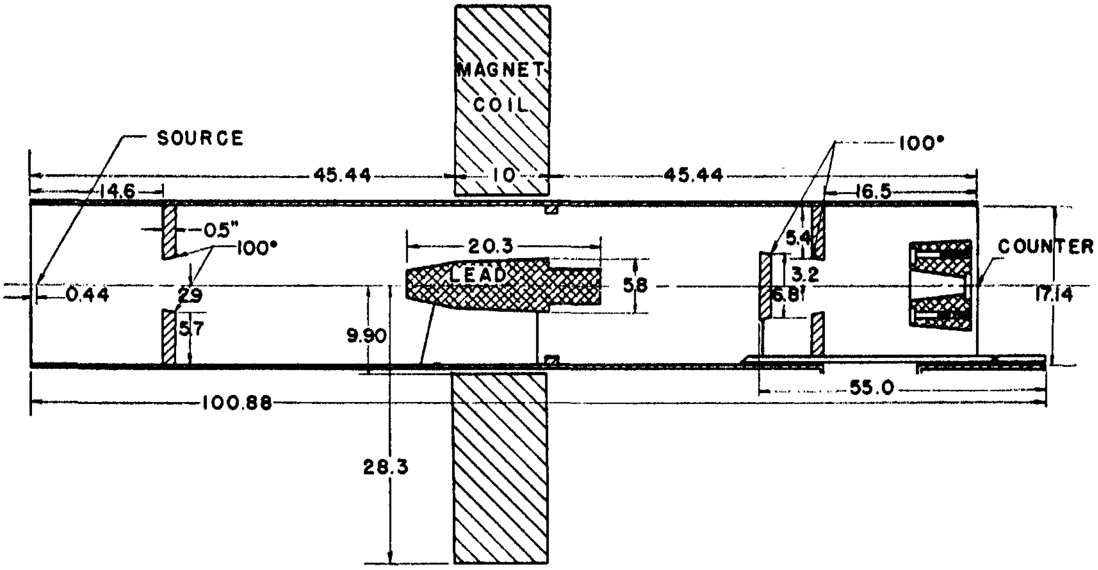

FIG. 2. Dimensions of the spectrometer at Iowa State College.

through this point. This will constitute a possible scheme for selecting electrons of a limited momentum range, providing we have an auxiliary set of baffles to limit the angles transmitted by the spectrometer. If the point has been chosen arbitrarily, then a range of momentum *CD*, determined by the angular selector, will pass through the discriminator. In this region of operation, varying the transmission of the angular selector will cause a linear variation in the "irresolution" (reciprocal resolution). This type of resolution-transmission behavior is characteristic of axial focus. If we now select the point where we place our final discriminator as the position of ring focus, this is equivalent to working at the minimum momentum of Fig. 1. Then a range of initial angles will allow the momentum interval *AB* (Fig. 1) to pass through the point. This type of operation of a spectrometer would exhibit an irresolution that should vary quadratically with the intensity. Hence, on the basis of such a crude analysis it might be expected that ring focus would yield an improvement of transmission, for a given resolution, over axial focus.

The dimensions of the spectrometer under consideration are shown in Fig. 2. The baffles indicated are those that have been used with the conventional axial-focusing selection.

TRAJECTORIES FOR A POINT SOURCE

From the equations of motion for an electron in a cylindrically symmetric magnetic field (no azimuthal component)[7,8] a single equation for an electron trajectory can be obtained. The magnetic field is described by a vector potential, which is always in an azimuthal direction. The two constants of motion—energy (or velocity) and (canonical) angular momentum about the axis of cylindrical symmetry—can be used to eliminate the time and the azimuthal variable. In particular, for any particle that starts at or passes through the axis, the angular momentum is zero, and the resulting equation for the "trajectory" (radial displacement r as a function of axial displacement z) is[9]

$$r''(k^2-A^2)/(1+r'^2)-r'A(\partial A/\partial z)+A(\partial A/\partial r)=0. \quad (1)$$

Here A is the vector potential per unit magnetizing current, and k is the electron momentum in "$H\rho$" units, also divided by the magnetizing current. Primes indicate differentiation with respect to z.

To determine the vector potential, the magnetic field was first calculated along the axis. For a coil of rectangular cross-section of axial length L, inner and outer radii a_1 and a_2, and n turns, the axial field per ampere of magnetizing current is given by[10]

$$H_0(z)=\frac{2n\pi}{10L(a_2-a_1)}(B(a_2)-B(a_1)), \quad (2)$$

where

$$B(a)=\left(z+\frac{L}{2}\right)\ln\left\{a+\left[a^2+\left(z+\frac{L}{2}\right)^2\right]^{\frac{1}{2}}\right\}$$
$$-\left(z-\frac{L}{2}\right)\ln\left\{a+\left[a^2+\left(z-\frac{L}{2}\right)^2\right]^{\frac{1}{2}}\right\}.$$

The values used were: $a_1=9.9$ cm, $a_2=28.3$ cm, $L=10$ cm, and $n=2799$. In using these values of the inner and

[9] The derivation of this equation is outlined in the Appendix. See also: N. F. Verster, Applied Scientific Research B1, 363 (1950); G. Liebmann, Proc. Phys. Soc. B62, 753 (1949).

[10] Deutsch, Elliot, and Evans, Rev. Sci. Inst. 15, 178 (1944).

outer radii for computing the field on the axis it was recognized that Eq. (2) only approximated the true field intensity. The magnetic coil is not in reality a continuum of turns as required in the derivation of Eq. (2). Seventeen cooling shims, each 0.2 cm thick, are inserted throughout the magnetic coil. The effect of these shims is to make the field at the center of the lens stronger than the value calculated by Eq. (2), and to reduce the field below the calculated value at distances greater than ten cm from the center.

The vector potential at any point (r, z) was calculated from the field H_0 on the axis by the well-known expansion[10]

$$A(r,z)=\frac{r}{2}H_0(z)-\frac{r^3}{16}\left(\frac{\partial}{\partial z}\right)^2 H_0(z)+\frac{r^5}{384}\left(\frac{\partial}{\partial z}\right)^4 H_0(z)$$
$$+\cdots+\frac{(-1)^s}{s!(s+1)!}\left(\frac{r}{2}\right)^{2s+1}\left(\frac{\partial}{\partial z}\right)^{2s} H_0(z)+\cdots. \quad (3)$$

The field H_0 was calculated by Eq. (2) at 2 cm intervals, and five successive derivatives of H_0 were obtained by differences. In calculating A by Eq. (3) only three terms in the series were retained. The errors introduced by neglecting sixth differences of H_0 were studied in the region of the lens for one trajectory. The error in A was found to be less than 0.2 percent, and the error in $\partial A/\partial r$ was no greater than 0.7 percent. The over-all effect on the path was less than this because the error in curvature reversed sign at four centimeters from the center of the lens. The error in r due to the error in field calculations in the region of ring focus is estimated to be about 0.8 percent (0.023 cm).

TABLE I. Positions of ring focus.

Momentum, k gauss cm/amp.	Radius r cm	Distance past center cm
960	2.823	22.65
990	2.872	24.57
1020	2.925	26.90
1050	2.979	29.30
1080	3.033	31.97
1110	3.090	34.30
1140	3.133	36.90

It might be pointed out that we deliberately avoided the paraxial approximation as we did not feel that it would yield sufficient information for a study of ring focus.

The actual computations involved in the numerical integration of the differential equation of motion were carried out on International Business Machines. It was advantageous to use automatic computing machines because in this way we could obtain at once a large number of trajectories. All of these trajectories werg desired to obtain information such as line shape for rine focus and the behavior of ring focus for different momenta. The numerical integration was carried out using

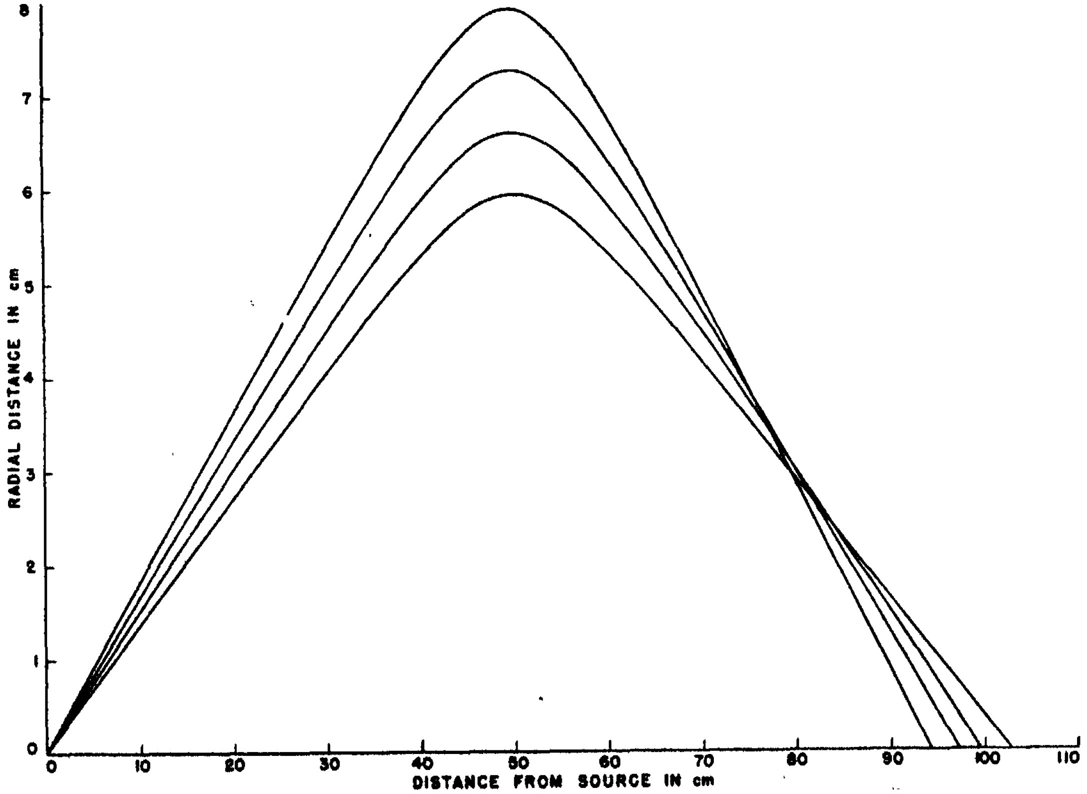

FIG. 3. Trajectories for electrons of a given momentum.

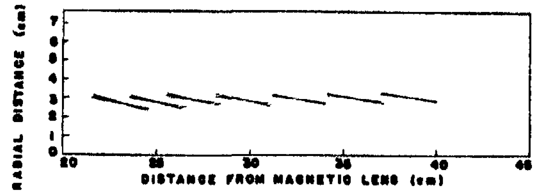

FIG. 4. Location of ring focus. The positions of ring focus are indicated by the intersection of extremal rays for different momenta. The z coordinate of the position of ring focus increases with increasing momentum.

two centimeter intervals in z (the axial distance). The method used is described in the appendix.

Forty-nine separate electron trajectories were calculated for a point source on the axis, using seven values of momentum and seven initial slopes. The selected values of initial slope and momentum were:

Initial slope (tanα)	Momentum (k) gauss cm/amp.
0.1350	960
0.1425	990
0.1500	1020
0.1575	1050
0.1650	1080
0.1725	1110
0.1800	1140

The seven trajectories for a given momentum were plotted together so that the location of ring focus could be determined (radius is plotted against axial distance from source). The set of trajectories for $k=1050$ gauss cm/amp. is shown in Fig. 3. The "aberration" of the lens which makes ring focus possible can easily be seen from this plot.

As was noted earlier, every point over a considerable region of the spectrometer is a point of ring focus for a definite momentum and some initial slope (actually for a small range of slopes). Likewise for a chosen electron momentum, every point along the envelope of trajectories for that momentum is a point of ring focus for some initial direction. A more practical way of discussing the location of ring focus than either of these is to consider a given range of initial electron directions and to describe how the position of ring focus varies with momentum for this range. Further, since we are interested in collecting electrons starting out through a finite range of solid angle, we define the point of ring focus as the intersection of the extremal trajectories. All the electrons of the chosen momentum and range of initial directions will pass between this intersection and the envelope of the trajectories. Intersections of the extreme trajectories for different momenta are shown in Fig. 4. We note that the locus of the point of ring focus approximates a straight line at nearly constant radius. The location of ring focus is tabulated in Table I.

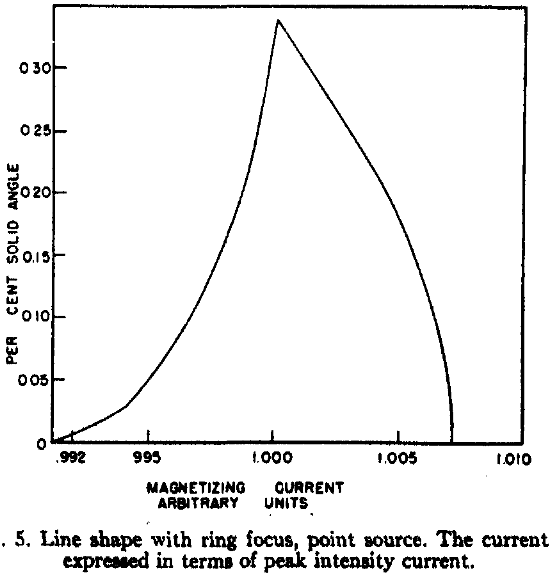

FIG. 5. Line shape with ring focus, point source. The current is expressed in terms of peak intensity current.

LINE SHAPE FOR A POINT SOURCE

The calculated trajectories contain the necessary information for determining line shape. With a monoenergetic source, for purposes of calculation, we have assumed that electrons are ejected from the source with the same intensity in all directions. Then, the intensity collected by the counter will be proportional to the difference in values of cosα (α is initial slope angle) between the extreme rays collected. We considered the ring for ring focus as an annular opening in a plane baffle perpendicular to the axis. To focus a given momentum, the width of the annulus was chosen just large enough to admit the extreme rays where they intersect, and also the envelope of trajectories of this momentum. Having chosen the axial position of the ring, we plotted, for several values of focusing current, the values of cosα as a function of the radius at which the trajectory in question crosses the plane of the annulus. In this way we determined the range in initial angles admitted by the annulus, and hence the line shape (see Fig. 5). In order to reduce the long tail on the low current end of the line, it was assumed that baffles placed between the source and the field coils eliminated all initial slopes outside of the range of values for which trajectories were calculated. These baffles do not appreciably affect the line shape near its peak. It was also assumed that the counter had a large enough window to collect all electrons passed by the baffles and the discriminating annulus.

A similar calculation was made for momentum discrimination by a 0.82 cm diameter counter placed on the axis without any annulus ("axial focusing"). The baffle system used in this calculation is shown in Fig. 2. Axial focus is somewhat more affected by baffle location than ring focus. The results are shown in Fig. 6.

To investigate the validity of Frankel's quadratic dependence of irresolution on transmission[3] for our spectrometer, line shapes were determined with various transmissions. The range of solid angle admitted was

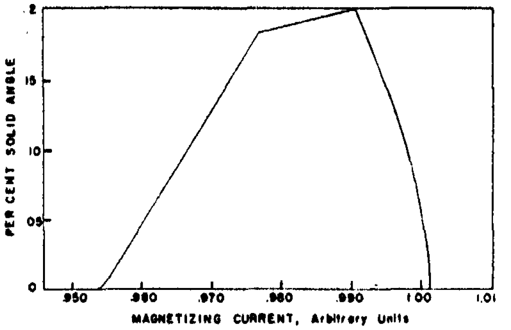

FIG. 6. Line shape with axial focus, point source. The unit of current is the same as Fig. 5.

altered by considering different minimum initial slopes, keeping the maximum initial slope fixed at 0.180. The irresolution is the full momentum width at half maximum (Δk) divided by the peak momentum (k). Intensity, Φ, is defined as the fraction of 4π-steradians transmitted. For these calculations the value of k for peak transmission was kept fixed at 1050 gauss cm/amp., requiring a shift in location of the plane of the discriminating annulus as well as changes in the radial dimensions of the annulus.[11] The results are approximated by the relation $\Delta k/k = (25\Phi)^2$.

Frankel has suggested that an optimum arrangement would be obtained using an annulus in a cone instead of a plane baffle. The cone would contain positions of ring focus of neighboring momenta for the initial angles admitted. We have found little difference in line shape between the two types of annulus for reasonable intensities.

EFFECT OF FINITE SOURCE SIZE

The effect of a finite source diameter was obtainable from the results of calculations made on an axial, point-source basis. The method of finding the trajectories of electrons originating off the axis, but still with zero angular momentum, made use of the symmetry of the magnetic lens about the mid-plane. It was only necessary to reverse any rays with a given calibration constant to obtain a new set of rays originating off the axis.

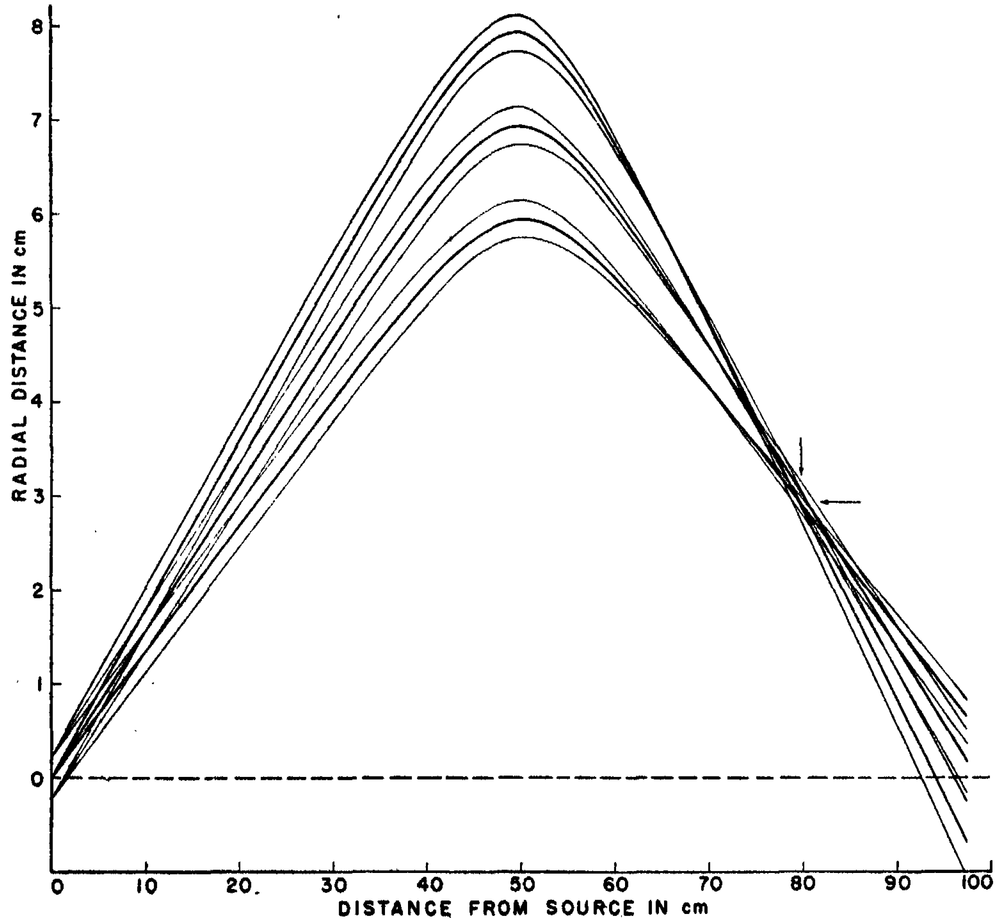

FIG. 7. Effect of finite source diameter on electron trajectories. These trajectories are for electrons with a given momentum and zero angular momentum about the central axis. Arrows indicate the location of ring focus for a point source.

---

[11] In practice one might equally well contemplate keeping the plane of the annulus fixed. This would imply a change in calibration constant (optimal value for k) as the range of the admitted angles was altered. Our choice of keeping k fixed was one of convenience. In tracking down sources of irregularities in the trajectories, we discovered that the business machines failed to perform properly one operation when the r value exceeded 6.3 cm ($r^5 > 10^4$). Working in the neighborhood of a chosen value of k required less recalculation. The trajectories for $k = 1050$ gauss cm/amp. were recomputed over the range of large r, using desk calculators. Corrections to the trajectories for $k = 1020$ and 1080 gauss cm/amp. were then estimated.

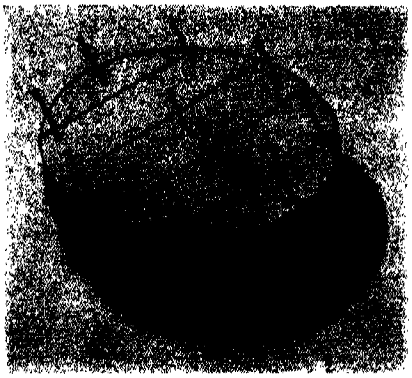

FIG. 8. The model illustrates a set of electrons starting out from an extended source in a given direction. Vectors one and five indicate electrons of zero angular momentum. The angular momentum of all electrons starting outside of the 1–5 plane is not zero. In subsequent calculations, the source was divided into zones as shown.

For rays starting off the axis, "zero angular momentum" means that if such an off-axis trajectory be extended (forward or backward) there will be at least one intersection with the axis.

A detailed examination was made of three trajectories with electron momentum $k=1050$ gauss cm/amp., initial slopes 0.1350, 0.1575 and 0.1800 (the mean and extreme rays). The entire set of trajectories of $k=1050$ gauss cm/amp. was reversed as described above. A linear interpolation was made and the three reversed rays found that had the same initial slope as the three reference trajectories. Assuming that a small displacement off the axis at the source would have only a small effect on the trajectories, a linear interpolation was made between off-axis and axial trajectories to obtain rays of a given initial slope originating from any source point.

The effect of a finite source diameter, neglecting angular momentum, is shown in Fig. 7. The two sets of off-axis trajectories were chosen to originate from points 0.225 cm off the axis.

A thorough treatment of finite source size must also take into consideration the cases where the angular momentum is not zero. This complicates the equation of an electron trajectory, but cannot change the physical behavior much. Consider electrons starting from the source in some particular direction. A finite source diameter replaces a single ray by an initially parallel beam. Let us think of the plane containing the axis and parallel to this initial direction. Displacement, in this plane, of a ray from an axial starting point gives rise to a trajectory of zero angular momentum. Displacement of a ray out of this plane gives rise to a trajectory of finite angular momentum. As the displacement which causes angular momentum is small compared to the maximum radius of the electron path, the effect of angular momentum must likewise be small. Figure 8 is a pictorial representation for the cases discussed.

The equation of an electron trajectory of arbitrary angular momentum in the presence of fields is obtained by replacing A, wherever it occurs, by $(A-pc/Ier)$, where p is the angular momentum of the focused electron, c the velocity of light, I the magnetizing current, and e the charge on the electron. The result is:

$$\frac{r''[k^2-(pc/Ier-A)^2]}{(1+r'^2)}+r'(pc/Ier-A)(\partial A/\partial z)$$
$$-(pc/Ier-A)(pc/Ier^2+\partial A/\partial r)=0. \quad (4)$$

Including angular momentum in the treatment of a finite source size has two effects. In the region of strong field, angular momentum alters the effective field slightly. In weak fields, the trajectories are approximately straight lines in space but they do not intersect the axis. When radius is plotted against axial distance, these straight lines appear as hyperbolas.

Figure 9 shows the effects of angular momentum on the sets of rays illustrated in Fig. 8. The rays were started and ended by matching them to the proper hyperbolas. Corrections through the region of strong field were aided by the fact that the trajectory of maximum angular momentum coincided, near the lens, with the axial point-source (zero angular momentum) trajectory. For clarity, in Fig. 9 only the paths for maximum angular momenta were continued beyond the point of intersection. It can be seen that the effect of angular momentum is such that only displacements of the source point in the axial plane (of zero angular momentum) containing the initial electron direction need be considered.[12]

The line shape for a finite source (0.56 cm diameter) was therefore calculated by dividing the source into sections as in Fig. 8 and weighting each section according to its area.

Line shapes for ring and axial focusing of a finite source are shown in Fig. 10 and Fig. 11. For axial focusing the same experimental arrangement (Fig. 2) was considered as for point source calculations on axial focusing. The geometry used for ring focus included, in addition to the ring selector, a set of auxiliary baffles. These were again the baffles of Fig. 2, but with their position relative to source and counter reversed. This gave a somewhat better line shape than the baffles considered for ring focus of a point source, and were convenient experimentally.

One effect of an extended source not previously mentioned is to broaden the ring focus. While a ring width of 0.12 cm passed the desired rays for a point source, twice this width seems a minimum reasonable value for the source size discussed. The line shape shown in Fig. 10 was calculated for a ring 0.36 cm wide. A still wider ring will allow our spectrometer to transmit more than twice the intensity that it passes with axial focusing, without exceeding the axial focus irresolution of approximately 3 percent.

---

[12] More generally, under the approximation that a displacement of the source point from the axis produces at any axial position z a change in radius proportional to the displacement of the source, there always exists (except where the trajectory approaches the axis) some direction in which source displacement has no effect. That this direction is nearly perpendicular to the plane of initial electron motion seems to be a property of a thin lens. A comparison of our analysis with that of DuMond[4] for a solenoid indicates that the same result would not hold in his case.

DISCUSSION OF RESULTS

Our calculated line shapes (Figs. 10, 11) agree roughly, though not in detail, with experimentally observed line shapes for internal conversion sources. In particular, the theoretical and experimental half-widths are in good agreement. Further, we have calculated a calibration constant from our line shape. From Fig. 11 we would obtain directly a value 1069.5 gauss cm/amp. The calibration constant is defined as the value of the momentum-per-unit-current k midway between the values for half-maximum transmission. This value must be corrected as follows (Appendix 3):

Effect of cooling shims in magnet coil..... 5.4.
Effect of higher differences in magnetic field. 1.8.

$$\begin{array}{r} 1069.5\\ 5.4\\ 1.8\\ \hline 1076.7\pm 4 \text{ gauss cm/amp.}\end{array}$$

The suggested uncertainty is half of the above corrections, combined with others errors discussed in the Appendix. Comparison of the theoretical constant with the best experimental value ($k=1078.5\pm 3$) gauss cm/amp. is satisfactory.

A further confirmation of our trajectories was obtained by Boley, Pratt, and Nichols,[13] who used photographic plates to detect electrons in the spectrometer and in this way were able to verify the location and width of the ring focus.

Our calculations have shown that using ring focus in a thin lens beta-ray spectrometer produces an increase in transmission of better than a factor of two for a given resolution ($\Delta k/k \leqq 3$ percent).

We would like to acknowledge the many helpful discussions with Messrs. L. J. Laslett, E. N. Jensen, W. W. Pratt, and F. I. Boley. We would also like to thank R. C. Ling for his preliminary calculations of the field and C. C. Mosier for the care with which he carried out the numerical integrations.

APPENDIX

1. Equations for the Trajectories

An axially symmetric magnetic field (with no azimuthal component) can be represented as the curl of a vector potential A_θ, whose direction is always azimuthal. The motion of a charged

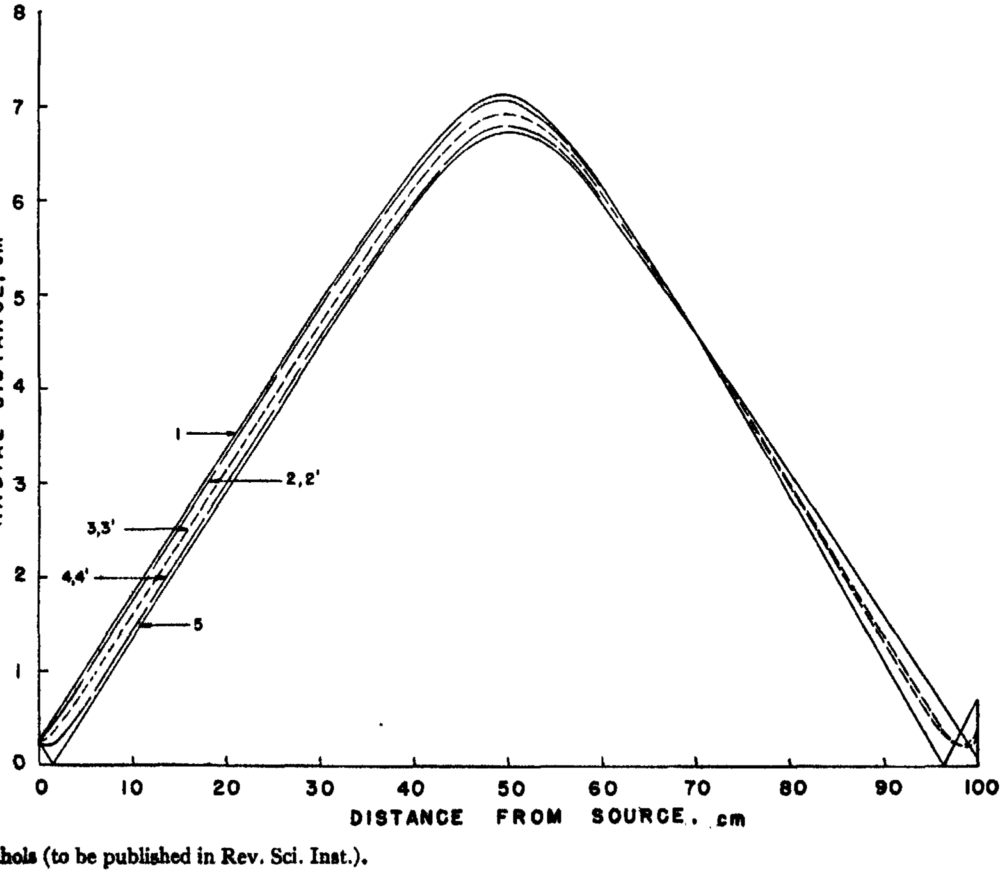

FIG. 9. Effect of angular momentum on electron trajectories. The trajectories are numbered the same as in Fig. 8. Only the rays of zero angular momentum (1,5) and maximum angular momentum (3,3') are continued past the central region.

---

[13] Boley, Pratt, and Nichols (to be published in Rev. Sci. Inst.).

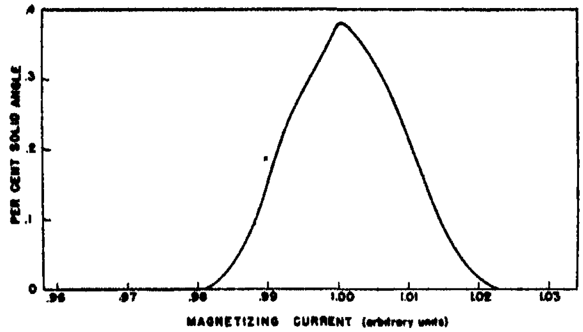

FIG. 10. Line shape with ring focus, extended source. The unit of current is the same as Fig. 5.

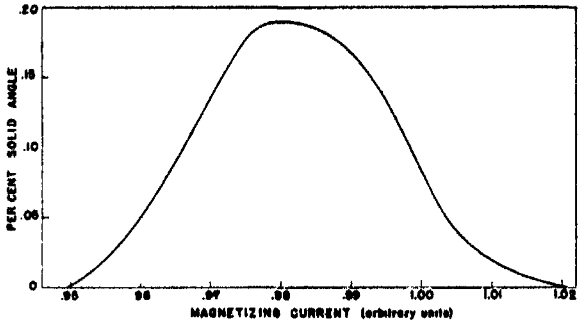

FIG. 11. Line shape with axial focus, extended source. The unit of current is the same as Fig. 5.

particle in such a field is governed by the equations

$$\begin{aligned}(d/dt)(m\dot{r}) &= mr\dot{\theta}^2+\frac{e\dot{\theta}}{c}\frac{\partial}{\partial r}(rA_0),\\ (d/dt)(m\dot{z}) &= (er\dot{\theta}/c)(\partial A_0/\partial z),\\ (d/dt)(mr^2\dot{\theta}+erA_0/c) &= dp/dt=0.\end{aligned}\tag{A-1}$$

In these equations, r, and z are the cylindrical coordinates describing the position of a particle of charge e and (relativistic) mass m at time t. A dot indicates time differentiation, and c is the velocity of light. The particle speed v and hence also the mass, is a constant of the motion, since a steady magnetic field can do no work on a charge. p, the canonical angular momentum about the symmetry axis, is also a constant of the motion. By introducing it into the first two equations, the angular velocity $\dot{\theta}$ can be eliminated, and the equations

$$\begin{aligned}(d/dt)(m\dot{r}) &= (e^2/mc^2)(pc/er-A_0)(pc/er^2+\partial A_0/\partial r),\\ (d/dt)(m\dot{z}) &= (e^2/mc^2)(pc/er-A_0)(\partial A_0/\partial z)\end{aligned}$$

result.

The equations for an orbit are obtained from the equations of motion by replacing time by some other quantity, say z, as the independent variable. The left-hand members of the last two equations will now be expressed as

$$\dot{z}\frac{d}{dz}\left(m\frac{dr}{dz}\dot{z}\right)=m\dot{z}^2\frac{d^2r}{dz^2}+m\frac{dr}{dz}\dot{z}\frac{d}{dz}(\dot{z})$$

and

$$m\dot{z}(d/dz)(\dot{z})$$

respectively. $\dot{z}$ in turn can be expressed in terms of the particle speed v by the relation

$$\begin{aligned}v^2 &= \dot{r}^2+\dot{z}^2+r^2\dot{\theta}^2\\ &= \left[1+\left(\frac{dr}{dz}\right)^2\right]\dot{z}^2+\frac{e^2}{m^2c^2}\left(\frac{pc}{er}-A_0\right)^2.\end{aligned}\tag{A-2}$$

Carrying out the indicated substitutions, we obtain the single differential equation[14]

$$\begin{aligned}r''\frac{[(mvc/e)^2-(A_0-pc/er)^2]}{1+r'^2}&-r'(A_0-pc/er)(\partial A_0/\partial z)\\ &+(A_0-pc/er)(pc/er^2+\partial A_0/\partial r)=0.\end{aligned}\tag{A-3}$$

Primes indicate differentiation with respect to z. The expression mvc/e is the momentum of the particle expressed in "$H\rho$" units. If we divide the equation through by I^2 (the square of the current), write k for mvc/eI, and A for A_0/I, as has been done in the body of the paper, Eq. (A-3) becomes Eq. (4). Setting $p=0$ reduces this to Eq. (1).

2. Numerical Integration

The trajectories, $r(z)$, were calculated at 2 cm intervals in z ($\Delta=2$ cm) by the following process. (We denote derivatives with respect to z by primes.) Assume $r(z)$, $r(z-\Delta)$, $r(z-2\Delta)\cdots$known.

1. Calculate $r'(z)$ by the approximate relationship

$$r'(z)=[3r(z)-4r(z-\Delta)+r(z-2\Delta)]/2\Delta.\tag{A-4}$$

2. Calculate A, $\partial A/\partial r$ and $\partial A/\partial z$ for the position (r, z).
3. Solve Eq. (1) for $r''(z)$.
4. Compute $r(z+\Delta)$ by the approximate relationship

$$r(z+\Delta)=2r(z)-r(z-\Delta)+\Delta^2r''(z).\tag{A-5}$$

The cycle is repeated to obtain $r(z+2\Delta)$ etc.

The integration was begun assuming no change in slope until 8 cm from the source. A and r and their derivatives were carried out to six decimal places.

3. Errors

There are two types of errors involved in the trajectory calculations: those inherent in the step-by-step method of calculating and those associated with the approximate calculation of the magnetic field. The first type of error is quantitatively much smaller than the second. It is discussed first because of the basic nature of the treatment of errors involved.

Errors Arising from Numerical Integration

(a) Replacing the differential equation by difference equations, as in Eq. (A-5), introduces a cumulative error in $r(z)$.

(b) The error in r due to (a) will produce an error in the calculated value of the second derivative since A and its derivatives will be calculated at the incorrect value of r. This will in turn produce further errors in r and its first derivative.

Since the magnetic field increases as r increases (i.e., as one approaches the field windings), at least in the strong field region, too large a value of r will produce too large a curvature. This will tend to compensate for the error in r. However, the slope of the calculated trajectories will be in error after the particle passes out of the strong field region. Errors of the types (a) and (b) have been estimated, and the correction applied to the trajectories, before any further calculations (on ring focusing, line shapes, etc.) were made.

r'' is also dependent on r' according to Eq. (1). r' is approximated by difference equation (Eq. (A-4)) and is also affected by any error in r. However, the dependence of r'' on r' is very weak, and errors in r'' due to incorrect values of r' have been neglected.

To study the propagation of errors we observe that:

$$r(z+\Delta)=r(z)+\Delta r'(z)+\Delta^2r''(z)/2!+\Delta^3r'''(z)/3!+\Delta^4r^{(4)}/4!+\cdots,$$

and

$$r(z-\Delta)=r(z)-\Delta r'(z)+\Delta^2r''(z)/2!-\Delta^3r'''(z)/3!+\Delta^4r^{(4)}/4!+\cdots;$$

then

$$\begin{aligned}r(z+\Delta)-2r(z)+r(z-\Delta)=\Delta^2r''(z)&+\Delta^4r^{(4)}(z)/12\\ &+2\Delta^6r^{(6)}(z)/(6!)+\cdots.\end{aligned}\tag{A-6}$$

---

[14] This equation also appears in the report of Frankel and Nelson, reference 3.

TABLE II. Errors.

Type of error	Error in r†		Error in calibration constant
	At ring focus	*At counter*	
1. Method Error			
(a)* and (b)*	0.0096 cm	0.016 cm	0.035%
(c)	less than 0.0003 cm	less than 0.0003 cm	negligible
2. Machine Error			
(d)*	0.03 cm	0.05 cm	0.1%
3. Field Error			
(a)	0.023 cm	0.04 cm	0.17%
(b)	0.053 cm	0.140 cm	0.50%

† Errors in r have been calculated for k 1050 gauss cm/amp.

* Errors marked with an asterisk have been corrected for in the initial calculation of the calibration constant. The values given for the error in r are for initial slope 0.180. The errors are less for lower initial slopes.

Equation (A-6) is an exact equation. In the numerical integration this is replaced by

$$r(z+\Delta)_{\text{calc.}}-2r(z)_{\text{calc.}}+r(z-\Delta)_{\text{calc.}}=\Delta^2 r''(z)_{\text{calc.}}. \qquad \text{(A-7)}$$

Subtracting Eq. (A-7) from Eq. (A-6), and denoting the correction $r(z)-r(z)_{\text{calc.}}$ by $\delta r(z)$ etc., we obtain

$$\delta r(z+\Delta)-2\delta r(z)+\delta r(z-\Delta)=\Delta^2\delta r''(z)+\Delta^4 r^{(4)}(z)/12+\cdots.$$

The left-hand side of this equation is approximately $\Delta^2(d^2/dz^2)\delta r(z)$, and dropping the . . . terms, we end up with the basic differential equation for propagation of errors:

$$(d/dz)^2\delta r(z)=\delta r''(z)+\Delta^2 r^{(4)}(z)/12. \qquad \text{(A-8)}$$

In the case that $\delta r''(z)$ arises because $r''(z)$ (or more correctly $r''(z, r)$) is calculated from Eq. (1) at an incorrect value of $r(z)$ we can approximate $\delta r''(z)$ by

$$\delta r''(z)=\delta r(z)\cdot\partial/\partial r(r''(z, r)).$$

If there were no errors, $\delta r''$, in the calculated second derivative, the principal effect of replacing the differential equation by difference equations could be obtained at once by integrating Eq. (A-8) explicitly.

$$\delta r(z)=[r''(z)-r''(z_0)-(z-z_0)r'''(z_0)]\Delta^2/12,$$

where z_0 is the value of z at which integration was begun. Since z_0 was in a nearly field free region, a good approximation, obtained by neglecting $r''(z_0)$ and $r'''(z_0)$, is given by

$$\delta r(z)=\Delta^2 r''(z)/12. \qquad \text{(A-9)}$$

In integrating the complete equation,

$$(\partial/\partial z)^2\delta r(z)=\delta r(z)(\partial/\partial r)(r''(r, z))+\Delta^2 r^{(4)}(r, z)/12,$$

expression (A-9) was used as a first trial value in the right hand member.

(c) The propagation of rounding off errors was studied by a similar equation, using as initial conditions at an arbitrary point z_0

$$\delta r(z_0)=a,$$
$$(d/dz)(\delta r(z_0))=a/\Delta;$$

a, the initial rounding off error, was taken as 10^{-6} cm.

(d) Machine Failure: The failure of the business machines to carry out correctly one operation was mentioned in reference 11. Calculations were repeated for the trajectories with $k=1050$ gauss cm/amp., corrections to the trajectories for $k=1020$ and 1080 gauss cm/amp. were estimated.

Errors Arising from Magnetic Field Approximations

(a) ***Errors due to neglecting higher order differences:*** In calculating A, $\partial A/\partial r$ and $\partial A/\partial z$, sixth and higher order differences in the magnetic field were consistently neglected. The effect of 6th order differences on r'' was calculated in the region of strong fields. Corrections to the trajectories were obtained by integration. The correction made the trajectory cross the axis of the spectrometer 0.25 cm nearer the lens. This was found to correspond to a change in calibration constant k of 0.17 percent. Here, and in the remainder of the Appendix, we are using k to mean that particular momentum-per-unit-current that the spectrometer focuses.

That this order of magnitude is reasonable follows from application of the thin lens formula. From the relation

$$1/P+1/Q=1/F,$$

where P, Q, and F are source and detector distances from the lens and "focal length" of the lens, we have that

$$dQ/Q^2=dF/F^2.$$

Since Q is approximately equal to $2F$, this equation reduces to

$$dQ/Q=2dF/F.$$

But for a thin lens

$$F\propto k^2;$$
$$dF/F=2dk/k$$

and so the fractional correction to k must be $\cong\frac{1}{4}$ the fractional change in Q.

(b) *Effect of cooling shims:* The trajectories were calculated for an idealized magnet carrying a uniform current density. For comparison of our results with experiment it was necessary to include the alteration in the field produced by the cooling shims of the experimental magnet.[6] The effect of these cooling shims was to increase the field strength in the center of the lens by about 1 percent, and to decrease it below the idealized value at distances greater than about 10 cm from the mid-plane of the instrument.

The error in k produced by neglecting the cooling shims was estimated as follows. According to the simple "very thin" lens formula[15]

$$k^2\propto\int H^2dz.$$

If, as before, we use the symbol δ to denote error ($\delta H=H_{\text{correct}}-H_{\text{calculated}}$, etc.),

$$\delta k/k\cong\int H\delta H dz\bigg/\int H^2dz.$$

By calculating δH at a few points and making a reasonable interpolation, we estimated $\delta k=0.5$ percent.

The error in r was found by calculating the error in r'' and integrating twice.

Errors are summarized in Table II.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 8 AUGUST, 1950

Lens Tester for Photographic Lenses

F. G. Back
Research and Development Laboratory, New York, New York

(Received March 30, 1950)

Testing lenses, particularly photographic lenses, in a simple, fast, and accurate manner is quite a difficult problem. One of the solutions to this problem is a lens tester which is basically a modified autocollimator with a built-in color filter arranged in conjunction with an assembly unit consisting of an adjustable microscreen and a lens holder. This latter unit may be rotated about an axis perpendicular to the optical axis of the instrument, giving an immediate reading of the tangential and sagittal foci. By means of this instrument it is possible to determine: (1) the flange focal distance, (2) the shift of axial focus with respect to the lens aperture, (3) longitudinal chromatic aberration, (4) tangential and sagittal foci for any angular distance from the axis and for any aperture, and (5) all these readings for various color bands. This new instrument makes possible the immediate reading of the results without further computation. The determination of the nodal point and the focal length for extra-axial aberrations is unnecessary. Built-in color filters allow testing for chromatic aberrations. Because of a special microscreen and reflection-free beam splitter arrangement, this instrument gives satisfactory readings also for small apertures.

Testing photographic lenses in a fast and accurate way presents a problem in many cases, especially if a great variety of lenses with different equivalent focal lengths have to be checked and the quality of the images evaluated. Very often it is not required, and even not desirable, to measure or determine the five basic aberrations separately because frequently they would not give a true picture of the real performance.

It is well known that certain aberrations mask others. On the other hand, aberrations of different kinds may appear as similar defects as far as the final photographic image is concerned. For instance, on a black and white photograph, longitudinal color and spherical aberration, especially zonal aberration, create the same fuzziness all over the image. Coma and astigmatism will show a similar fuzziness toward the edges of the frame.

It is therefore very often better to determine the combined effect of all aberrations on the actual picture quality of the photographic lens for different relative apertures and different field angles.

These measurements cannot be obtained quickly and accurately by conventional methods. The Hartman method as well as the nodal slide method, although accurate, are time consuming. The Hartman method requires photographic processing and determines axial aberrations only. The bench method necessitates a very accurate determination of the nodal point and the equivalent focal length. The results obtained by the interferometer measurements are difficult to translate into actual picture quality.

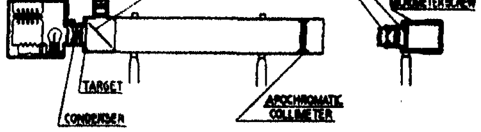

Fig. 1.

The lens tester is based on the principle of the autocollimator. This same principle has been used by Townsley and Foote[1] in their "microfocuser." The basic difference between the lens tester and the "microfocuser" lies in their different purpose. The "microfocuser" has been designed to determine the "flange focal distance," i.e., the distance between the flange of the test lens to the image plane, which is the only standardized size in motion picture optics and is therefore preferable to the customary back focal length.

The "microfocuser" also allows accurate calibration of the focusing scale of the test lens for objects at finite distances, as well as checking the coincidence of running motion picture film with the image plane of the camera lens.

All these measurements can only be made on sufficiently corrected lenses. If the lens is afflicted with heavy aberrations, the instrument cannot be focused. It is therefore self-evident that the "microfocuser" cannot be used for a quantitative measurement of lens aberrations. The lens tester, on the other hand, is primarily intended to measure lens aberrations.

Both instruments use a peculiarity of the autocollimator, namely, that the longitudinal magnification of such a system is twice as large as the longitudinal magnification of any other system of equal lateral magnification. This gives to both instruments a sensitivity which cannot be obtained with the ordinary bench method. Townsley and Foote have furnished a very elegant mathematical proof of this phenomenon which need not be repeated here.

Figure 1 shows a schematic cross section through the lens tester. It can clearly be seen that the instrument consists of two units—the collimator unit and the micrometer unit.

The collimator unit consists of:

(A) A low voltage filament lamp burning at two intensity levels: the lower level for measurements under normal conditions; the higher level for measurements with dark filters or very small apertures.

---

[1] M. G. Townsley and P. C. Foote, J. Opt. Soc. Am. 37, 42 (1947).

(B) A four-way filter disk with a white window and a red, green, and blue filter.

(C) A condenser system which images the filament on the collimator lens.

(D) A target consisting of a thin metal plate showing a transparent cross and a concentric dotted circle.

(E) A beam splitter consisting of a plano parallel glass plate with a semitransparent and semireflective coating on one side and antireflection coating on the other side, set at a 45° angle to the optical axis of the system with the semireflective coating away from the target.

[The author prefers the coated semitransparent mirror to the block glass-type of beam splitter used in the "microfocuser" because it eliminates internal reflections. These reflections are objectionable because they diminish the contrast of the image seen through the eyepiece, thus making it difficult to obtain accurate reading for small lens apertures. The anti-reflection coating on the reverse side of the semi-transparent mirror reduces the brightness of the secondary image. Whatever remains of this unwanted image is rendered harmless by the thickness of the semi-transparent mirror which provides ample separation between the primary and secondary image.]

(F) An eyepiece arranged perpendicular to the optical axis of the system in such a way that its focal plane and the target (D) are equidistant from the point where the optical axis of the system intersects the semireflective coating of the beam splitter (E).

(G) A collimator consisting of a cemented triplet corrected for primary and secondary color and designed in such a way that zonal spherical aberrations are at a minimum.

[The collimator lens of the "microfocuser" is a long focus achromatic doublet which is fully sufficient for the purposes for which the "microfocuser" was designed. On the other hand, an instrument which measures aberrations has to use a much higher corrected objective to avoid the contribution of its own aberrations to those of the lens under test. The author has succeeded in designing a sufficiently thin triplet to avoid transversal color, which is the bane of most apochromats.]

The above-mentioned components are mounted in one metal unit on the standard optical bench. This unit collimates the target at infinity and transmits a bundle of parallel rays toward the lens to be tested.

The micrometer unit comprises:

(A) A microscreen consisting of a finely ground but unpolished silver-coated first surface glass mirror arranged perpendicular to the optical axis of the test lens. This microscreen is the basic point of difference between this instrument and the "microfocuser." Although ground as fine as possible to achieve maximum resolution, the microscreen still obeys Lambert's law and therefore reflects the incident rays diffusely. The receiver of the "microfocuser," on the other hand, is a highly polished mirror. This explains why, in the presence of stronger aberrations, the "microfocuser" cannot be focused, as there are an infinite number of coincidence planes equally out of focus. A quantitative analysis of lens performance is therefore impossible with the "microfocuser."

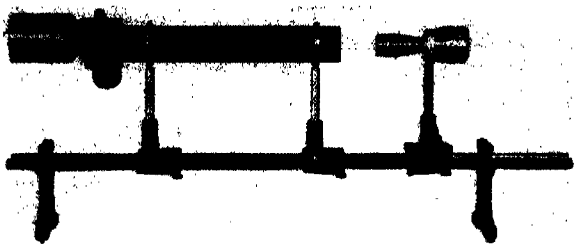

FIG. 2.

(B) A micrometer screw attached to the screen for moving it back and forth along the optical axis.

(C) An interchangeable lens mount which holds the test objective and which is dimensioned in such a way that the flange of the lens mount has the proper focal plane distance from the screen when the micrometer is set at zero.

A differential action of the aforementioned micrometer screw prevents the microscreen from rotating and at the same time permits an accurate reading.

This second unit can be rotated around an axis perpendicular to the optical axis of the system, and the angle of rotation is indicated on a dial. Since the microscreen remains always perpendicular to the optical axis of the lens to be tested, it is not necessary that this axis of rotation coincides with the transverse axis of the test objective. It is also unnecessary to keep any accurate distance between the two measuring units because the rays between the collimator and the lens are parallel.

The novel features of the aforementioned instrument give an accurate indication of the lens performance in the following readings.

(1) The distance from the lens flange to the image plane for an object at infinity in the center of the field with the iris closed to the smallest setting, measured with white light. This distance represents the flange focal distance of the lens. The flange focal distance is measured from the flange because the flange distance is the only standardized dimension on a camera and therefore most suitable as a reference point for photographic lenses.

(2) Determination of the same distance as (1), but for different iris settings. This measurement shows the shift of the focal plane caused by spherical aberration. Our measuring method integrates the total spherical aberration for that particular relative aperture and determines automatically the circle of least confusion for this iris setting.

(3) Same as (1) and (2), but measured with green, red, and blue light. These data determine the primary and secondary longitudinal color of the objective for the paraxial region as well as for the higher orders of this aberration.

(4) Distance between the flange and the two focal surfaces for objects at infinity not located on the optical axis but subtending, with the latter, various angles with the iris closed. The difference between these two distances represents the amounts of pure astigmatism with which the lens is afflicted at that particular field angle; while the difference between each of these two measurements and the flange focal length as measured according to (1) represents the tangential and sagittal field curvature.

(5) Same as (4), but for different iris settings to determine the additional influence of coma and oblique spherical aberration.

It should be noted here again that the measurements (2) and (5) do not represent the mathematical image point for that particular aperture but rather the circle of least confusion, taking into consideration the sum total of all aberrations which come into play at the image formation for that particular point of the field. The variations of these distances give a reliable measure for the evaluation of the lens performance under actual working conditions.

Figure 2 shows the instrument mounted on a standard optical bench.

It is obvious that, from the standpoint of production engineering, the necessary computations have been reduced to an absolute minimum. Nearly all data required to plot graphs of the resolution of the lens at different apertures and field angles can be directly read off from the instrument.

The instrument is also very sturdy and needs no adjustment once it is set. Like the "microfocuser," it can be operated by an unskilled worker after very short instruction.

An instrument of this type has been in practical daily use for over a year and has given most satisfactory results.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 8 AUGUST, 1950

Improvements in Mass Spectrometers for the Measurement of Small Differences in Isotope Abundance Ratios

C. R. McKinney, J. M. McCrea, S. Epstein, H. A. Allen, and H. C. Urey
Institute for Nuclear Studies, University of Chicago, Chicago, Illinois

(Received March 30, 1950)

A Nier-type mass spectrometer and its associated electronic units have been constructed for the purpose of measuring small variations in the abundances of oxygen of mass 18 and of carbon of mass 13 in carbon dioxide, and of oxygen of mass 18 in oxygen gas, to an accuracy of ±0.01 percent of the abundance of these isotopes.

The electronic units of the necessary stability for this degree of accuracy are described. A gas feed system is described which permits fast alternate introduction of the sample of gas to be analyzed and a standard gas into the mass spectrometer. All measurements of the variation in the abundance of the oxygen and carbon isotopes are made with reference to a standard.

During recent years great progress has been made in developing mass spectrometers for the measurement of the relative abundance of isotopes. Particularly sensitive instruments have been developed by Nier, Thode, and others.[1] Basically, the mass spectrometer and electronic units in our research were those described by Nier. We report only the changes we made in these that assisted us in being able to measure small differences in the abundance of the rarer isotopes in gaseous compounds. The method has been applied to carbon and oxygen in carbon dioxide and to oxygen in oxygen gas. Our success in securing this greater sensitivity depends both upon increasing the intensity of the ion beam and upon increasing the absolute sensitivity of detection. In doing this, it has been necessary to improve the stability of the beam intensity and output from the amplifiers by the use of more stable power supplies, more reliable amplification systems, and an improved emission regulator. Also, it has been necessary to use a method for rapid change of samples in order to decrease errors due to general variability of the instrument with time, and it has proved essential that a recording potentiometer be used to detect and record the state of balance of the simultaneously collected ion beams. The instrument has been constructed with the objective of measuring small differences in isotopic abundances of the oxygen isotopes as a means of measuring paleotemperatures, but the instrument and our procedures may be useful in other researches.

POWER SUPPLY FOR ELECTROMAGNET

Figure 1 shows the circuit diagram of the power supply used to furnish the current for the magnet windings and to supply some of the power requirements for the high voltage electronic unit.

---

[1] A. O. Nier, Rev. Sci. Inst. 18, 398 (1947). Thode, Graham, Ziegler, Can. J. Research B23, 40 (1945). For an excellent review of this subject, see M. G. Inghram, Advances in Electronics 1, 219 (1948).

Several measures are used to achieve good stability of the output of this power supply. The voltage to the screen of the 6L6 tubes (1V4 and 1V5) and the plate supply of the 12AU6 (1V13) amplifier tube is obtained from a separate power supply regulated by using OA2 (1V6 to 1V9) miniature voltage regulator tubes. A 5651 voltage regulator tube (1V11) is used to obtain a reference voltage. The ripple of the output is minimized by adjusting potentiometer 1P2. This potentiometer controls the balance of the bridge circuit operating through the isolating cathode follower tube (1V10) and the screen of the amplifier tube (1V13). The "*H*" network of which 1P2 is a part is designed so that the d.c. level of the output voltage is nearly independent of the setting of 1P2. This type of circuit is similar to the one described by McCrea and LeRoy.[2] Since the response of this circuit is rapid, the single condenser 1C3 provides ample smoothing of the input.

To further increase the stability of the power supply, the current for the heaters of the critical amplifier tubes (1V10, 1V12, and 1V13) is supplied by the output of the power supply itself. By using switch 1S3, the unit is allowed to warm up under reduced output voltage. Relay 1S2 protects the circuit from excessive voltage rise during operation. A properly adjusted power supply unit has an output of 250 volts and supplies a current of about 200 milliamperes. The ripple is 1.5 millivolts, peak to peak, with a noise level of about 0.6 millivolt. The internal resistance for direct current conditions is 0.35 ohm and for 60 cycle load variation about 0.6 ohm. A 1.1-volt (1 percent) variation in the alternating current input appears as a 0.000184 percent, or a 0.5 millivolt, variation in the output. The 115-volt power line is regulated by a Sola Constant Voltage Transformer.

The magnet current can be varied by varying the resistance in series with windings by means of controls 1P4 and 1P5 and switches 1S4 and 1S5. A Helipot 1P5, connected to a motor by a clutch mechanism, allows

automatic magnetic scanning for the desired mass range.

HIGH VOLTAGE SUPPLY

The high voltage supply shown in Fig. 2 furnishes a continuously variable regulated voltage in the range 600 to 2200 volts for accelerating the ions in the mass spectrometer. The voltage of the output is varied by means of decades 2D1 to 2D4, which are ganged with 2D1A and 2D2A to keep the load across the rectifier and transformer nearly constant. Condenser 2C4 and resistor 2P2 are included to eliminate tendencies for oscillation. Tube 2V3 performs the function of applying part of the output ripple in a degenerative manner to the grid of 2V2 which in turn acts to reduce the ripple of the output. A 1 percent variation in the line voltage appears as a 0.001 percent variation of output at 600 volts and as 0.005 percent at 2200 volts, with internal resistances of 1 and 4 ohms respectively at these outputs.

The reference voltage of 250 volts, the heater current for control tubes 2V1, 2V2, and 2V3, and the other necessary voltages are obtained from the appropriate places in the magnet power supply (*C*, *D*, *A*, and *B*). The thermal time delay relay 2S3 protects the cathodes of 2V4 and 2V5.

THE ELECTRON EMISSION REGULATOR

The emission regulator circuit as shown in Fig. 3 consists of two parts. One part is a power supply similar to the one used in the magnet circuit. Since the requirements for this power supply are less critical than the one used for furnishing current to the magnet windings, the plate supply voltage for the amplifier tube (3V12) is obtained from the unregulated direct current from the rectifiers. This power supply provides the electron accelerating voltage and the trap voltage in the ion source.

Regulation of electron emission of the filament in the source is accomplished by the second part of the emission regulator. Electron emission currents from the filament in the ion source flows through resistors 3R10 and 3P2 and the resulting voltage drop is amplified and applied to the grid of a series control tube (3V14) which

controls the current flowing through the primary of transformers 3T4 and 3T5. The secondaries of these transformers supply the current to the filament in the mass spectrometer. Tube 3V13 serves to maintain proper wave form of the primary current. The controlled range of electron emission from the filament in the mass spectrometer extends from 100 to 500 microamperes depending upon the setting of 3P2. A 1 percent change in line voltage input results in a 0.02 percent change in average emission. Switch 3S5 is a three-position switch

which allows meter 3M2 to read either trap current, total emission current or to indicate the zero adjustment of 3P6 so that meter 3M1 reads electron accelerating voltage.

ION CURRENT AMPLIFICATION

Essentially the same amplifier design as described by Nier was used initially in this research. A stable d.c. amplifier is obtained by using our previously described power supply and by using the tubes described in Fig. 4. To allow collection of currents of approximately 3.7×10^{-9} and 1.5×10^{-11} ampere for masses 44 and 46 respectively, and to get sensitivity of 0.2 permil in determining the ratio of mass 46 to mass 44, the respective sizes of the resistors 4R1 of the two amplifiers must be approximately 1.5×10^{10} and 1.5×10^{11} ohms.

Since the inherent difficulties present in sensitive d.c. amplifiers did not permit day to day use of the mass spectrometers for analyses with the accuracy required in this research, a different amplification system was tried. A vibrating reed electrometer with its associated amplifier in conjunction with a null system described by Nier, Ney, and Inghram,[3] where the vibrating reed replaces the FP54 electrometer, gave continuously satisfactory performance.

A schematic diagram of this system is given in Fig. 5.

GAS FEED AND RECORDING POTENTIOMETER

Since the amplifiers always drift with time and have a noise level as high as or higher than the sensitivity required, it is necessary to have a record of the state of balance of the potentials produced by the two peaks being compared, and it is necessary to be able to change from one sample to another very rapidly.

Two complete feed systems with gas volumes, mercury leveling reservoirs, and capillary leaks of the type previously described by Nier were attached to the mass spectrometer through a magnetically operated valve which delivered one sample to the mass spectrometer and the other to a waste vacuum line. In this way the flow of the two samples could be reversed rapidly. Since the valve is on the high vacuum side of the leaks there is a very small lag in changing from one sample to the other. The tube leading from the valve to the mass spectrometer must be fairly large in order that the hold up in this region is small. In our instrument the volume of the valve and connecting tube is about 10 cc and the internal diameter and length of the feed tube within the mass spectrometer head are 3 mm and 12 cm, respectively. The greater resistance of a 2-mm I.D. tube considerably increased the time lag. The gases replace each other in a few seconds. The construction of the valve is shown in Fig. 6. The memory effect of each gas is small and hence when samples of nearly identical composition (differing by, say, 5 permil in the ratio) are compared, this effect is insignificant. However, if samples of substantially different isotopic composition are used, say differing by a few percent in the ratio, then some minutes must elapse before steady conditions are established. If carbon dioxide containing oxygen of double the normal concentration or higher is used, the

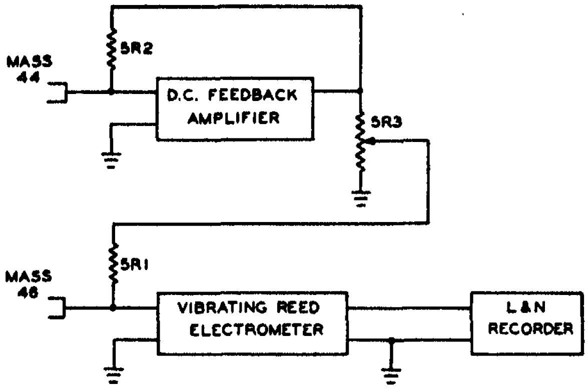

FIG. 5. Parts list for ion beam balancing circuit. 5R1—1.5×10¹¹ ohms, Victoreen Hi-Megohm resistor. 5R2—1.5×10¹⁰ ohms, Victoreen Hi-Megohm resistor. 5R3—Put and take decade resistance potentiometer, made up of General Radio decade resistance units 510A, 510B, 510C, 510D and 510E. Vibrating reed electrometer—obtained from The Applied Physics Corporation, 30 West Green Street, Pasadena, California. D. c. feedback amplifier—as shown in Fig. 4.

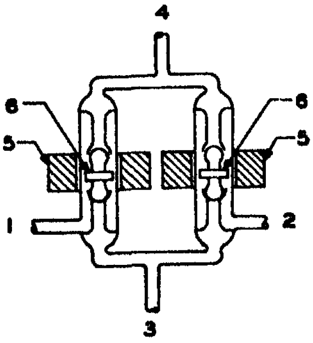
feed system that contained the concentrated gas will contaminate succeeding samples so that analysis to high precision, i.e., differences of the order of 0.2 permil in the ratio, cannot be made until the apparatus has been pumped and swept out for many days.

It is not possible to judge the steadiness of the balance of the two potentials by watching a galvanometer when it is desired to detect differences of the order of the unsteadiness of the potentials being observed. The galvanometer fluctuates unsteadily, and whether the mean has any reliable meaning cannot be judged. The recording potentiometer makes a trace which can be averaged over a satisfactory period of time.

We have used recording potentiometers to observe the balance between the potentials of the two peaks. The recorder draws an irregular line down the chart with negligible drift (if the instrument is in proper adjustment). If erratic fluctuations occur the instrument is unreliable. Of course, if the small but statistically regular fluctuations are too great the precision desired cannot be secured. By observing the record for some time it is possible to judge the stability of the amplifier circuits particularly as well as the mass spectrometer as a whole, and thus decide whether analyses can be made.

FIG. 6. Valve for reversing samples. 1, inlet for sample 1; 2, inlet for sample 2; 3, outlet to waste vacuum; 4, outlet to mass spectrometer; 5, coil windings; 6, soft iron washer on glass valve.



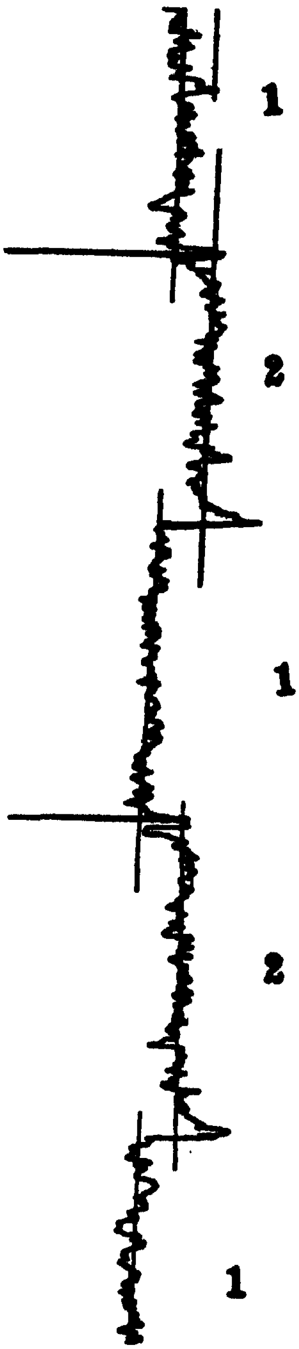


FIG. 7. Sample potentiometer record.

The use of the recording potentiometers is essential to securing differences to a precision of 0.2 permil of the oxygen isotope ratio.

The type of traces obtained are shown in Fig. 7, where trace 2 represents the null point of the standard and trace 1 represents the deviation from the null point by an increase of 0.63 permil in the intensity of ion beam of mass 46. If the deviation from the null point was large, part of the increase or decrease in mass 46 was taken up by changing the setting on the decade resistor system. Straight lines are drawn through the irregular

curves and extended to the point where the samples were changed and the differences are read at these points. The displacement on the chart is easily calibrated in terms of the dial settings in the resistance panel. The average of some five or seven readings is then used to correct the ratio read from the resistances.

CONCLUSION

Two instruments of this type have been constructed and operated, one for 18 months, the other for 6 months. At present electronics technicians can keep the instruments in operation from 50 to 75 percent of the time. The analyses are made by laboratory technicians. Altogether some two thousand high precision comparisons of oxygen isotopic abundances in carbon dioxide, some hundreds of carbon abundances in the same gas, and perhaps a hundred comparisons of oxygen isotopes in oxygen gas have been made with these instruments. Examples of check analyses are given in Table I. The recorded figures are the differences in permils of the normal ratios between the sample and the standard working gas, i.e.,

$$\delta=\left(\frac{R_{\text{sample}}}{R_{\text{standard}}}-1\right)1000,$$

where R_{sample} and R_{standard} are the ratios of $CO^{16}O^{18}$ to CO_2^{16} for the unknown sample and reference gas respectively. These examples of analysis on carbon dioxide are taken from our working notebooks and are a group of consecutive duplicate analyses selected at random and with no omission of any results. These duplicate analyses are on different preparations of the gas from the same samples of calcium carbonate and hence the fluctuations include any variations due to the chemical preparation of the gas. (The calcium carbonate is heated to 475°C for 15 minutes in a stream of pure helium gas and the carbon dioxide liberated by reaction of the carbonate with 100 percent orthophosphoric acid.) Thus the operation of the instrument is at least as reproducible as indicated by these results. On the basis of analyses made before the vibrating reed amplifier was adapted to the instrument, we believe that variations greater than 0.2 permil are due to variations introduced by the method of preparing the gas, a subject which will be discussed elsewhere.

The first example of the oxygen gas analyses is for two preparations from a silicate rock. The last three examples are all for tank oxygen. The most recent of our analyses are given here since they represent the precision we have been able to attain in our most recent work. It is expected that this precision will be maintained and in fact improved in the future as we acquire more experience in these analyses.

Vacuum Tests of Rubber, Lead, and Teflon Gaskets and Vinyl Acetate Joints

ROBERT W. CLOUD AND SANBORN F. PHILP
Massachusetts Institute of Technology, Cambridge, Massachusetts

(Received April 10, 1950)

Rubber, Teflon, and vinyl acetate sealed systems are compared, by an approximately quantitative method, with a lead gasket sealed system which is shown to give off negligible gas at room temperature. Rubber is shown to evolve relatively large amounts of gas with an apparent vapor pressure above a micron at room temperature and about 0.1 micron at liquid air temperature. Continuous pumping for several days produces no improvement, nor does the use of metal-to-metal joints. Vinyl acetate joints are shown to improve with pumping over a period of several days, reaching a condition exhibiting an "apparent vapor pressure" of 5×10^{-7} mm of mercury, or less, at room temperature. Heating to 45°C raises the apparent vapor pressure to the 10^{-4} mm range, and heating to 100° raises the apparent vapor pressure to the micron range. If this behavior is caused by the vapor pressure of the vinyl acetate itself, continued baking in vacuum will, of course, produce no improvement.

THE experiments were designed to give a comparison of the amount of gas evolved in vacuum as a result of using rubber, lead, and Teflon gaskets and vinyl acetate in the typical application of sealing flanges in a vacuum chamber. Gas evolved in vacuum must arise from the evaporation of the vacuum materials themselves or from the desorption of gas previously occluded by the materials. The former are, of course, "condensable" gases, whereas the latter are not necessarily so. Attempt was made in each case (except that of Teflon) to determine if condensable gases were present to an important degree.

The apparatus consisted of an aluminum vacuum chamber (Fig. 1) of approximately ½ liter volume having two side ports covered by aluminum flanges and a steel flange to which was mounted a valve closing the chamber from the vacuum pump. To the side port flange was attached a glass ionization gauge. The pump was a D.P.I. MHG 50.02 pump (mercury) with a trap consisting of concentric stainless steel cylinders 15 cm and 11 cm by 60 cm. The pumping speed to the vacuum chamber was measured to be 25 liters per second (flat from about 5×10^{-6} to 10^{-4} mm of mercury).

The experimental procedure was to close the valve and observe the pressure (measured with an HK-54 used as an ionization gauge) as a function of time after closing the valve. The slope of the pressure-time curve and the known volume of the chamber may be multiplied to give a rate of gas evolution in mm-liters/sec. It is the initial rate of gas evolution calculated in this way and the equilibrium pressure of the system with the chamber valve open which constitute the basis for comparison of the materials studied.

Figure 2 shows pressure-time curves for various stated materials used to seal the vacuum chamber. "Metal-to-metal joints" refers to flanges specially designed to provide as much metal-to-metal surface between the system and the gasket as possible, thus giving a low pumping speed from the gasket to the system. In this case the metal-to-metal joints were as

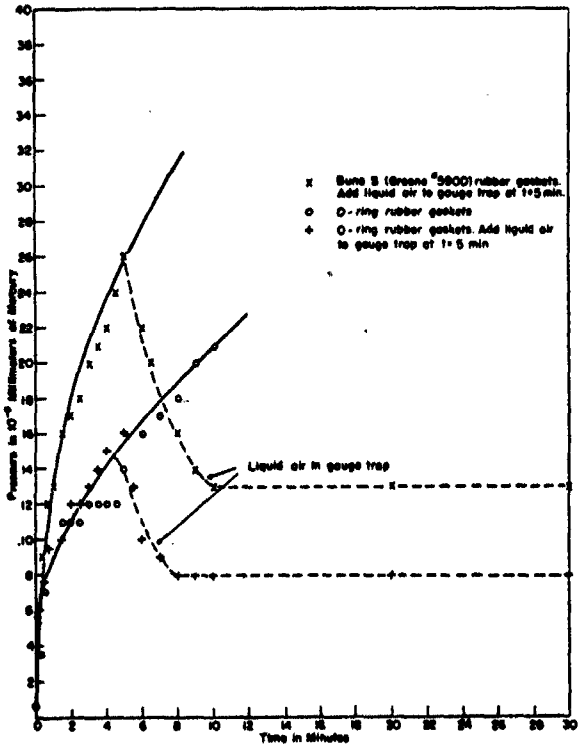

FIG. 3. Pressure as a function of time after closing valve. Chamber equipped with rubber gaskets in metal-to-metal joints (a graph).

shown in Fig. 1. In view of the inaccuracies involved, chiefly due to (1) the use of an ionization gauge and (2) the fact that the system had to be opened to the atmosphere to install each different gasket material, differences such as those which appear to exist between rubber gaskets with and without metal-to-metal joints, and between lead gaskets and vinyl acetate joints, must be regarded as insignificant. An ionization gauge reading constitutes a measure of the over-all ionization probability of the atmosphere in which the gauge is operating. It is therefore by no means an absolute measurement of pressure, although probably an effective measure of vacuum insulating strength. Furthermore, the gauge has a tendency to clean up the vacuum, as is well known. Dushman suggests that the plate collector voltage be applied only as necessary to make readings and thereby minimize the clean-up effect. This procedure was tried with both plate and grid voltages, and readings were found to be roughly 20 percent and 70 percent higher, respectively, than in the case of continuously applied voltages—a correction which is not particularly significant for this experiment. Still another effect of the ionization gauge involves the decomposition of large, complex molecules which come in contact with the filament. This could have an important effect in the case of an organic vapor from vinyl acetate. In an attempt to detect a variation in readings due to the gauge, two gauges were used to measure pressure in the chamber with the bellows coated with vinyl acetate.

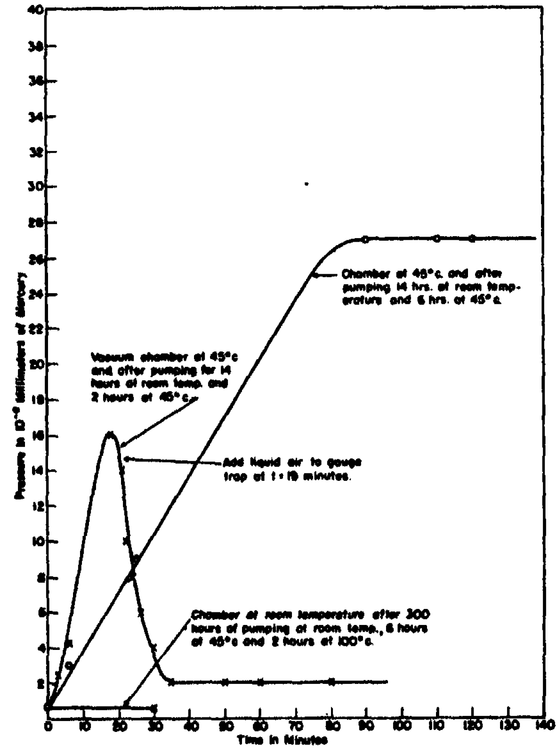

FIG. 4. Pressure as a function of time after closing valve (all joints sealed with vinyl acetate) (a graph).

(chamber at 45°C)	14+6 at 45°						2×10^{-8}
Vinyl acetate (chamber at 100°C)	14+6 at 45°	1.8×10^{-6}		$>10^{-3}$	$>10^{-3}$	2×10^{-6}	5×10^{-7}

Presumably any variation would be magnified by the second gauge. While pumping on the chamber, each gauge reading was independent of whether the other was off or on. With the valve shut and the pressure rising in the chamber, however, results were rather inconclusive since the second gauge seemed to be "gassy." Nevertheless, readings with the second gauge were unaffected by the first gauge, which seems to indicate that decomposition effects, if any, do not seriously affect the results.

Figure 3 shows results obtained by adding liquid air to a trap located between the ionization gauge and the vacuum chamber (referred to in the graphs as the "gauge trap") a stated time after closing the valve. After addition of liquid air to the trap, a marked decrease in pressure followed by a constant pressure would seem to indicate the presence of a vapor whose vapor pressure at liquid air temperature is approximately equal to, or less than, the constant pressure obtained by condensing the vapor in the trap.

Figure 4, which shows results for the vinyl acetate sealed chamber at room temperature, 45°C, and 100°C, indicates that the gas evolved at these temperatures is likewise almost entirely vapor from the vinyl acetate. The curve for vinyl acetate joints at 45°C rises to 2.7×10^{-5} mm, and then becomes constant, apparently indicating that the vapor pressure of vinyl acetate must be of this order of magnitude at 45°C.*

Measurements were also made with a vinyl acetate covered sylphon. This exposed an area of approximately 127 cm² of vinyl acetate to the system. The equilibrium pressure (lead gaskets, liquid air in high vacuum trap) was 7×10^{-7} mm, and the rate of gas evolution 7.5×10^{-8} mm-liters/sec. after 60 hours of pumping. Generally speaking, it required two or three days of pumping on vinyl acetate to obtain a vacuum in the 10^{-7} range.

Table I summarizes the results giving comparative equilibrium pressures, "apparent vapor pressures" (i.e., the equilibrium pressures obtained in the chamber with the valve closed and under stated conditions), and the approximate initial rate of pressure rise.

Apparent differences between results which differ by no more than a factor of two are probably insignificant, and any comparison of results which differ by less than an order of magnitude must not be taken too seriously.

A leak in the vacuum chamber or in the valve which shuts the chamber off from the pump could introduce severe errors into the results. A VEECO helium leak detector was used to test the soundness of the vacuum chamber and other joints throughout the system. The tightness of the valve was checked in the following way: The chamber valve was closed and then the diffusion pump heaters turned off and the pump boiler allowed to cool. (The pump stalls in 3 to 5 min. after turning off the heaters.) The pressure on the pump side of the valve thus becomes considerably higher than in the case of leaving the diffusion pump on. The pressure-time curve taken under these circumstances was compared with readings taken closing the valve with the pump left operating during the time when the valve was shut. No significant differences were found, and its was therefore concluded that leakage through the valve was too small to affect the results.

ACKNOWLEDGMENT

This work was assisted by the joint program of the ONR and AEC.

---

* Vinyl acetate AYAT (the most highly polymerized variety commercially supplied by the Bakelite Corporation) was used for these joints, the method of application being (1) to heat the parts to be joined in 150°C and melt the solid vinyl acetate stick on to the mating surfaces, or (2) to apply a solution of one part of vinyl acetate in 10 parts of toluene by weight to the surfaces to be joined. The coating is allowed to dry, and the parts are then heated to 150°C for about ½ hour to eliminate the toluene. In either case the seal is made by raising the temperature of the abutting surfaces to 150°C. At this temperature, vinyl acetate is very plastic, and the parts must be kept clamped or bolted together until it is cool.

Boron Trifluoride Proportional Counters

I. L. Fowler and P. R. Tunnicliffe*
National Research Council of Canada, Atomic Energy Project, Chalk River, Ontario

(Received May 4, 1950)

Boron trifluoride proportional counters of calculable efficiency for neutron beam measurements are described. It has been found possible to obtain excellent pulse-size distributions with a filling of 60 cm of purified BF_3 by "soaking" the counters for a long time (up to three months) with BF_3 before putting in the final filling. These fillings are stable. Fillings of less than 5 cm BF_3 made up to 50 cm with argon have also been studied. With these fillings the pulse-size distributions are very good for both beam and total irradiation conditions. A discussion of the counter efficiencies with particular reference to end correction is given.

I. INTRODUCTION

THE detection of slow neutrons by the exothermic reaction, ${}_0n^1+{}_5B^{10}\rightarrow{}_3Li^7+{}_2He^4$ is well known, and counters filled with boron trifluoride have long been used for this purpose.[1] The principal requirements of a neutron counter are (a) that the pulses be of uniform size to enable the efficiency to be calculated, and (b) that the sensitivity be as high as possible. In counters containing a low pressure of BF_3 the distribution of pulse sizes is sufficiently good for the number of boron disintegrations in the sensitive volume to be accurately counted. Thus "low pressure" counters can satisfy requirement (a). To satisfy requirement (b) as well, a high pressure of BF_3 is necessary, but until recently counters containing more than 20 cm Hg pressure of BF_3 have given unsatisfactory pulse-size distributions because of electron capture. Work by Steljes and Hudswell[2] at Chalk River had suggested that it was possible to prepare samples of gas, on occasion, but not reproducibly, in which electron capture was markedly reduced. For this reason the technique of filling BF_3 counters to near atmospheric pressure was pursued. The results obtained are in agreement with experimental work by Bistline[3] on electron capture in BF_3 which indicated that it should be possible to make satisfactory counters filled to near atmospheric pressure.

It has been found that the counters must be aged with a temporary filling of BF_3, for a period of up to three months for the high pressure type, before the final filling is inserted. The results on high pressure fillings have been obtained on a rather small number of counters because of this long time required in the experiments. However, publication of the results to date is felt to be justified.

The counters are intended principally for applications where a neutron beam is directed axially down the counter. The beam is admitted by a thin copper window at one end. The high pressure counter is filled to 60 cm Hg pressure, with BF_3 enriched to 96 percent in B^{10}, and shows good pulse distributions when used in applications where the neutron beam is less than one inch in diameter. The low pressure counter is filled with not more than 5 cm Hg pressure of BF_3 together with sufficient argon to bring the total pressure to about 50 cm and shows excellent pulse distributions under both beam and total irradiation conditions.

II. CONSTRUCTION

Details of the counter construction are shown in Fig. 1. The outer shell (a), which is also the cathode, is a seamless copper tube 25 in. long, 2½ in. outside diameter, with a wall thickness of 0.081 in. The threaded brass end cap (b) carries the copper-glass seal (c) which serves as an insulator for the anode lead (d). The pumping tube is attached to the copper-glass seal. A window (e) of 0.010-in. thick copper is soldered to the other end of the tube. The anode wire (f) is 0.002-in. diameter tungsten, which, at the window end, is wrapped around a heavier tungsten wire (g) and both are sealed into the end of a 3-mm diameter "Nonex" glass tube (h). A nickel tube 0.060 in. diameter (j) is assembled over the anode wire and held in the tube (h), when the seal is made (the nickel tube is held mechanically rather than sealed). A short length of 0.030-in. diameter tungsten wire (k) is sealed into the other end of the glass tube (h), and this wire is then soldered into a further short length of nickel tube (l). The nickel tube (l) is soldered to the center of the window (e) to give a sound mechanical joint and the solder is prevented from spreading over the surface of the window. The other end of the anode wire is soldered to a tungsten tension spring (m) which is attached to a heavier tungsten lead (n) sealed into the end of the glass tube (o). The nickel tube (j) and the glass tube (o) serve to define the counting volume.

All soldered joints are made with a silver solder containing no cadmium.†

After assembly the counters are thoroughly cleaned using dilute sulfuric and chromic acids. It is most important to remove all traces of the borax soldering flux. Many washings of distilled water complete the cleaning.

Following the cleaning the counters are pumped dry with gentle heat applied and then sealed on to the filling system as soon as possible. When refilling is required, a break seal combination is used to reconnect the counters to the system.

The boron trifluoride is prepared from calcium fluoborate (a boron trifluoride-calcium fluoride complex) in a similar manner to methods already described.[3–5] The complex contains boron enriched to 96 percent of the B^{10} isotope.‡ Details of the filling apparatus and procedure are given in the Appendix.

After filling and initial test, the high pressure counters are allowed to stand for a period of up to three months. They are then reconnected to the system by means of the break seal, the initial filling is taken out, and, without further baking, the final filling inserted.

This double filling procedure with a long "soak period" in between has been found necessary due to rapid deterioration of the pulse-distribution characteristics of the high pressure counters following initial filling. It is suggested that chemical action following the initial filling produces gas with strong electron attachment properties. If a trace of water vapor is left in the counter, its action on the boron trifluoride can produce hydrogen fluoride. This will react with the silica in the glass to produce silicon tetrafluoride and water. Traces of silicon tetrafluoride have been detected in a sample of a counter filling gas by mass spectrometer analysis.

It would thus appear that in spite of extreme care in outgassing the counters and trapping of water vapor in the filling system, a trace may still be left in the counter sufficient to cause marked deterioration.

It seems possible, therefore, that "soaking" produces a wall layer which effectively prevents, or slows down very considerably, the continued production of silicon tetrafluoride following refilling.

III. METHOD OF TESTING

A preamplifier is mounted directly on to the end of the counter, and is followed by an amplifier with adjustable time constants, giving a total gain of 8000. High voltage to the central wire is supplied through a 10-MΩ resistor and the input time constant to the head amplifier is 100 μsec. The amplifier time constants are adjusted to give a pulse rise time of about 0.2 μsec. and a differentiating time as required. The counter shell is grounded. The high voltage is adjusted so that the maximum pulse size from the amplifier is about 80 volts, corresponding to a gas multiplication of approximately 20 for the low pressure counters.

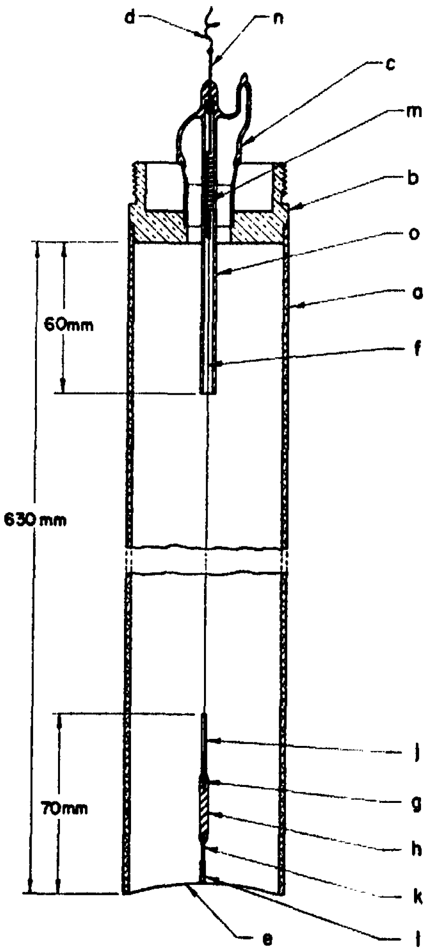

FIG. 1. Details of neutron counter construction.

The pulse distribution is measured with the aid of the 30-channel pulse analyzer described by Westcott and Hanna.[6] The counters are tested using either a well-collimated beam of thermal neutrons from the

IV. RESULTS AND DISCUSSION

A. Low Pressure Counters

Typical pulse-size distributions for a counter containing 1 cm BF_3 and 47 cm argon tested with a 1-in. diameter neutron beam parallel to the anode are shown in Fig. 2. For a differentiating time constant of 1.6 μsec. (curve a), the pulses are confined mainly to two narrow peaks which correspond to the formation of Li^7 in the excited and ground states. The relative positions and intensities are consistent with a recent determination in this laboratory.[7] The broadening of the peak when the differentiating time constant is reduced to 0.16 μsec. (curve b) indicates that the pulse rise time is of the order of 0.5 μsec. and it is consistent with the expected rate of electron collection. The uniform distribution of small pulses in curve (a) is attributed to boron disintegrations occurring near the ends of the sensitive volume.

Figure 3 shows the pulse distribution given by the same counter as in Fig. 2 under total irradiation conditions. The distribution is similar but the number of small pulses is greater, due to disintegrations occurring near the wall.

B. High Pressure Counters

High pressure counters (60 cm BF_3) are poor and unstable if they are inadequately "soaked" with BF_3. This is illustrated in Fig. 4. The pulse distributions shown were taken using a neutron beam, (a) just after filling and (b) several weeks later. It will be seen that the distribution peak was initially very broad, and soon deteriorated until there was no sign of a peak at all.

Figure 5 shows similar results after the counter had been "soaked" at only 1 cm pressure for three months and then refilled to high pressure. It will be noted that the distribution is much better and the deterioration not so marked.

Figure 6 shows the pulse distribution given by a counter "soaked" at 60 cm pressure of BF_3 for three months and then refilled to the same pressure. No evidence of deterioration has been noted for a period of three months.

Figures 7 and 8 show the properties of this counter under different irradiation conditions. In Fig. 7 the neutron beam was reduced from 1 to ⅜ in. in diameter resulting in a marked narrowing of the pulse-distribution peak. Figure 8 shows the results obtained for total volume irradiation of the same counter at various amplifier differentiating time constants. It will be seen

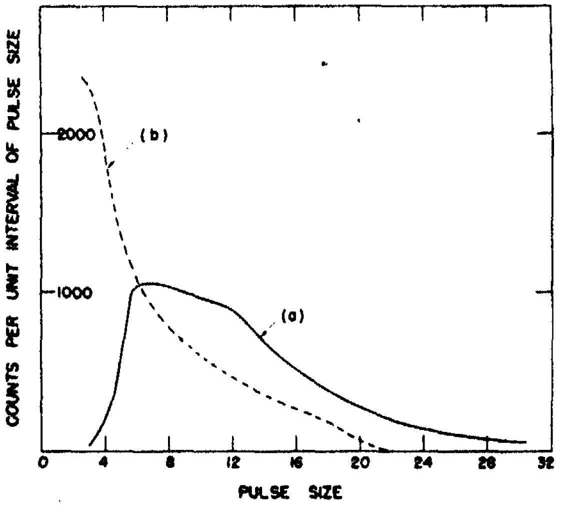

FIG. 4. Pulse distribution of a high pressure BF_3 counter (66.3 cm BF_3), 1-in. diameter neutron beam, H.T. = 3200 v. (a) Immediately after first filling. (b) Several weeks after filling.

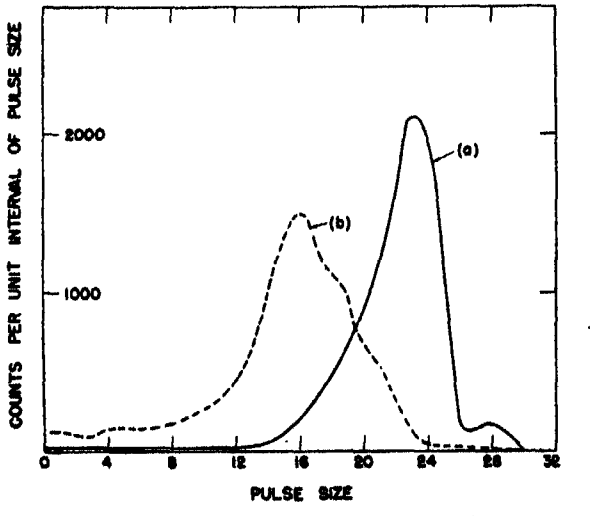

FIG. 5. Pulse distribution of a high pressure BF_3 counter (58.7 cm BF_3), 1-in. diameter neutron beam, H.T. = 2200 v, "soaked" for 3 months at 1 cm pressure BF_3. (a) Immediately after refilling. (b) Three weeks later.

---

[7] G. C. Hanna (private communication).

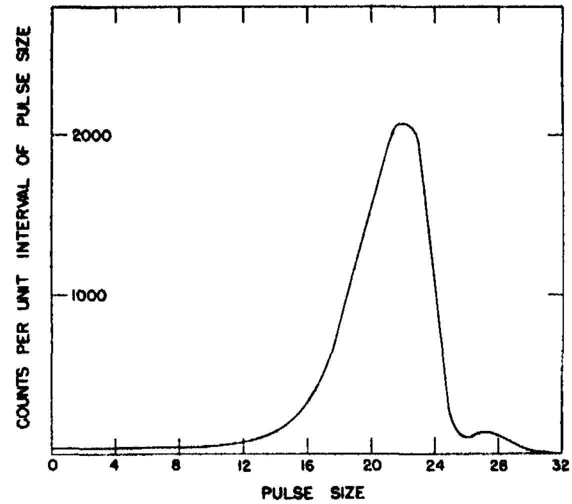

FIG. 6. Pulse distribution of a high pressure BF_3 counter (60.3 cm BF_3), H.T. = 2520 v, 1-in. diameter neutron beam, "soaked" for 3 months at 60 cm pressure BF_3, after refilling.

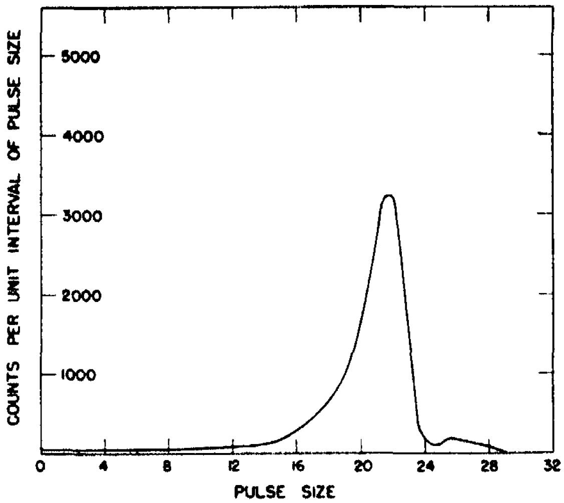

FIG. 7. The same as Fig. 6 using a ⅜-in. diameter neutron beam, H.T. = 2520 v.

that the distribution is very broad and that the maximum pulse size is markedly reduced if the differentiating time constant is reduced below 3 μsec. The broad peak and the effect of differentiation are in general agreement with the results of Bistline[3] for the mean free drift distance and drift velocity respectively of the electrons at ratios of field to pressure which exist near the counter wall. This effect is attributed to those boron disintegrations which occur within 1 cm of the counter wall.

These counters are very satisfactory for the requirements of most beam experiments, but consideration is being given to means of purifying the gas further and raising the field to pressure ratios near the wall. It is expected thereby to improve the pulse distribution under total irradiation conditions, and there is some recent evidence that increased gas purity alone may effect this. It is also considered likely that the minimum "soak" period necessary to produce satisfactory stable counters may be much less than three months with certain precautions, and this is being investigated further.

C. The Counter Efficiencies

Direct calculation of the counter efficiencies using the known boron cross section cannot be made owing to uncertainties introduced by end effects. Disintegrations occurring just within the sensitive volume can send particles into the insensitive end space, and disintegrations occurring in the insensitive end space just outside the sensitive volume can project particles into the sensitive volume. Both types of boundary disintegrations will produce small pulses and the fraction of these which is counted depends on the bias setting. In an ideal counter where the ends of the sensitive volume are so defined that there is no disturbance of the electric field distribution at the ends of the anode wire, it can readily be shown that a pulse distribution would be obtained consisting of a narrow peak together with a number of smaller pulses uniformly distributed from the peak down to zero size. This applies in the case of the boron disintegrations when there are two particles and assumes that the ionization along the tracks of the disintegration particles is uniform. It can also be readily shown in such an ideal counter that if the counting circuit discriminator bias is set at a value equal to half the pulse size in the peak the counting rate will be the same as if it were assumed that every disintegration occurring in the sensitive volume gave a pulse of uniform size, i.e., that no ionization was lost at the ends of the sensitive volume. This is still true when the variation of specific ionization with particle energy is taken into account. However, as shown previously, the pulse-distribution curve has two peaks, corresponding to the formation of Li^7 in the excited and ground states,

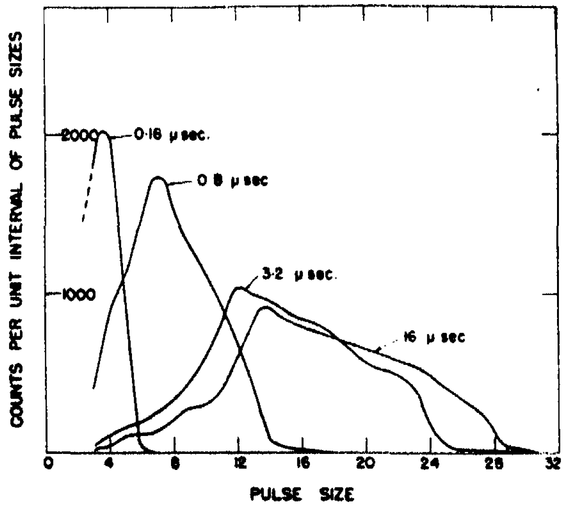

FIG. 8. The same counter as Figs. 6 and 7 but showing pulse distributions under total irradiation conditions showing the effect of various differentiating time constants 0.16, 0.8, 3.2, and 16 μsec., H.T. = 2520 v.

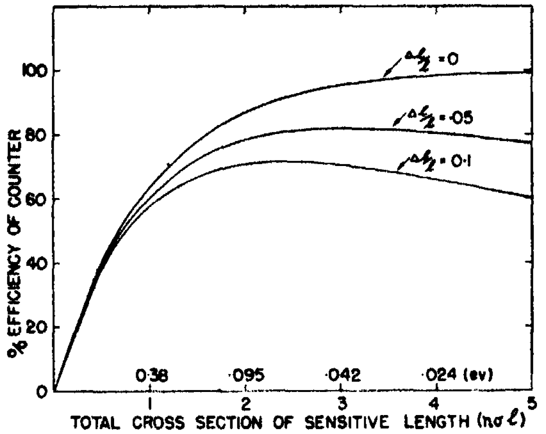

FIG. 9. Efficiency curves of BF_3 counter against total cross section of sensitive length for axial beam irradiation at various ratios of end space Δl to anode length l.

so that the discriminator bias setting for zero end correction in the ideal counter is slightly greater than one-half the pulse size of the main peak.

Ideal conditions as indicated above might be approached by mounting guard rings at the ends of the counter wire, with the potential so adjusted that there is little disturbance of the field. However, for simplicity of construction an attempt has been made to define the sensitive volume by means of the nickel tube (j) (see Fig. 1) and the glass sleeve (o). It is certain that the nickel tube has the effect of making the effective length of the counter less than the geometrical length of the exposed wire, by disturbance of the field. On the other hand, at least some of the ionization occurring in the volume nominally screened by the glass sleeve may be collected by the wire and therefore effectively increase the length. The magnitude of this latter effect will depend on the insulating properties of the glass and the amount of ionization in this region.

The behaviors of the high and low pressure counters as regards end effects are somewhat different and are discussed separately. The discussion is limited to beam applications where there is no wall effect and, in the case of the high pressure type, to beams of small diameter so that the pulse distribution approaches the ideal shape.

1. *Low Pressure Counters*

If the self-absorption of the counters can be neglected, a determination of the efficiency is in principle relatively simple. If two counters of different sensitive lengths but of otherwise identical construction and filling are successively placed in the same neutron beam and the counting rates obtained under identical operating conditions, the difference of these counting rates will represent the counting rate in an ideal counter whose length is equal to the difference between the geometrical lengths of the sensitive volumes of the two counters. The efficiency of such a counter can be calculated. The pulses from this ideal counter will all lie in the pulse-distribution peak. The effective length of one of the counters can then be found (under the given operating conditions) by comparing its counting rate with that of the "ideal" counter.

In practice the counters are not ideally thin and therefore allowance must be made for the self-absorption of the neutron beam. If this is done, the total correction to the geometrical length of the counters due to end effects may be written as

$$\delta l \approx \frac{C_2(l_1 - al_1^2/2) - C_1(l_2 - al_2^2/2)}{C_1(1 - al_2) - C_2(1 - al_1)},$$

where l_1 and l_2 are the geometrical lengths, C_1 and C_2 are the counting rates in the two counters, and $a = n\sigma$, where n = number of B^{10} atoms/cc and σ = the boron cross section.

The value of δl is of course a function of the operating conditions, in particular the setting of the discriminator bias. Two simple conditions may be chosen. The common method of extrapolation of counting rate to zero pulse size, either by means of a bias curve or a pulse-distribution curve, may be used; or the simpler condition of setting the discriminator bias at a value equivalent to half that for the distribution peak. In practice some bias must always be used to avoid spurious counts due to gamma-rays and amplifier noise.

Measurements were made using two counters of identical construction except that l_1 was equal to twice l_2. These were filled simultaneously so that the fillings would also be closely identical.

There are considerable practical difficulties in making the measurement, from fluctuations of neutron beam intensity, difficulty of accurate positioning of the counters, counting statistics, and consistency of the two fillings. The effective length was found to be within two percent of the geometrical length of the standard counter (500 mm). Further work would be required to assess the effects of the two ends separately.

For efficiency calculations it is also necessary that a sample of the filling gas be taken at the time the counters are filled for analysis on the mass spectrometer since the repeated distillations during the filling process may change the isotopic proportions slightly. In addition, the filling pressure must be measured accurately and corrections amounting to a few percent made for scattering and absorption in the window, the gas in the end space, and the glass bead supporting the anode wire.

With all these precautions, the efficiencies of the counters at a given neutron energy are calculable to an accuracy of a few percent. These low pressure counters are intended for applications where high efficiency is not necessary and they are easier to fill than the high pressure type.

2. *High Pressure Counters*

The efficiency of high pressure counters can be calculated in applications where the neutron beam is sufficiently small in diameter to yield a narrow pulse distribution. The inactive region at the window end has a marked effect on the efficiency which can be expressed as:

$$\text{Efficiency} = \exp(-n\sigma\Delta l)[1-\exp(-n\sigma l)],$$

where l = measured length of anode, n = number of B^{10} atoms/cc, σ = cross section of B^{10}, and Δl = length of inactive region at the window end. ($\Delta l/l \approx 0.1$ for the counters described.)

With the geometry and filling of these counters the efficiency is practically independent of $n\sigma l$ (the total cross section/cm² of the sensitive length) over the energy region of 0.03 to 0.1 ev. This is apparent from Fig. 9 which gives counter efficiency curves against values of $n\sigma l$ for various ratios of $\Delta l/l$.

The geometrical value of Δl is readily determined during construction. Its effective value is, however, sensitive to the end effects in the counter in the same way as the counter length. Since these counters are almost completely absorbing at near thermal neutron energies, the only important end effects will occur at the window end. Δl is a function of the bias, but if it is assumed that the nickel sleeve behaves ideally and the discriminator bias is set at the half-value point as discussed, the value of Δl will be the geometrical value. Under these assumptions the uncertainty in Δl will probably not be more than five percent leading to a much smaller error (one percent) in the calculated efficiency.

Thode of the Chemistry Department of McMaster University for mass spectrometer analyses of samples of counter filling.

APPENDIX. FILLING PROCEDURE

A diagram of the filling apparatus is shown in Fig. 10. The complex is contained in a flask surrounded by a small thermostatically controlled oven. Initially it is heated to 100°C under vacuum for approximately 48 hr. to remove water vapor, with dry ice surrounding trap 2, and liquid air surrounding trap 5. Little BF_3 is lost in this process and the vacuum is maintained at better than 10^{-8} mm Hg. The complex is then allowed to cool to room temperature while pumping is continued to as good a vacuum as possible before tap 1 is turned off and traps 2 and 5 removed for cleaning. Thereafter the counter filling procedure for high pressure counters is as follows.

1. The counter is sealed on, evacuated, and checked for leaks. (Liquid air surrounds trap 5 since a mercury vapor pump is used.)

2. The counter is flame baked to approximately 500°C for at least 45 min. or until the outgassing is considered complete as evidenced by the pressure while still hot. (Flame baking is used solely for convenience owing to certain physical difficulties of assembly and removal of an oven with the present set-up.)

3. Pumping is continued until a vacuum of 10^{-6} mm Hg is reached with the counter cooled to room temperature. The counter is then turned off.

4. Tap 1 is turned on, and the complex pumped for a further period of one hour while heated to 100°C.

5. Dry ice is placed around trap 1, and liquid air around trap 2. The complex temperature is raised to 250 to 300°C. The BF_3 distills into trap 2, and when almost all has come off, the complex is allowed to cool and tap 1 is closed.

6. The frozen BF_3 is pumped for 30 min. more or until a satisfactory vacuum is reached. The McLeod gauge is turned off.

7. Tap 3 is closed, trap 2 is allowed to warm up until a few centimeters pressure is recorded on the manometer. At this point tap 2 is closed and the liquid air promptly replaced around trap 2.

8. Tap 3 is slowly opened allowing the small amount of BF_3 in the system to freeze in trap 5. (This first fraction is always rejected.)

9. Tap 2 is opened, the McLeod gauge turned on, the system again pumped down, and the counter opened to the system. When as good a vacuum as possible has been obtained the McLeod gauge is again turned off.

10. Dry ice is put around trap 4, tap 3 is turned off, and then trap 2 is allowed to warm up until the pressure in the system reaches the desired pressure of BF_3. At this point tap 2 is closed and the liquid air replaced around trap 2.

11. Liquid air is placed around trap 3 and, when all the BF_3 has frozen into it, tap 3 is reopened and the system again pumped to a hard vacuum.

12. Tap 3 is again closed, trap 3 is allowed to warm up and the counter thus filled to the required pressure.

13. The counter is sealed off.

14. All remaining BF_3 is then taken over into trap 5 and from thence to storage pending recombination with ether.

The counters are tested shortly after filling and set aside to "soak" for up to three months. This "soak" period appears to be a major factor in obtaining good characteristics without serious deterioration over a period of time. Refilling following the "soak" is to be the same schedule as the original filling, with the omission of step 2.

As mentioned, the foregoing schedule applies to high pressure counters. For low pressure counters the procedure is slightly different as follows.

1 to 4. Same as high pressure schedule.

5. Dry ice is placed around trap 1 and liquid air around trap 2. The complex temperature is raised to 250°C for a short time to collect a small quantity of BF_3 in trap 2. The complex is allowed to cool and tap 1 is closed.

6. Same as high pressure schedule except that counter is opened to the system after 15 min.

7. Tap 3 is closed, trap 2 is allowed to warm up, and BF_3 enters the system and counter at a low pressure. The counter tap is closed and the counter allowed to stand overnight to "soak."

8. The BF_3 in the system is frozen into trap 5 and then taken over for storage.

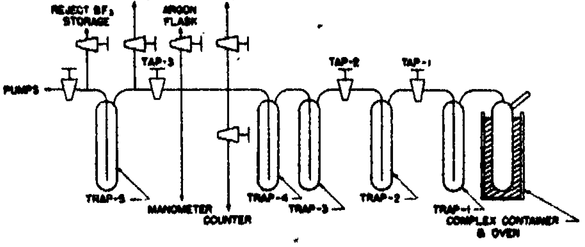

FIG. 10. Diagram of the BF_3 filling apparatus.

9. Next morning the BF$_3$ is pumped out of the counter into trap 5, and the counter pumped down to a hard vacuum.

10 and 11. Same as items 5 and 6 high pressure schedule.

12 to 14. Same as items 10 to 12 high pressure schedule.

15. Argon is admitted to make up to the total pressure to 50 cm. After several hours to allow proper mixing of the gases, the counter is sealed off.

16. Same as item 14, high pressure schedule.

A gold foil is included in the pumping line to the counter to trap residual mercury vapor. Other than those mentioned in the schedule, no special precautions are taken except those compatible with good vacuum technique. Conventional stopcocks are used and all traps can be taken apart for cleaning. Taps and the trap ground joints are greased sparingly with Apiezon *L* or *M* grease.

The amount of complex required for a given filling is calculated and a little more than this quantity put in the flask. This allows the first and last fractions to be discarded, and since all the BF$_3$ is taken off each time, each filling is comparable.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 8 AUGUST, 1950

The Design of a Magnetic Focusing Coincidence Spectrometer[*]

C. M. Fowler[**] and R. G. Shreffler[†]
Randall Laboratory of Physics, University of Michigan, Ann Arbor, Michigan

(Received April 13, 1950)

Design and operating features are described for a semi-circular magnetic focusing coincidence spectrometer. The primary function of the spectrometer is that of determining whether or not two different radiations from a radioactive sample are in the same branch of the nuclear decay scheme. Although the instrument is designed primarily for studies between conversion electron groups, it is also suitable for studies between conversion groups and beta-spectra.

A feature of the instrument is its extraordinarily good coincidence resolving power. Applications of the spectrometer to two activities are briefly discussed, and an explanation of the high resolving power is given.

1. INTRODUCTION

THE primary function of the magnetic focusing coincidence spectrometer is to determine whether or not two different electron radiations of an active element are in cascade, that is, in the same branch of a decaying nucleus. The electrons may arise from the continuous beta-spectrum of an activity and from conversion electrons. Although no experimental data is offered for the case of photo-electrons, studies could include these as well.

The basic principle of the instrument involves the magnetic focusing of electrons from one of the radiations into one Geiger tube, while those of the other radiation are focused into a second Geiger tube. If the two radiations are in cascade, then a coincidence circuit collecting the inputs of the two Geiger tubes will record true coincidences. If no true coincidences are observed, the radiations are not in cascade.

Fig. 1. Fully assembled coincidence spectrometer.

For decay schemes exhibiting gamma-radiations which are moderately or strongly converted, the spectrometer offers a useful and certain method for properly ordering the radiations. The advantage of the spectrometer over the usual absorption coincidence techniques is that the radiations may be focused and studied in pairs through their conversion electrons, thus leaving no ambiguity as to which of several radiations may be in coincidence.

Feather,[1] as early as 1940, described a coincidence spectrometer designed primarily for coincidence studies between one conversion electron group and a beta-spectrum. Feather, Kyles, and Pringle[2] first reported the results of a specific investigation of this type in 1948.

The spectrometer described here is designed primarily to study coincidences between two conversion electron groups, and as will be shown later, exhibits very high coincidence resolving power. Among other details, it differs from that described by Feather, in that the coincidence radiations focused into the two Geiger tubes both travel through the same portion of the active source, and do not pass through the sample backing. This feature accounts in part for the high resolution of the spectrometer.

Limitations to which the spectrometer is subject include: 1. Only radiations suitably converted may be studied. A rough rule (modified considerably for branched decay schemes) is that the product of the conversion coefficients of the radiations studied should not be appreciably less than 0.001. 2. Only conversion groups which can be focused two or more centimeters apart on the focal plane may be studied as a pair. This is a design limitation arising from the finite widths of the Geiger tubes. This restriction is usually only severe for high energy radiations (greater than 200 kev) or for elements of low atomic number. This is true, since for studies between gamma-radiations of nearly the same energy, by proper adjustment of the magnetic field, one Geiger tube may collect electrons from the K conversion group of one radiation, while the other tube may collect L conversion electrons from the other radiation. 3. Operational times required to build up adequate statistics are frequently quite long. This is an inherent difficulty brought about by large solid angle losses required for focusing. For activities of lifetimes less than a few days, the method becomes unfeasible unless the radiations are highly converted. 4. Two radiations delayed long with respect to the resolving time of the coincidence circuit will not yield appreciable true coincidences. It is therefore necessary to know from other investigations whether or not long delays are present in an activity before it can be assumed that two radiations are not in cascade, when they produce no true coincidences.

2. DESIGN DETAILS OF THE SPECTROMETER

Figure 1 is a photograph of the fully assembled coincidence spectrometer. The assembly consists of a camera, a vacuum system, a magnet, and a recording system. These components are described in the following sections:

The Camera

The design of the camera (scale drawing, Fig. 2) is based upon the principles incorporated in the photographic semi-circular spectrometer. Instead of a photographic plate, two movable Geiger tubes, controllable from outside the camera, open upon the focal plane.

The camera is constructed of $\frac{3}{8}$ in. brass plate. Bronze bolts seat the removable top on a rubber gasket, which in turn is contained in a channel milled around the top edges of the camera sides. When the camera is in proper position between the magnet pole faces, a flanged connection can be coupled to the vacuum line.

A rigid three-sided frame, supporting the sample, slit, and Geiger tube assemblies is mounted upon the camera floor, and secured by set screws. The sample and slit assemblies are shown in the plan view of Fig. 2 The slits are made of Lucite, and can be separated from 0 to 2 centimeters. Provisions are also made to allow variation of the separation of source and slit planes from one to five centimeters.

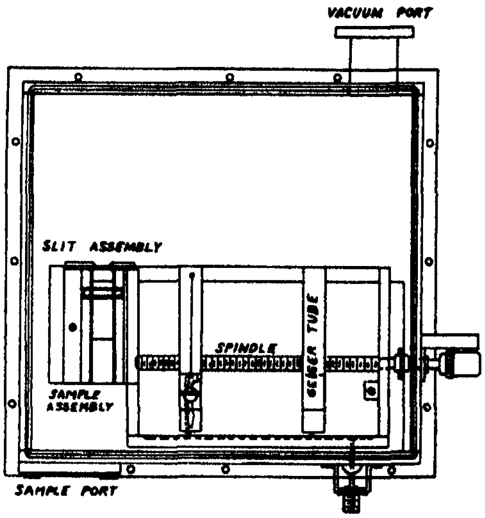

FIG. 2. Camera plan view; scale drawing.

The Geiger tubes are moved by threaded spindles, rotated by control knobs outside the camera. Veeder-Root counters, connected to the spindles, record the positions of the tubes. The control knob assembly can be separated from the drive spindles by uncoupling flanged connections, when it is necessary to remove the frame from the camera. The Geiger tubes receive their anode voltages through spring loaded contact pieces which make contact with copper bar conductors. These conductors are embedded in the Lucite rear wall of the frame. The spring loaded contacts are also mounted in Lucite pieces, which are bolted onto the ends of the Geiger tubes. Soldered to the copper conductor bars in the frame, are female sockets into which covar conductors slide, when the frame is properly placed within the camera. The covar conductors are permanently mounted on the camera, and lead through the camera walls to external amphenol fittings.

A $\frac{1}{32}$ in. celluloid lining, over all interior parts of the camera exposed to radiation, practically eliminates detectable scattering.

The Vacuum System

The vacuum system comprises two stages, a mechanical fore-pump, and a water-cooled, oil diffusion pump. Thermocouple vacuum plug units are installed in the system so that pressures within the camera, and between the two pumps can be read. A manometer, with a double stopcock arrangement, is incorporated into the system so that pressures may be built up slowly when the camera is opened. This procedure avoids undue strains on the Geiger tube windows.

Normal operating pressures of approximately one micron are used. These low pressures minimize electron air scattering and are more than sufficient to prevent the high anode voltages from breaking down within the camera.

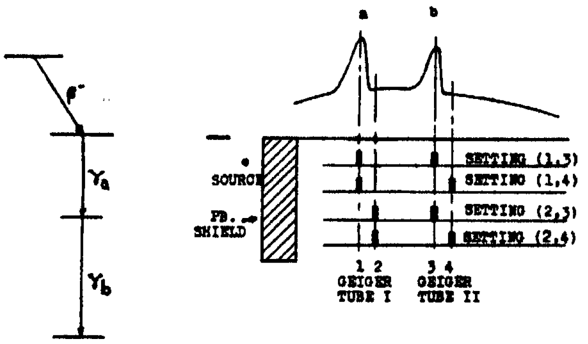

FIG. 3. Sketch illustrating offset method.

The Magnet

The chief property required of the magnet is stability. As will be shown later, the slightest drifting of the magnetic field greatly reduces the effectiveness of the instrument.

The stability required was obtained by butting a large number of Alnico No. 3 cylinders (1 in. $D \times 3$ in.) between the yoke and pole pieces. After establishing a convenient magnetic field, by pulsing current through fixed exciting coils, slight drifts up to one percent occur during the first few hours. After 24 hours, no further detectable changes are observed over periods of months.

By spacing the Alnico cylinders uniformly over the pole faces, except for a small increase in density near the face edges to help compensate for fringing flux, fields uniform out to nearly a half pole-gap width from the face edges may be obtained.

Recording System

Individual Geiger tube pulses are monitored by commercial IDL scalars. Pulses are then sent to a Rossi type coincidence circuit, including a pulse height selector discriminator circuit. Coincidences are recorded by a thyratron driven mechanical recorder. The time constant of the coincidence circuit can be varied by switching in various pairs of different valued grid leak resistors. By suitable choices of the *RC* constant of the Rossi circuit and pulse heights, the over-all circuit resolving time may be varied from 0.2 to 2 μsec.

For the Geiger tubes employed, drift time losses were found to be negligible for resolving times greater than 0.45 μsec.

3. ANALYSIS OF COINCIDENCE DATA

The procedure used in the study of two radiations sometimes varies, but the most useful one usually consists of fixing one Geiger tube at about the peak of one of the electron groups, while the other tube is set at various locations about the other line. A plot of the coincidence rates so obtained *versus* the position of the variable tube gives rise to the coincidence lines shown in Figs. 8, 9, and 10. The most noticeable feature of these lines is their sharpness, as compared to the lines seen when the instrument is operated as an ordinary non-coincidence spectrometer.

Studies to be published later will discuss the application of the spectrometer as a tool to resolve L_{I}, L_{II}, and L_{III} conversion electron groups in a more quantitative manner, as well as its use in distinguishing conversion lines arising from gamma-radiations of almost the same energies.

Observed coincidence rates consist of spurious coincidences and coincidences resulting from cascade radiations of the active isotope. Both require discussion.

Spurious Coincidences

There are two sources of spurious coincidences: accidentals and cosmic-ray coincidences.

Accidental coincidences are subtracted from all observed rates according to the well-known formula, $q_A = 2\tau n_1 n_2$, q_A being the accidental rate, τ the resolving time of the coincidence circuit, n_1 and n_2 the input counting rates entering the coincidence circuit.

Experimental studies showed that, to within the statistical accuracy of the research, hard components of cosmic radiation contributed a coincidence rate depending only upon the Geiger tube separations, the rate decreasing as the separation increases. From each observed coincidence rate, a cosmic-ray rate is thus deducted.

True Coincidences

When the spurious rates have been deducted from the observed rates, the resultant rates represent coincidences arising from nuclear cascade radiations. However, in addition to the coincidence rates sought between conversion electron groups, there exist smaller true coincidence rates between the conversion electrons focused in one Geiger tube, and portions of the continuous beta-spectrum focused in the other tube. Further, if the source shielding (see Fig. 3) is insufficient to absorb all of the lateral gamma-radiation, coincidences between the gamma-ray leakage and both conversion electrons groups and the continuous beta-spectrum will be present.

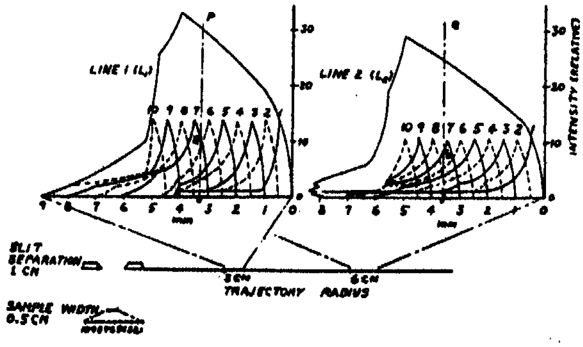

FIG. 4. Contributions of source increments to gross line densities. The number specifying the sample increment also identifies the contribution of this increment to the two gross lines.

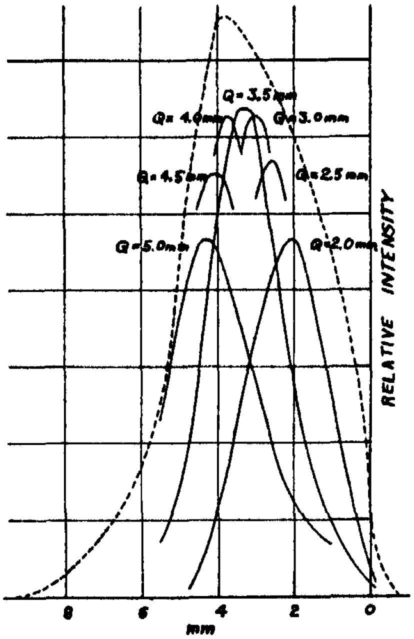

FIG. 5. Effect of fixed Geiger tube location on the shape and position of the coincidence lines. The values of Q given at the peaks of the curves locate the center of the fixed Geiger tube with respect to the leading edge of the gross density curve of line L_2. Geiger tube window widths: 1.5 mm.

The combined rates of all these cross coincidence terms may be eliminated by use of the "offset" method described below, leaving a net rate for the conversion electron coincidences alone.

In Fig. 3, let c_a and c_b represent conversion electron groups, between which coincidence studies are to be made. Suppose the positions 1 and 3 represent arbitrary points, one for each of the lines, at which the Geiger tubes are centered. Points 2 and 4 are offset points, such that the inner edges of the Geiger tube windows just clear the leading edges of the conversion lines. Then the true coincidence rate $Q(1,3)$ for the Geiger tubes centered at points 1 and 3 is given by the following equation:

$$Q(1,3)=q(1,3)-q(1,4)-q(2,3)+q(2,4). \quad (1)$$

The small q's are the coincidence rates for the pairs of settings shown in Fig. 3. These rates are supposedly corrected for spurious coincidences.

Details of the proof for this formula, and its degree of validity are discussed in the Appendix.

4. COINCIDENCE LINE SHARPENING

The high coincidence resolution is a consequence of two effects, one arising from a minimization of source scattering of the electrons (an effect which accounts in considerable part for line broadening in non-coincidence spectrometry, particularly for lower energy radiations) and the other, a so-called natural line sharpening effect.

Both of these effects have as their common source the feature that a true coincidence can result only from electrons leaving the same atom of the source.

That the relatively intense scattered line portion seen in non-coincidence spectrometry is minimized here follows since both electrons forming a possible coincidence traverse about the same portion of the source; thus if one electron is scattered from the line peak, on the average, so would the other electron be scattered from its peak. Therefore unscattered electrons focused into one Geiger tube located at a line peak would be less likely to have highly scattered electrons in coincidence with them.

Aside from the reduction of line broadening due to source scattering, the following discussion shows that a natural line sharpening effect is also present. The arguments are given for a two-dimensional spectrometer and are thus only qualitative, but the important features entering into line sharpening are brought out clearly.

Suppose L_1 and L_2 are two conversion lines between which coincidence studies are to be made. The envelopes of the curves shown in Fig. 4 give the densities of the two lines. However, rather than the complete density curves, it is necessary to know the contribution of each element of the source to the density curve. In the discussion that follows, the complete line density curve will be referred to as the gross line, in distinction to the coincidence lines to be considered later. The integration of the gross line density curve over a Geiger tube window width, results in the lines as seen by either Geiger tube as it sweeps across the gross line.

Plotted below the gross density curves in Fig. 4 are shown the contributions to the curves from small elements of the source. The method of construction of these increment curves follows a treatment previously given by the authors.[8]

The total coincidence rate between a point P of line L_1 and a point Q of line L_2 is given by the sum of the coincidence rates furnished by each element of the

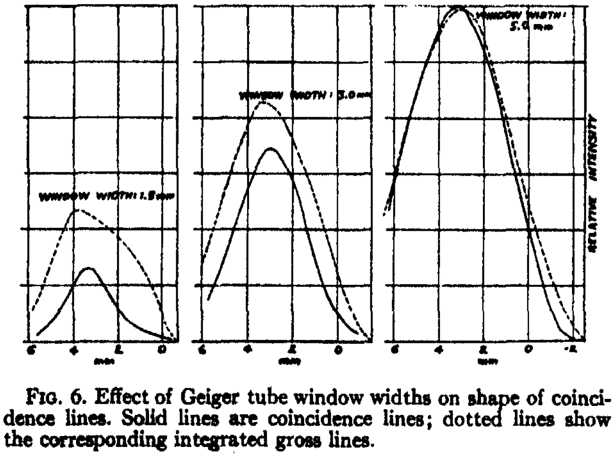

FIG. 6. Effect of Geiger tube window widths on shape of coincidence lines. Solid lines are coincidence lines; dotted lines show the corresponding integrated gross lines.

---

[8] Fowler, Shreffler, and Cork, Rev. Sci. Inst. 20, 966 (1949).

source for these two points. For example, the coincidence rate between P and Q arising from the small source element 7, is given by the product $(oa)\cdot(ob)$. Contributions from all the source elements add to give the total coincidence rate for the pair of points P,Q.

In this manner, a rectangular grid can be drawn up giving the coincidence rates between any pair of points, one being taken from each of the two lines, L_1 and L_2.

The construction of these grids (one is necessary for each pair of gross lines to be studied) greatly facilitates the integrations over the Geiger tube window widths. In practice, it is found convenient to select equal spacings between the points P and Q, of the gross lines, such that an even number of these spacings are subtended by the Geiger tube windows. The total coincidence rate observed for specified locations of the two Geiger tubes will be comprised of the contributions from all pairs of points, P, Q, falling within the window widths covering portions of the gross lines. By use of conventional numerical integration formulas, the simultaneous integration over both Geiger tube window widths is readily accomplished, using the grid described above.

As mentioned previously, one of the procedures adopted in this research for coincidence studies, involves fixing one Geiger tube on one of the two lines, while the other tube is placed at various points of the other line. The distribution of coincidence rates plotted *versus* the movable tube setting gives rise to the sharp coincidence lines.

Theoretical coincidence lines following this procedure were then studied with gross line radii of 3.0 and 6.0 centimeters. The slit spacing was one centimeter, while a very wide source of 0.5 centimeter was used. The choice of this wide source was made to see if coincidence sharpening was still appreciable, and also to lend more accuracy to the numerical studies carried out, since the source could be conveniently divided into more increments.

Figure 5 shows the predicted coincidence lines, as the movable Geiger tube traverses the line L_1. The different curves arise from selecting different locations for the fixed Geiger tube on the line L_2. In this figure, both Geiger tube windows were taken as 1.5 mm wide.

Figure 6 shows the effect of Geiger tube window widths on the coincidence lines. For all these curves, the fixed Geiger tube was centered at the same point on line L_2. Since the gross line curves, integrated over different window widths are not the same, over each of the coincidence lines is plotted the window integrated gross line.

Some of the important observations from Fig. 5 are:

(1) The coincidence line intensities are strongly dependent upon the position of the fixed Geiger tube, being greatest when this tube is located on the leading edge of the gross line somewhat past its peak.

(2) The coincidence line widths are about half that of the integrated gross line width, thus showing coincidence sharpening. Even greater calculated sharpening should be expected with exact calculations replacing the triple numerical integrations.

(3) The locations of the peaks of the coincidence lines are also dependent upon the location of the fixed Geiger tube.

Some further observations from Fig. 6 are:

(4) The line sharpening improves as the window widths are decreased. For example, the ratio of half-widths of coincidence line to gross line decreased from 0.95 to 0.52 as the window widths changed from five mm to 1.5 mm.

(5) The coincidence line peak intensities increase with the window width.

5. APPLICATIONS OF THE SPECTROMETER

The Hafnium 181 Activity

For convenience of discussion of the coincidence studies, the decay scheme for this activity is given in Fig. 7.

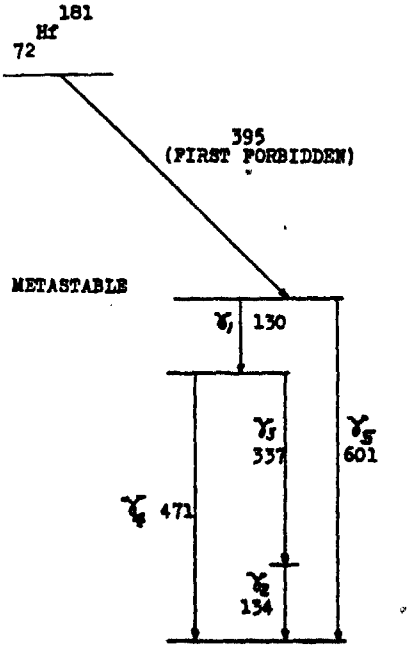

FIG. 7. Proposed decay scheme for Hf 181. All energies in kev.

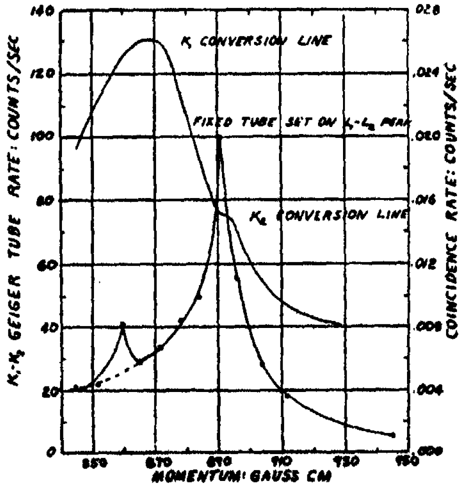

FIG. 8. Hafnium coincidence curve.

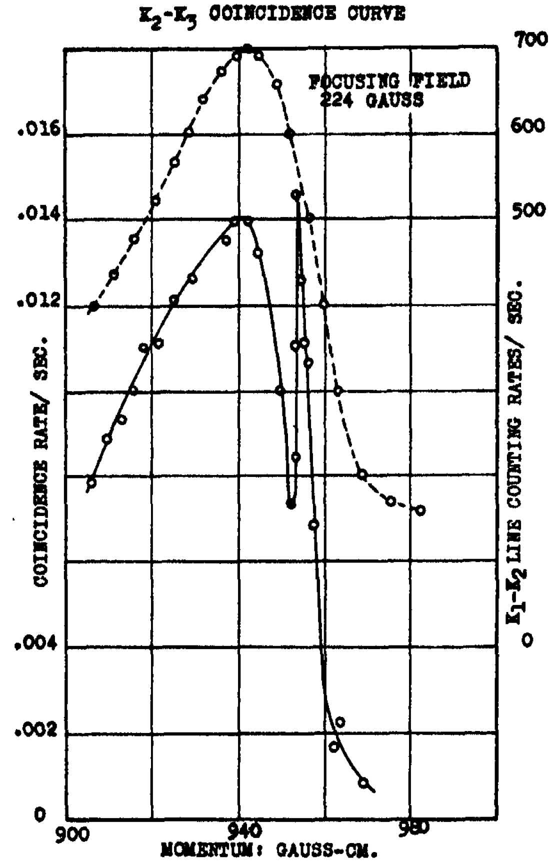

FIG. 9. Europium coincidence curve.

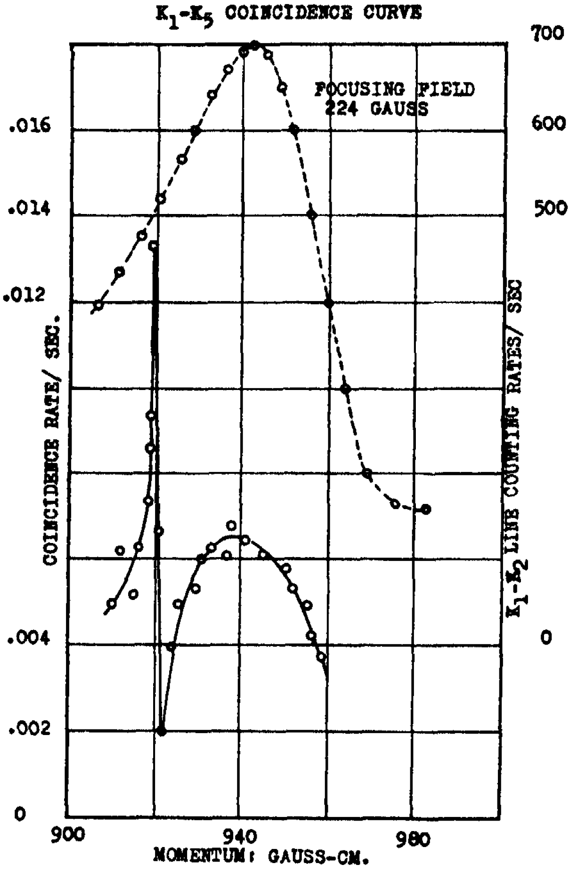

FIG. 10. Europium coincidence curve.

The initial report on the 48-day hafnium activity by Hevesy and Levi[4] has been followed by numerous papers. DeBenedetti and McGowan[5] first reported a metastable state of 22 microseconds following the initial beta-decay. Recently Chu[6] reported on the radiations from this element and proposed a decay scheme consistent with his analysis of the conversion and secondary spectra.

A preliminary survey of the conversion electron spectrum was undertaken by the authors in collaboration with E. Salmi. The results of this effort, with minor changes, agree with the report of Chu. The continuous beta-spectrum was found to be first forbidden with an end point of 395 kev; and a weak *K* conversion line corresponding to a gamma-energy of 601 kev was found with an intensity measured in units of the normalized beta-spectrum of approximately 0.0005. Chu reported the beta-spectrum to be allowed, and omitted the weak gamma-ray.

By making coincidence studies between various pairs of conversion electron groups, it was established that γ_1 is in coincidence with γ_2 and γ_3, and also that γ_2 and γ_3 are in coincidence, all in agreement with the decay scheme shown. Due to smaller coincidence intensities encountered it was difficult to show with statistical accuracy the anti-coincidence which should exist between conversion groups of γ_4 and either γ_2 or γ_3. No conversion line was found in coincidence with the continuous spectrum, establishing the previously reported position of the metastable state. Figure 8 shows a typical coincidence line. It records data confirming the coincidence between γ_1 and γ_2, and also illustrates the technique of employing the *L* conversion groups for radiations resulting from gamma-rays of nearly the same energies. Here, the fixed Geiger tube subtended portions of both *L* conversion groups, being centered at the peak of the unresolved *L* doublet.

Applications to the Long-Lived Europium Activities

When naturally occurring europium is subjected to thermal neutron bombardment, among others formed, are two long-lived activities (greater than five years) which exhibit a host of internal conversion lines.[7,8] Among these are two very intense lines of nearly the same energy: γ_1 (123 kev) and γ_2 (121 kev). Coincidence studies were made among these lines, and two of lesser intensity: γ_3 (244 kev) and γ_5 (344 kev).

[6] K. Chu, Thesis (University of Michigan, 1949).

[7] Cork, Shreffler, and Fowler, Phys. Rev. 74, 240 (1948).

[8] F. Shull, Phys. Rev. 74, 917 (1948).

Figures 9 and 10 show some of the results of these studies. In both figures the dotted lines show the unresolved K conversion lines of γ_1 and γ_2, as seen by a single Geiger tube. The solid curves show the coincidence lines obtained, as the inner Geiger tube is swept across the K doublet, while the outer Geiger tube is fixed under the K conversion line of γ_3 in Fig. 9, and under the K conversion line of γ_5 in Fig. 10. Although the cross coincidence terms have not been subtracted from the data of these figures, it is clear that γ_1 and γ_5 are in coincidence, as are γ_2 and γ_3.

As an example of the "offset" method, γ_3 and γ_5 were shown not to be in coincidence. Positions 1 and 3 correspond to the two line peaks, while 2 and 4 are points such that the inner edges of the Geiger tube windows just clear the conversion lines. The observed rates, corrected for spurious coincidences, were as follows:

$$q(1,3) = 0.00345 \pm 0.00009 \text{ coinc/sec.}$$
$$q(1,4) = 0.00353 \pm 0.00012 \text{ coinc/sec.}$$
$$q(2,3) = 0.00283 \pm 0.00011 \text{ coinc/sec.}$$
$$q(2,4) = 0.00285 \pm 0.00011 \text{ coinc/sec.}$$

From Eq. (1) this leaves as the net coincidence rate between K_3 and K_5:

$$Q(1,3) = -0.00006 \pm 0.00022 \text{ coinc/sec.}$$

This result is taken as evidence that γ_3 and γ_5 are not in coincidence.

With the coincidence data obtained supplementing other information known about these activities, it has been possible to propose plausible decay schemes for these activities, incorporating such features as K-capture, the presence of an isomeric state, three beta-spectra and numerous gamma-rays.[9]

Figures 9 and 10 together show the complete separation of the K conversion lines of γ_1 and γ_2. The remarkable coincidence resolution is evident upon noting that the radii of curvature of the conversion groups are only slightly greater than four centimeters.

ACKNOWLEDGMENTS

The authors are greatly indebted to Professor J. M. Cork for many valuable suggestions, as well as for continued encouragement. Acknowledgment is also due Dr. W. C. Parkinson of the University of Michigan Physics Staff for valuable discussions concerning the line sharpening effect. Finally, thanks are due to Professor E. K. Chapin of the Kansas State Physics Department and H. B. Keller of the University of Michigan, both of whom very kindly assisted the authors in the preparation of photographs.

APPENDIX

Referring to the simple decay scheme of Fig. 3, it is seen that in the case of incomplete gamma-ray shielding, the Geiger tube counting rates are due not only to conversion electrons, but beta- and gamma-radiation as well. Thus for the setting (1,3), the total counting rates for the two tubes may be written as:

$$n_1 = n_{1c_a} + n_{1\beta} + n_{1\gamma}$$

and

$$n_3 = n_{3c_b} + n_{3\beta} + n_{3\gamma}.$$

The terms on the right represent partial rates from the conversion electrons, continuous beta-spectrum and gamma-ray leakage, respectively. The numerical subscripts refer to the positions of the Geiger tubes.

In addition to the coincidence rate between conversion electrons, which will involve the factor $n_{1c_a}n_{3c_b}$, cross coincidences between various combinations of the partial counting rates will occur, for example between the pairs $(n_{1c_a}, n_{3\beta})$ and $(n_{1\beta}, n_{3\gamma})$.

To indicate the proof of Eq. (1), the partial coincidence rate due to the cross term n_{1c_a} and $n_{3\beta}$ will be computed. Let ω_1 be the fraction of conversion electrons of group c_a collected by Geiger tube I at setting 1, and ω_3 the fraction of the continuous beta-spectrum collected by Geiger tube II at setting 3. Let N be the total source strength. Then for each particle collected by tube II, there will be ω_1 coincidences with the converted electrons focused in tube I. Since there are $N\omega_3$ beta-particles collected per second in tube II, the partial coincidence rate may be written:

$$q(1c_a, 3\beta) = N\omega_3\omega_1 = n_{1c_a}n_{3\beta}/N.$$

The contributions of all other coincidence terms for each of the settings of Fig. 3 may be computed in similar fashion.

If it is now assumed that the small offsets of the Geiger tubes shown in Fig. 3 do not change the partial rates due to the beta-spectrum and gamma-ray leakage, we can write:

$$n_{1\beta} = n_{2\beta} \quad n_{1\gamma} = n_{2\gamma} \quad n_{3\beta} = n_{4\beta} \quad n_{3\gamma} = n_{4\gamma} \tag{A.1}$$

Using these approximations, and substituting all of the cross term coincidence rates, as computed above, for the various settings of Eq. (1), the net result becomes:

$$Q(1,3) = n_{1c_a}n_{3c_b}/N. \tag{A.2}$$

The offset procedure then eliminates all coincidence combinations except that between the conversion electrons.

The method of proof may be generalized to cover more complex decay schemes, taking account of branching, Geiger tube efficiencies etc., but in all cases, the offset method leaves only the rate arising from conversion electrons.

The assumptions involved in Eq. (A.1) are ordinarily quite good, since most beta-spectra are quite flat over the narrow regions subtended by conversion lines. In all cases, if necessary, a correction factor, based upon the shape of the beta-spectrum can be applied to the observed offset rates, if the offsets are quite large as may be required in case several closely spaced lines must be skipped before arriving to a line free portion of the beta-spectrum. Measurements of gamma-ray leakage have shown that over the narrow offsets employed, the decrease in intensities are scarcely detectable.

Finally it should be remarked that, although the offset procedure correctly leaves only the coincidence rates between conversion electrons, the final formulas given by the above proof, such as Eq. (A.2) have failed to take into account the line sharpening effect existing between the conversion groups. Implicitly assumed in the above proof, was the uniformity of coincidence rates between the various cross terms over all increments of the Geiger tube windows. This assumption is essentially correct for all the combinations except that where both of the terms are from conversion lines. Here, the sharpening effect must be considered for an accurate calculation of this coincidence rate.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 8 AUGUST, 1950

A High-Low Temperature Microscope Stage

R. E. Cech
Research Laboratory, General Electric Company, Schenectady, New York

(Received May 8, 1950)

A microscope stage has been designed and constructed which permits microscopic observation of metal specimens from the temperature of liquid nitrogen to an upper temperature usually determined by the melting point of the specimen.

The stage consists of a vacuum-tight water or liquid nitrogen-cooled copper chamber in which a specimen is heated by passage of an electric current. A quartz window in the chamber permits "at temperature" observation of the specimen. Operation of this stage is described.

INTRODUCTION

USUALLY, structures stable at high temperatures are deduced from microscopic observation at room temperature on specimens which have been rapidly quenched. This technique is most useful in those instances in which the high temperature structure is retained at room temperature. In many cases, however, transformations occurring during the quench alter the microstructure and make the correct interpretation very difficult. It is possible by the use of high temperature microscopy to examine metals at temperature and in many cases determine the structure directly.

A high temperature microscope stage generally consists of a tiny furnace in which a very small sample is placed. The furnace and sample are located within a chamber which may be evacuated or contain an inert atmosphere. An observation window in this chamber permits a microscope to be focused on the specimen within the furnace.

Burgess,[1] Wright,[2] and Stadnichlenko[3] were among the first to make use of high temperature microscopy as a research tool. In their apparatuses an electrically heated strip constituted the microfurnace. Williams[4] recently has designed and built a high temperature microscope stage similar to that of Burgess but differing in that the heating current was passed directly through the specimen. This has been used in an elevated temperature study of the refractory metals and their alloys. In a number of other researches high temperature microscope stages have been constructed using, instead of a strip heater, a resistance winding on a refractory core for a microfurnace.[5–10] This type of microfurnace has the inherent disadvantage of radiating a large quantity of heat upward since the volume of furnace is large as compared to the specimen. It is difficult in this case to keep the microscope objective properly cooled. Also, with a microfurnace of this type contamination of the specimen at very high temperatures is likely to occur.

It is desirable that the microscope stage be adaptable for observations at sub-zero as well as at elevated temperatures. This requirement is necessary for a direct microscopic study of the martensite transformation when it occurs below room temperature.

The microscopic observation of metals below room temperature has been accomplished by a method parallel to high temperature studies, that is, by inserting the specimen in a stage at room temperature and cooling by conduction to a liquified gas supply. There appears to be no published work of a microscope stage capable of quenching a specimen under observation directly from a high temperature to any desired sub-zero temperature. The microscope stage described in this paper was designed to be cooled with a liquified gas if desired, thus permitting its ambient temperature to be that of the liquified gas. This type of design makes possible a microscopic investigation of martensite type transformations below room temperature by direct rapid quench from the temperature of a stable parent phase.

EXPERIMENTAL: CONSTRUCTION

The stage described in this report was constructed so as to use a specimen in the form of a strip which is heated by passage of an electric current. A separate strip heater having a specimen in thermal contact with it could also be used. Details of construction of the stage are shown in the cross-sectional view, Fig. 1. A copper tube $1\frac{1}{2}$ in. in diameter, $1\frac{1}{2}$ in. long forms the chamber. The specimen or strip heater is mounted in the end of this chamber and a quartz observation window with sealing gaskets of silicone rubber placed over it. This window is held in position by a retaining ring and the top ring of the stage turned down to form a vacuum tight seal. This top ring also serves to suspend the stage in a tank of the desired cooling medium. The chamber is sealed at the bottom with a ceramic disk through which thermocouple leads and the insulated power lead pass. The stage serves as one side of the electrical circuit, thereby necessitating only a single insulated power lead. The electrical connections to the chamber and power lead are not shown in Fig. 1. Inert gases are admitted to the stage or it is evacuated through two ⅛ in. diameter copper tubes. Provision is made to either flow a gas over the specimen surface so as to sweep away volatile materials evaporated from the metal or to direct the gas perpendicularly to the specimen surface to permit rapid gas quenching.

The heat generated by the electrically heated specimen or strip heater is conducted to the specimen mounts and then to the copper chamber where it is dissipated by the cooling medium used. The stage may be partly immersed in a small tank of water if a room temperature ambient is desired. When a sub-zero ambient temperature is required the stage is placed in a Dewar flask of liquified gas. It is necessary in this case to replace the observation window gaskets of silicone rubber with gaskets of "Teflon" plastic. Also, the top ring must be thermally insulated and a small auxilliary filament heater placed on top of the quartz window to prevent frost formation.

Specimens to be observed microscopically are cut to the shape of slivers $\frac{1}{32}$ in.×$\frac{3}{16}$ in.×$\frac{7}{8}$ in., polished, and mounted in slotted copper blocks as shown in Fig. 2a. These are then heated directly by passing a heavy current through them. For some specimens such as copper or silver or isolated metal particles a separate heater is needed. Platinum and molybdenum strip heaters have been used for this type of specimen. Separation of the heater and specimen is obtained by interposing a thin flake of blown quartz or by placing the specimen in a quartz capsule. These are illustrated in Figs. 2b and 2c. These heaters, of a more permanent nature, are brazed to copper mounting blocks. The stirrups in the strip increase the length of the heated portion, thus permitting greater temperature uniformity in the center section. Heaters of this type have been used in the study of the solidification behavior of small metal droplets.[11]

FIG. 1. Cross section of asembled stage with specimen.

After mounting the specimen between copper blocks it is mounted in the chamber as shown in Fig. 3. A rigid low resistance connection is made to the grounded side of the chamber by means of a copper wedge. Electrical contact to the other side of the specimen is made with sliding contacts on the insulated portion of the chamber interior. Mica sheet separates this insulated portion from the rest of the chamber. Electrical connection to the chamber exterior is made through the single power lead. The massive copper construction used in the specimen mounts permits rapid removal of heat from the mounting blocks, thus keeping them very close to the ambient temperature. This is necessary to obtain a rapid quench from an elevated temperature.

Power for heating the specimens is supplied by a 30:1 step down transformer controlled by a Variac transformer and operated from a constant voltage source. The temperature of the specimen is controlled manually by adjustment of the Variac setting. The power requirements of the microscope stage vary according to the type of specimen and temperature of operation. In the average specimen at a temperature of 1200°C a current of about 150 amperes at 1 volt is required. Temperature may be maintained constant within 5°C by a constant power input and constant heat loss from the stage.

Temperatures are determined by means of a 0.005-in. Chromel-Alumel thermocouple welded to the specimen in the area of microscopic observation. For temperatures above 1200°C in vacuum or inert atmosphere a 0.010-in. platinum-platinum rhodium thermocouple is used. A manually balanced portable thermocouple potentiometer is used for direct reading and a self-balancing potentiometer recorder is used when permanent records are desired. The maximum temperature of observation is limited only by the melting point of the specimen or the temperature at which rapid vaporization of metal to the window makes observation difficult. The upper temperature limit of thermocouples has thus far imposed a limit on the maximum practical temperature of observation.

[11] D. Turnbull and R. E. Cech, J. App. Phys. (to be published).

PERFORMANCE AND OPERATION

The described microscope stage has been used at temperatures up to 1550°C in the study of the solidification of small metal droplets. Because of the small area of heater providing radiation upward there is little likelihood of overheating the microscope objective even upon prolonged observation. With ordinary objectives magnifications of 250× are easily obtained and with the use of the newly developed reflecting objectives magnifications of 500× or greater are possible.

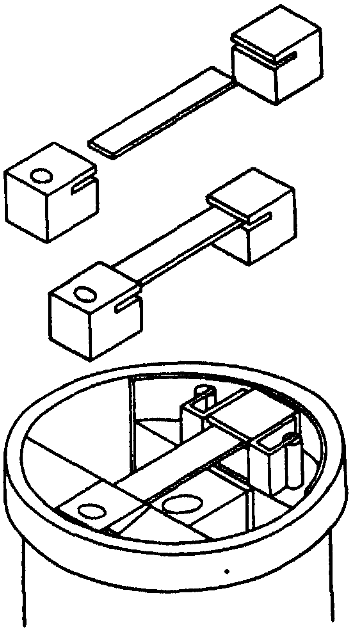

FIG. 3. Details of specimen mount.

Specimens may be heated very rapidly by applying full power to the specimen from room temperature. A rapid quench is attained by merely shutting off the power to a specimen at elevated temperature. Heat conduction to the copper mounting blocks and to the atmosphere in the chamber causes rapid cooling to take place. The rate of cooling can be further increased by forcing a blast of gas on to the specimen surface through the tube provided for that purpose. This tube is coiled around the chamber exterior to insure that the entering gas will be at the ambient temperature when entering the chamber. A rapid quench, such as is provided here, is a necessary requirement for the study of the martensite transformation.

An experimental determination of heating and cooling rates was made using a specimen of an alloy of 70 percent iron, 30 percent nickel, 0.020 in.×0.250 in. in cross section, mounted as shown in Fig. 2a. Chromel and Alumel wires 0.005 in. diameter were spot welded to opposite sides of the specimen heated portion. Thermocouple e.m.f. was recorded using a General Electric photoelectric potentiometer recorder having a period of 0.5 second.

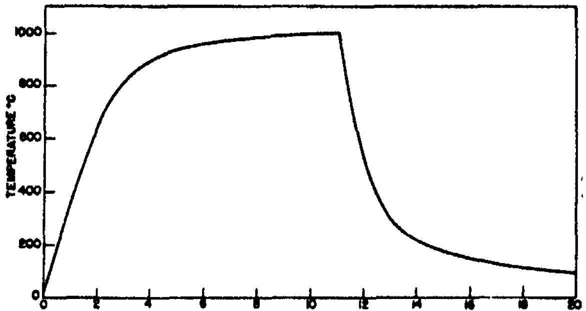

FIG. 4. Heating and cooling curve of specimen in stage.

The specimen was heated by applying full power from room temperature and cooled by switching off the power while at the same time admitting a blast of gas to the specimen surface. The heating and cooling curve obtained has been replotted and is shown in Fig. 4.

It is seen that in both the heating and cooling portions of the curve, the initial rate, extending to about $\frac{3}{4}$ of the temperature interval, is approximately 300°C per second. The rate rapidly decreases as the specimen approaches the final temperature. This is caused by the slower temperature equilibration of the mounting blocks. The resulting temperature curve is a superposition of the rapidly changing specimen temperature and the more slowly changing temperature of the mounting blocks. The temperature lag of the mounting blocks is most noticeable on quenching as the rapid quenching rate extends to only about 300°C and decreases markedly below this temperature.

To operate the microscope stage at a low ambient temperature it is assembled as described earlier and suspended in a Dewar of liquid nitrogen. As the chamber cools to −195°C power is slowly applied to the specimen to keep it at room temperature. Liquid nitrogen must be continuously added to the Dewar flask through a small tube. When the stage has cooled completely the desired heat treatment may be given the specimen while being observed or photographed. It has been possible to observe martensite formation at sub-zero temperatures after direct quench from above 1000°C by this method.

ACKNOWLEDGMENT

The author wishes to express his appreciation for the valuable assistance of Mrs. A. L. Williams and Dr. David Turnbull in the design of the high-low temperature microscope stage.

Random Coincidence Rates with Unsteady Sources

R. M. Littauer
Cavendish Laboratory, Cambridge, England

(Received May 17, 1950)

The random coincidence rate between two sets of pulses can be measured by delaying one of the sets through a time greater than twice the resolving time of the coincidence detector, thus destroying all true coincidences. A circuit using this principle for supervising the random rate continuously is described.

INTRODUCTION

When coincidence experiments are carried out with unsteady sources, whose strength is known not as a function of the time but only as a time average, it is difficult to estimate the correction for random coincidences. For instance, the source may be a target under bombardment with artificially accelerated particles whose flux is subject to periodic and random fluctuations (ripple on the accelerating voltage, random variation in beam position and intensity).

Suppose each disintegration yields two particles, A and B, coincident within the resolving time τ of the apparatus. Let there be $n=n(t)$ disintegrations per second, and let α and β be the efficiencies of detection for A and B respectively. Then the counts recorded by the two detectors in time t will be

$$S(A)=\alpha\int_0^t ndt$$

and

$$S(B)=\beta\int^t ndt,$$

while the number of true coincidences in this time is

$$C=\alpha\beta\int_0^t ndt.$$

The random coincidence rate is given by

$$r=2\tau\cdot\alpha n\cdot\beta n=2\alpha\beta\tau\cdot n^2,$$

so that the random count

$$R=2\alpha\beta\tau\int_0^t n^2dt.$$

The usual method of estimating R is to express it in terms of the measured $S(A)$ and $S(B)$; this can be done only if the shape factor $k=\langle n^2\rangle_{\text{Av}}/\langle n\rangle^2_{\text{Av}}$ is known and constant for the source used. Since

$$R=2\alpha\beta\tau\langle n^2\rangle_{\text{Av}}t$$

and

$$S(A)=\alpha\langle n\rangle_{\text{Av}}t,$$

we have in that case

$$\begin{aligned}R&=2\alpha\beta\tau k\langle n\rangle^2_{\text{Av}}t\\&=2\tau k\cdot S(A)\cdot S(B)/t.\end{aligned}$$

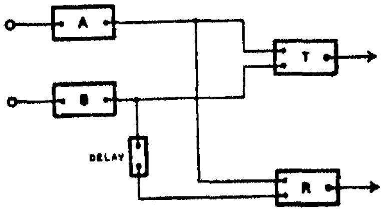

FIG. 1. Block diagram of the coincidence circuit.

For radioactive sources, k can be calculated from a knowledge of the lifetime:

$$k=\lambda t(1-e^{-2\lambda t})/2(1-e^{-\lambda t})^2,$$

where λ is the decay constant of the source ($=0.69$/half-life) and t is the time of counting. As $\lambda t\rightarrow 0$, k approaches unity, the value for a steady source.

For disintegrations produced during artificial bombardment, however, k is generally not constant, but depends on the exact adjustment of the apparatus. Thus in the case of a high tension set accelerating protons or deuterons, the shape factor of the bombarding beam striking the target usually depends critically on the exact setting of the analyzing magnet and on the instantaneous position and focusing of the beam. An experimental method of measuring R is thus required in all cases where R is not negligible compared with the true rate C.

Such a method has already been proposed by Hereward,[1] who operates two coincidence gates of resolving times τ_1 and τ_2 simultaneously from the same set of pulses A and B. If $\tau_2\gg\tau_1$, then the second gate records predominantly random coincidences, and the correction to be applied to the first gate is given by $(N_2-N_1)\tau_1/(\tau_2-\tau_1)$, where N_1 and N_2 are the counts in the two gates. The experimental difficulty in this method lies in the construction of two coincidence gates with widely different resolving times, for which the factor $\tau_1/(\tau_2-\tau_1)$, however, remains constant.

The method to be described in this paper is represented schematically in Fig. 1. The pulses from the two channels A and B are fed directly into a coincidence gate T, where the total coincidence count is recorded. They are also led to a second gate R, but in this case one of the pulses is first delayed by a time greater than twice the resolving time of the gates.

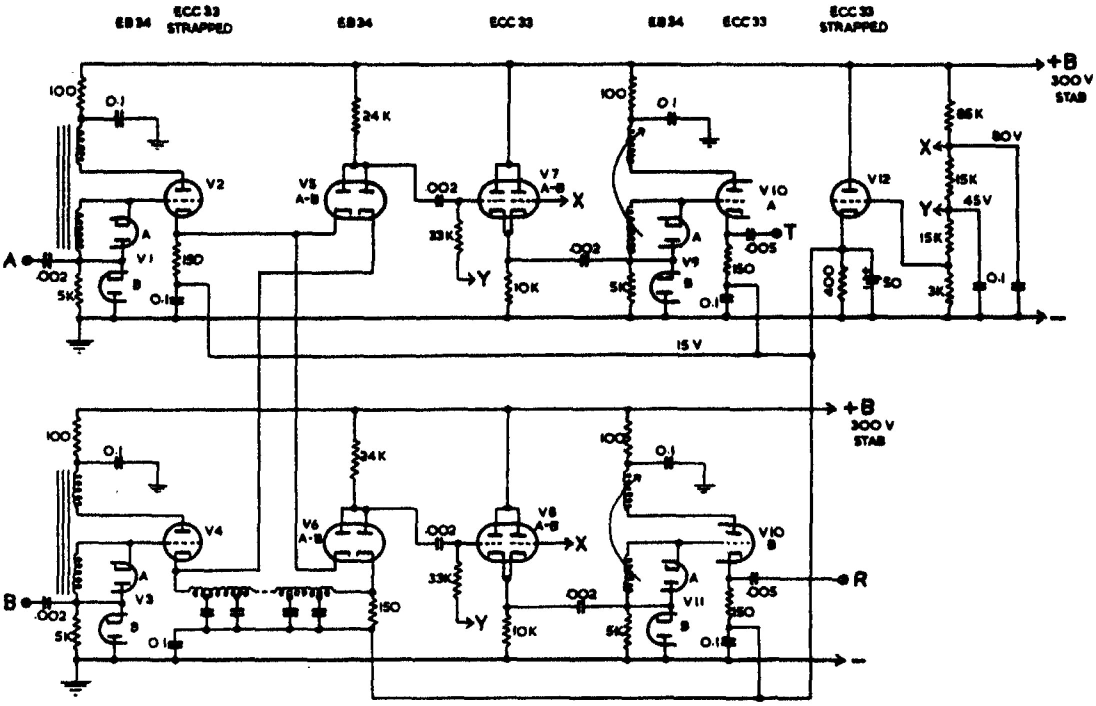

Fig. 2. Complete circuit. Resistance values in ohms, capacities in μF.
Approximate American valve equivalents:

$EB34 = 6H6$
$ECC33 = 6N7$

Pulse transformers: 45–45 turns on laminated high permeability cores, 0.5 cm^2 cross section.

This second gate records only random coincidences, since all the true coincidences have been destroyed by the delay.* If the two gates have the same resolving time, then R gives directly the random component of the coincidences recorded in T.** The advantage of the method lies mainly in this direct indication of the number of random coincidences; but also in the fact that it is not difficult to construct two coincidence gates whose resolving times remain in a constant ratio if this ratio is close to unity.

EXPERIMENTAL METHOD

Figure 2 shows the complete circuit diagram of the apparatus. The main components are as follows: two square wave generators (V_{1-4}), two diode coincidence gates (V_5, V_6), and two discriminators (V_{7-11}). V_{12} serves merely to maintain the bias line for the pulse generators at a constant potential of +15 volts.

To make the resolving times almost independent of the pulse sizes and discriminator levels, the coincidence gates are fed with nearly square pulses. These are generated in the blocking oscillators V_1, V_2 and V_3, V_4. The transformers employed have laminated cores of high permeability material, thus ensuring a coupling factor very close to unity. This is necessary in order to reduce the ratio of the time of rise of the pulse to the pulse duration. In place of the usual $R-C$ combination to give a blocking action, two diodes are employed. In this way the deadtime of the circuit after it has produced a pulse is reduced considerably.

The blocking oscillators are triggered by short positive pulses delivered from a discriminator in each counting channel. When the oscillator is fired, the current in the triode increases rapidly until it reaches such a value that the magnetizing forces due to the grid and anode currents in the transformer are almost equal and opposite. This state is maintained by the steadily rising flux in the transformer, which produces the requisite e.m.f. in the grid circuit. The reset of the pulse appears to be initiated when the iron begins to reach saturation; we have, however, no exact knowledge of the behavior of laminated cores under these high frequency conditions. With the valves used, the current in the cathode reaches 0.7A, so that a 100-volt pulse is produced across the cathode resistor of 150 ohms.

The blocking oscillator in the B channel employs a 150-ohm delay line, properly terminated, as cathode load. The line has 80 sections, giving a total delay of 4 μsec., and does not appreciably distort the shape of

---

* This assumes, of course, that the resolving time τ (and thus the delay $>2\tau$) have been so chosen that all the events to be recorded as being coincident do, in fact, occur within this time of each other.

** Strictly speaking, the number of coincidences in R will be too great in the ratio $S(A)\cdot S(B)/[S(A)-C]\cdot[S(B)-C$, but this correction can be neglected if $C \ll S(A)$, $S(B)$, which is almost always the case in practice.

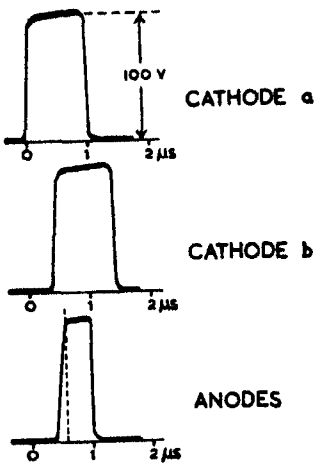

FIG. 3. Pulse shapes on the coincidence gate, V_1.

the pulses from the cathode. The square pulses are approximately 1 μsec. long, as this was the value of resolving time required in the present application.

The coincidence gates each consist of a pair of diodes. Figure 3 shows the wave forms obtained on the various electrodes when pulses with a certain time overlap are applied to the cathodes. The anode pulse rises at a rate determined by the standing current and the stray capacities attached to the anodes, provided that the cathode pulse has a leading edge steeper than this value. This is actually the case, for the anode rate of rise (with 12 mA and 18 pF) is limited to about 600 volts/μsec., while the input pulse, even after passage through the delay line, rises considerably faster than this. Thus the shape of the anode pulse is independent of the exact shape of the input leading edge. The rate of rise of 600 volts/μsec. means that a relative variation of 3 volts in the discriminator levels following the coincidence gates does not affect the resolving time by more than ½ percent. The fact that virtually the same pulses are used in the two gates ensures that the ratio of resolving times is independent of the length of the input pulses.

The discriminator following the coincidence gate consists of a cathode follower biased off by approximately 35 volts. Pulses exceeding this amplitude are passed to a further blocking oscillator, which produces the output pulse for registering in a scaling circuit. The total and random coincidence pulses appear respectively at T and R.

The ratio of the resolving times of the two channels can be measured by applying completely random pulses to the two inputs A and B; in the present instrument this ratio was found to be 1.02, and has not measurably changed in the course of the investigations so far made.

CHOICE OF SOURCE STRENGTH

When the mean source strength is under the control of the experimenter, it is desirable, apart from other considerations, to choose it in such a way that the maximum statistical accuracy can be achieved in a given counting time.

Let C, R, and T be the true, random, and total coincidence counts recorded in time t. Then, as shown in the introduction,

$$C = \alpha\beta\langle n\rangle_{\mathrm{Av}} t$$

and

$$R = 2\alpha\beta\tau\langle n^2\rangle_{\mathrm{Av}} t,$$

so that

$$R/C^2 = 2\tau k/\alpha\beta t,$$

which is independent of the source strength chosen, provided that the other quantities, especially k, remain unaffected. (k *may* depend on the absolute source strength.)

The experimentally measured quantities are T and R, from which C is deduced by putting $C = T - R$. If ΔC is the standard statistical deviation of C, we have

$$(\Delta C)^2 = (\Delta T)^2 + (\Delta R)^2 = T + R = C + 2R.$$

Thus

$$(\Delta C/C)^2 = 1/C + 2R/C^2.$$

Hence we see that the fractional error in C cannot be reduced below the value $(2R)^{\frac{1}{2}}/C$, which is a constant independent of the source strength. This strength will thus be chosen (if other considerations permit) such that $1/C \ll 2R/C^2$, i.e., that $R > C$; any further increase in source strength would not affect the statistical accuracy, but would, on the other hand, increase the errors introduced by any inequality of resolving time in the gates T and R.

Absolute Determination of the Emission Rate of Beta-Rays*†

R. K. CLARK**
Radiological Research Laboratory, College of Physicians and Surgeons, Columbia University, New York, New York

(Received May 17, 1950)

A technique for the absolute determination of the rate of disintegration of beta-particle emitters is described. The method consists of measuring the rate at which charge is carried away from the active material by the emitted electrons. The effects of ionization are eliminated by placing the material in a high vacuum. The effects of the surroundings (excluding the parts required to support the active material) are reduced by using a tank of large dimensions, and the magnitude of these effects is determined by the use of supplementary surrounding surfaces with various potentials applied to them. Some information is obtained about the effects of the source supporting structures by placing over the active side of the source supporting foil a cover foil identical to it. It is shown that this technique makes possible the measurement of beta-ray activities with high accuracy.

I. INTRODUCTION

SINCE the advent of artificial radioisotopes, the Geiger-Mueller counter has been the principal instrument used for the determination of the emission rate of beta-rays. In measuring emission rates it is used with a fixed geometry and corrections are made for solid angle, absorption, scattering, and the production of "secondaries" by the surroundings. Sometimes calibrations are made by means of a sample of another material of known activity, although this requires correction for the difference in energy spectrum. All these corrections are difficult to make, especially in the low energy regions. Methods have been devised to reduce the importance of these sources of error, one of the best (in principle) being coincidence counting.[1] Although in this case the over-all efficiencies of both the gamma-counter and the beta-counter cancel, the number of random coincidences may be an important fraction of the total if the source is quite active. When the source is weak, the background coincidences may be important. There are ways of reducing these difficulties, but when this technique is applied to activity measurements, the decay scheme must be completely known and is limited to those isotopes that yield at least one gamma-ray as well as the beta-ray.

When the radioactive material emits at least one charged particle per disintegration, a simple and direct method of measuring activity is to observe the rate at which charge is carried away from the active material by the emitted electrons. This technique requires relatively little knowledge of the decay scheme; when both positrons and electrons are emitted by the isotope, as in the case of Cu^{64} the ratio must be known; in the case of positron emission the branching ratio must be known; and the number of particles emitted per disintegration must be known. This information is easier to obtain than complete decay schemes as are required for coincidence counting, and is already completely known for practically all isotopes which emit only negative particles.

Wien[2] was the first to use this technique. Rutherford[3] and Makower[4] modified the method, and Moseley[5] improved it. The first three of these experiments are summarized by Rutherford.[6] The fourth is summarized by Rutherford, Chadwick, and Ellis.[7] These workers had three sources of inaccuracy. They were limited to natural radioactive materials, necessitating the use of absorbers to stop the alpha-rays. They were unable to produce very low pressures, having to correct for ionization effects. They did not investigate the importance of the production of secondaries in all parts of the apparatus, although the extrapolation techniques of Makower and, later, of Moseley tended to reduce the importance of secondaries from the source and its supporting structures.

The method presented in this paper is a modification and development of that described above. The principal improvements consist of a reduction of the magnitude and the determination of the various secondary contributions to the observed current.

II. PRINCIPLES OF THE MEASUREMENT

In the ideal situation where the active material has no absorber nor scatterer associated with it and there is no material of any sort around it, the current observed would be exactly that constituted by the emitted electrons and would therefore be an exact measure of the activity. In isotopes producing internal conversion electrons or Auger electrons, corrections would have to be made for the effects of these particles. Likewise, in those isotopes decaying by emitting both positrons and electrons the ratio of the numbers of the two types of

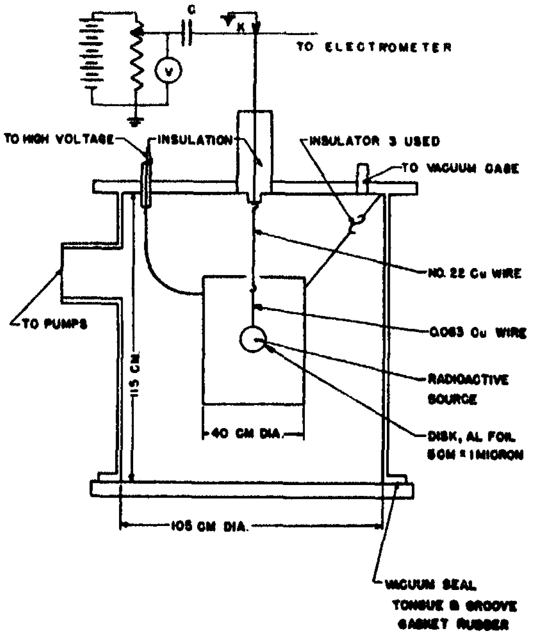

FIG. 1. Schematic diagram of apparatus. The active material is dried on the aluminum foil. Retarding or accelerating voltages are applied between the can and the foil (which is at ground potential). *The figure shows the large can in place. In determining* the effects of the surroundings (except for those involved in supporting the active material), this can was replaced by a screen of the same size, and by another can and screen each of one-half the linear dimension of the first can.

particles would have to be known, and in the case of pure positron emitters the branching ratio would have to be known. The problem is, then, one of approximating the ideal situation, and determining the magnitude of the effect of the unavoidable scattering and absorbing materials of the apparatus.

The effects of ionization can be completely eliminated by placing the active material in a highly evacuated tank. The tank walls and all structures except that supporting the active material can affect the observed current by scattering primaries and producing secondaries, some of which will be caught by the source structures. The magnitude of this effect can be reduced by the use of apparatus of large dimensions, and it can be studied by varying the dimensions and by applying retarding or accelerating potentials between the surroundings and the source structure.

The dimensions are varied by introducing in turn two "cans" of the same shape, but differing in linear dimensions by a factor of two. Two screens are also introduced in turn. One of these has the same dimensions as one "can," the other the same as the other "can." The screens thus provide a change that can be determined with precision in the number of particles from the surroundings. A change in the linear dimensions of a "*can*" does not change the total number of particles leaving it (since in any case it occupies a solid angle of 4 pi), but only changes the solid angle subtended by the source structures at a point on the can. When the can is made negative with respect to the source, some particles of energy greater than the applied voltage will be deflected so that they are caught and measured, and this "focusing" action is not a simple function of the dimensions of the can. Introducing, then, a screen in place of a can of the same dimensions does not change the focusing properties, but does change the total number of particles from the surroundings by a large factor since there is much less material to produce secondaries and reflect primaries. Thus this makes possible a more reliable computation of the magnitude of the component of the observed current due to the surrounding structures.

The resulting data show that under certain conditions the correction for the effects of the surrounding materials amounts to only a few percent of the observed current and can be determined to a few tenths of a percent of the observed current.

The material involved in supporting the active isotope will affect the observed current by producing secondaries and by absorbing primaries. These effects can be studied by varying the amount of inert material associated with the active isotope. When the observed change for doubling the amount of inert material is small, it is possible to determine the number of secondaries and to extrapolate to zero absorber by assuming that the effect of the original material is the same as that of the added material. It is true that such an extrapolation is not exactly justified, but since the observed changes are small the error is certainly small.

III. APPARATUS

In observing the current carried from the source and its supporting structures by the beta-rays, a Lindemann electrometer is used in conjunction with a "compensating condenser." One terminal of the condenser is connected to the electrometer and the source support, and the other terminal goes to a source of e.m.f. the magnitude of which can be varied easily. In use, the electrometer is kept with the needle as close to "zero" potential as possible and the mean time rate of change of voltage required to maintain this balance is determined. The desired current is then equal to the capacitance of the condenser multiplied by the average rate of change of voltage. This is known as the Townsend method.[8] Thus the observed currents are recorded in terms of volts per second. One curie gives 5.93 times 10^{-9} amperes, and with this method (in other experiments) currents of the order of 10^{-15} amperes have been observed in this laboratory. This is equivalent to about 0.17 microcuries. Thus there is more than adequate sensitivity for measuring weak sources—of the order of a hundred microcuries.

The active material is dried on an aluminum foil approximately one micron thick after the foil has been attached to an aluminum supporting ring with Aquadag. The ring is about 2 inches in diameter, 6.5 mils thick, and 30 mils wide. This assembly is then suspended in the center of the tank by means of two links of copper wire. The lower (about 6.5 mils diameter) is about 7 inches long, while the upper (No. 22 wire) is about 18 inches long.

---

[8] See reference 6, p. 103.

The materials which have been studied so far (P^{32} and Na^{22}) were applied in water solution and dried at about 60 degrees C. About one ml of solution distributes the material over an area about one centimeter in radius, and is the quantity which has usually been used. (Although the foil will support as much as two ml, it was felt that this amount of solution distributed the active material over somewhat too large an area.) This manner of preparation of the source allows the use of standard sampling methods. Thus it is possible to calibrate a solution, and to establish other instruments as secondary standards which can be rechecked as desired.

The limitations on the solution to be applied are as follows. The *p*H must be close to 7.0 so that the foil will not be attacked. The active material must be in the form of a compound that will not volatilize on drying and, especially, under the reduced pressures used in measurement. The non-volatile material (carrier, impurities, etc.) must not amount to more than about 2 milligrams per milliliter for such material as P^{32}, and should be less for lower energy emitters. This much solid does not seem to affect appreciably the activity determination for the more energetic isotopes, although it is certainly preferable to keep the solids to a minimum.

Because certain inconsistencies in the observed currents were found to be associated with the joints between the suspending wires (which were simply hooked together), all such joints were treated with Aquadag. These inconsistencies might arise either from poor conductivity or from varying contact potentials, but in any case the trouble was eliminated by the addition of the Aquadag.

A stainless steel tank 42 inches in diameter and 46 inches high is the vacuum chamber (Fig. 1). The pumping system is such that pressures as low as 1.2 or 1.3 times 10^{-6} mm of mercury have been obtained. Experiment has shown that ionization effects are completely eliminated by pressures as low as 10^{-5} mm of mercury under the conditions of these measurements.

In the center of the top of the tank is mounted the polystyrene insulated lead-through which supports the source in the center of the tank and connects to the measuring apparatus outside.

A lead-through is provided in the top of the tank for the application of potentials to whichever "can" or "screen" is in position.

Three insulating hooks ("Pyrex" tubing) are provided for suspending in the center of the tank the following structures in turn: the "small can" of galvanized iron similar in shape to the tank and one-fifth as large in linear dimension, the "small screen" of copper wire (No. 22) (with a mesh ½″×6½″, giving a transmission of about 94 percent) of the same size as the can, the "large can" of the same material as the first can but twice its linear dimension, and the "large screen" of the same construction as the first screen but the same size as the large can (and having a mesh 1″×8½″, giving a transmission of about 97 percent).

IV. RESULTS

The first question studied was the effect of changes in pressure. A Distillation Products ion gauge was used with a standard type circuit. Although the construction of these gauges is such as to make their rated sensitivity reliable, it was checked at higher pressures with a McLeod gauge (a liquid air trap was used) and satisfactory agreement was found. Preliminary measurements with none of the screens or cans present showed any change in the observed current for pressures below about 10^{-3} mm of mercury. With the small screen at zero volts, no effect was observed on changing the pressure from 2.0 times 10^{-5} mm to 8.0 times 10^{-4} mm. With the small screen at −1800 volts (with re-

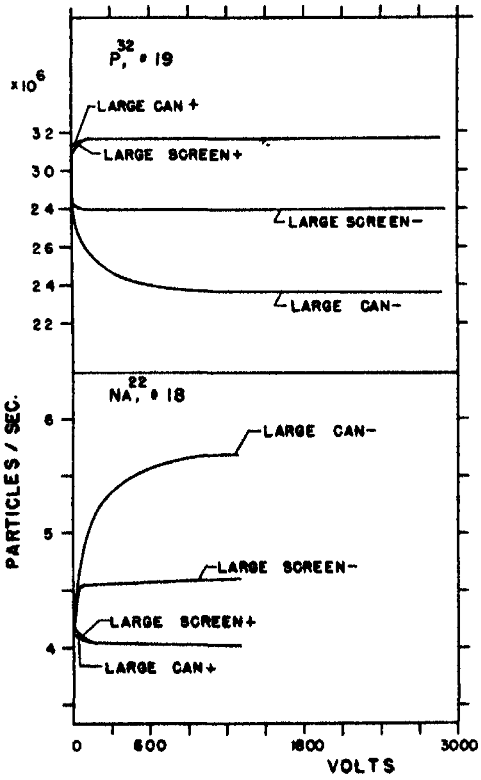

FIG. 2. Typical data. This shows the numbers of particles per second observed under various conditions with P^{32} and Na^{22} sources. A negative voltage means that the can—or screen—was negative with respect to the source.

Note the reversal of the changes due to the fact that Na^{22} is a positron emitter.

TABLE I. Summary of results. (The uncertainties attached to these figures are based exclusively on the observed internal consistency of the current measurements.)

spect to the source) there was also no change observed on changing the pressure from 4.0 times 10^{-5} mm to 8.2 times 10^{-4} mm. However with the small screen at + 1800 volts, there was considerable change in the region of 10^{-4} mm. Because of this, all subsequent data were taken at pressures below 10^{-5} mm. In order to detect any unexpected effects due to pressure changes, the pressure was recorded with each observation of current throughout the data. No effects due to changes of pressure were noted other than those described above.

The effect of applying different potentials to the surrounding structures is shown in Fig. 2. The observed current was found to vary rapidly with the potential applied to either can up to about 600 volts, with essentially no change between 600 volts and 3000 volts (the present upper limit of the apparatus) for P^{32} and Na^{22}. The form of these curves justifies the division of the electrons into three groups: "low energy"—below 600 electron volts; "intermediate energy"—between 600 electron volts and 3000 electron volts; and "high energy"—above 3000 electron volts.

A detailed analysis of the situation under various conditions may be made as follows: With a can at a negative potential greater than 600 volts, the low energy group from the source structure is suppressed, the remainder being unaffected. The low energy group from the can is completely focused onto the source structure, its magnitude depending only on the efficiency of production of this group. The high energy group from the can, being unaffected by the potential, depends on the solid angle subtended by the source at a point on the can (proportional to the square of its linear dimension) and on the efficiency of production. That part of the intermediate energy group which is sufficiently focused (deflected by the applied field) to be caught by the source structure is, in effect, included with the low energy group. Since this focusing (for a particular potential) depends only on the dimensions of the can, it is the same for the screen of the same size. Thus this effect will be taken care of if the term representing the low energy group from the can is eliminated algebraically from the equations for the can and its corresponding screen.

The current observed with a screen at a negative potential greater than 600 volts includes the same terms as a can, except that the magnitude of the contribution from the screen also depends on the area of the material constituting the screen. In addition there are some particles from the tank reaching the source structure. The low energy group from the tank is suppressed by the potential on the screen. The effect of the remaining particles is small because of the large dimensions of the tank, and therefore can be approximated by neglecting the intermediate energy group, the effects of which are complicated by the fact that the screen defocuses them while they are outside it, and focuses those which pass through. The magnitude of the remaining high energy group, being unaffected by the potential, depends on the transmission coefficient of the screen (squared, since both the particles from the source and those from the tank must pass the screen), on the solid angle subtended by the source at a point on the tank and on the efficiency of production.

When a positive potential greater than 600 volts is applied to a can, none of the energy groups from the source structures is suppressed, but the low energy group from the can is now defocused so that it is not included, while the high energy group is still unaffected by the potential. The intermediate energy group from the can tends to be defocused, and is therefore partly included with the low energy group, and partly with the high energy group.

When a positive potential greater than 600 volts is applied to a screen, the effects are the same as those with a can, except that some of the particles from the tank will be included. However, the effect of a positive screen on these particles is not simple. The screen has a tendency to catch some of the particles from the source which otherwise would escape to the tank. Likewise, it catches some of the particles from the tank. In addition it will have some focusing action on those particles which miss the screen, so that some which otherwise would have missed the source structures are measured.

The currents observed with "zero" potential applied to a can or a screen are very sensitive to small changes in voltage (from the shapes of the curves) and, since differences in contact potential certainly exist, it is impossible to give any specific relation between these currents and the others.

Thus, the currents observed with each can positive (more than 600 volts) and with each can and each screen negative (more than 600 volts) can be expressed in terms of known geometrical factors and of six unknowns with the aid of the following assumption:

> The total number of particles emerging from unit area of material per particle striking the material is the same for the cans, the screens and the tank.

This assumption is roughly justified since the atomic numbers of copper, zinc and iron are roughly the same.

The six unknowns then are the three components of the current from the source structures, the efficiency of production of low energy particles in the surrounding materials, the efficiency of production of intermediate energy particles in the surrounding materials and the efficiency of production of high energy particles in the surrounding materials. These six unknowns can be reduced to four by noting: first, that there are few particles of intermediate energy leaving the source structures as indicated by the screen data; second, that even with the cans there are few particles of intermediate energy observed, so that the efficiency of production of this group in the surrounding material may be assumed to be zero. (See Table I.)

Making the following definitions:

I = number of particles of high energy leaving the source structures per unit time.

i = number of low energy particles leaving the source structures per unit "I."

b = number of high energy particles from the small can per unit "I," which are caught by the source structure (essentially the efficiency of production of measured high energy particles in the small can).

c = number of low energy particles per unit "I" from the small can which are caught by the source structure with the can negative (600 volts) (essentially the efficiency of production of measured low energy particles in the small can).

d_S = the ratio of the solid angle subtended by the source structure at a point on the large screen to the solid angle subtended by the source structure at a point on the small can. (d_S is then the square of the ratio of the radius of the small can to that of the large screen.)

d_C, d_c, d_s are defined in the same way as d_S, with the large can, small can and small screen, respectively, substituted for the large screen.

f_S = the ratio of the area of metal in the large screen to the area of the large can.

f_s = the ratio of the area of metal in the small screen to the area of the small can.

The following equations can then be written.

For the small can:

$$I_{c+}=I(1+i-b), \qquad (1)$$

$$I_{c-}=I(1-b-c). \qquad (2)$$

For the large can:

$$I_{C+}=I(1+i-d_Cb), \qquad (3)$$

$$I_{C-}=I(1-d_Cb-c). \qquad (4)$$

For the small screen:

$$I_{s-}=I(1-d_sf_sb-(1-f_s)^2d_tb-f_sc). \qquad (5)$$

For the large screen:

$$I_{S-}=I(1-d_Sf_Sb-(1-f_S)^2d_tb-f_Sc). \qquad (6)$$

The numerical values of the d's and f's are: $d_C=1/4$, $d_s=1$, $d_S=1/4$, $d_t=1/25$, $f_s=1/16.4$, $f_S=1/33.0$. The precision required of these magnitudes is not high, since they enter the most important equations (for the two screens) only through small correction terms. It is estimated that the uncertainty in these values is not greater than 5 percent, which is quite acceptable.

Since there are more equations than necessary, there is more than one way to obtain the values of the unknowns. The remaining equations are then available as a further check on the over-all internal consistency of the data. The above numerical values may then be introduced and the unknowns computed as follows:

The value of "b" may be computed from Eqs. (1) and (3) or from Eqs. (2) and (4). When computed from the first two (the can positive equations) it is termed "b_{pos}," when from the second two, as "b_{neg}." The difference between b_{pos} and b_{neg} in the case of sodium probably arises because of the difference in the focusing of the intermediate energy groups by the two cans, and by the two screens, when they are negative (the current observed with the large screen changes by about 2 percent in going from −600 volts to −1200 volts). The small difference in the case of phosphorus may arise

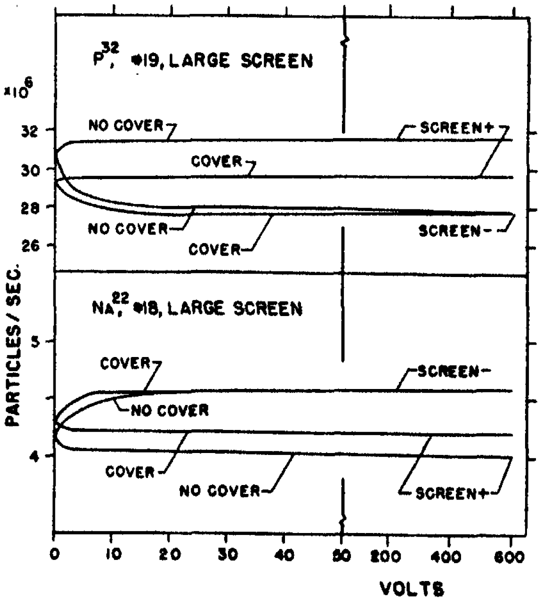

FIG. 3. Cover foil effects. This shows the numbers of particles per second observed for various potentials applied to the large screen. A negative voltage means that the screen was negative with respect to the source. The curves labeled "No Cover" were for the active material on the supporting foil with no other material associated with the source. The curves labeled "Cover" were for the same source, but with a second foil identical to the supporting foil covering the active material. (See also Table II.)

TABLE II. Effect of impurities and cover foil.* (The uncertainties attached to these figures are based exclusively on the observed internal consistency of the current measurements.)

Source number	Isotope	Approx. solids deposited	Cover foil	Computed number of particles leaving source structures: With an energy greater than 600 ev (I)	Computed number of particles leaving source structures: With an energy less than 600 ev, per unit I (i)
10	P^{32}	0.5 mg/mc	Not used	$36.4 \pm 0.2 \times 10^4$	0.129 ± 0.005
19	P^{32}	0.3	Not used	27.9 ± 0.2	0.170 ± 0.005
19	P^{32}	0.3	Used	27.8 ± 0.2	0.090 ± 0.005
29	P^{32}	0.0	Not used	3.37 ± 0.02	0.085 ± 0.005
29	P^{32}	0.0	Used	3.38 ± 0.02	0.077 ± 0.01
18	Na^{22}	0.5	Not used	4.50 ± 0.03	0.116 ± 0.005
18	Na^{22}	0.5	Used	4.52 ± 0.03	0.080 ± 0.005

* The amount of solids deposited is taken from the Oak Ridge data for the material in question, except for Na^{22}, which was estimated from the appearance of the deposit as compared to the P^{32} sources.
The cover foil is a foil identical to the foil upon which the active material was dried. When used, it was placed over the active surface of the supporting foil.

in the same way, although the change observed is not larger than the uncertainty in the observed currents.

The value of "I" can next be computed from either Eqs. (2) and (5) or from Eqs. (4) and (6). In this computation it is reasonable to pair the equations in this manner since (as discussed above) the focusing of a screen should be the same as that of a can of the same dimensions. "b_{neg}" is used since these equations are for negative potentials. The value computed from Eqs. (2) and (5) is termed "I" in Table I and that from Eqs. (4) and (6), "I_{check}." This amounts to a check on the consistency of the data from the two screens. It is thus an indication of the reliability of the determination of the magnitude of "I."

The value of "c" can be computed either from Eqs. (2) or (4), using "b_{neg}." Since these were the equations used in computing "b_{neg}," this allows no check.

The value of "i" can be computed either from Eqs. (1) or (3), using "b_{pos}." Since these were the equations used in computing "b_{pos}," this also allows no check.

Table I includes the computed values of these unknowns for P^{32} and Na^{22}. The observed numbers of particles per second listed are for typical sources of these materials, and are the values from which the unknowns listed were computed. It must be emphasized that the uncertainties attached to these figures are based exclusively on the observed variations in the observed currents.

Table I also includes the values of the correction factors by which the observed large screen negative currents must be multiplied to obtain the average of the computed "I's".

In order to determine the effect of the supporting foil on the number of particles observed, measurements were made with a "cover" foil over the active side of the supporting foil. This foil was identical to the first, including the aluminum supporting ring and the 6.5 mil copper wire. It was attached to the supporting foil by means of loops of fine wire or thread, and all points of contact were Aquadagged. The addition of the cover foil can change the number of primaries or of secondaries leaving the active side of the source structure. The number of primaries can only be decreased, of course, while the number of secondaries could either increase or decrease depending on the relative efficiency of production of aluminum *versus* that of whatever materials may be deposited with the active material. Since the added foil only affects half the particles, the change observed upon adding it will be the same, except for reflected particles, as the previously unknown effect of the original supporting foil. Because of the existence of reflected particles, this gives an upper limit to the correction for the presence of the supporting foil.

The data presented in Fig. 3 shows that the cover foil does not make any significant change in the number of particles of energy greater than about 100 ev for P^{32} or about 40 ev for Na^{22}, while there is a considerable change in the number below this energy. Table II shows that i for P^{32} varies with the amount of solids deposited, although rather erratically. Except for Source No. 29, the average thickness of the solids was of the order of 1 micron, so that the erratic behavior may be attributed to local variations in the thickness of the deposit. However, the reduction of i by the cover foil to essentially the same value as for minimal solids (Source No. 29) with no cover would indicate that most, if not all of these particles are secondaries. Since the effective atomic number and the surface condition differ for the deposited solids and the clean foil, a change in the efficiency of production of such low energy secondaries is to be expected. The interpretation of these low energy particles as secondaries is also consistent with theory[9] which shows that secondaries should be mostly of very low energy, with the number decreasing rapidly with increasing energy as Fig. 3 demonstrates. The Na^{22} data confirm this interpretation in two ways. First, since it is a positron emitter, all negative particles must be secondaries. The low energy particles from this isotope are clearly negative, from Fig. 2, and are of about the same energy distribution as for the phosphorus sources of comparable amounts of solids. Secondly, the distribution with the cover foil in place is essentially the same as for the covered phosphorus source. Thus there are very few, if any, primary particles observed of energy less than 600 ev.

Since few particles are found in the energy region between 600 ev and 3000 ev, as shown by Fig. 2, there are few secondaries of energy greater than 600 ev. This is confirmed by the observation that there is no detectable change in the number of particles in this energy range caused by the addition of the cover foil.

Because there are few, if any, primaries of energy less than 600 ev and there are at most few secondaries of energy greater than 600 ev, the current as observed with the large screen at a negative potential of 600 volts with respect to the source, corrected by the computed factor, gives an accurate measurement of the activity of these isotopes.

---

V. DISCUSSION

In the case of P^{32} it will be seen from Table I that the observed current leaving the source structures can be corrected for the effects of the surrounding structures. Thus the magnitude of the current leaving the source can be determined with a known maximum uncertainty representing the sum of the known uncertainties. From the observed internal consistency of the measurements there is an uncertainty of about 0.5 percent. From the compensating condenser calibration, about 1 percent; from the voltmeter calibration, about 0.5 percent. Thus the maximum uncertainty in the current leaving the source is about 2.0 percent. However, this still leaves the uncertainties in interpretation of this observed current. In view of the cover foil experiments described above, the maximum error introduced by taking all particles of energy less than 600 ev as secondaries and all of energy greater than 600 ev as primaries may be estimated as about 3 percent. Accordingly the over-all accuracy in measuring the activity of P^{32} by this technique may be estimated to be about 5 percent under the conditions of this experiment.

As a check on the possible existence of systematic errors, an indirect inter-check with P^{32} was made with the Bureau of Standards. This inter-check was made near the first of November, 1948, and the agreement was well within experimental error.

For Na^{22}, the same sources of error exist as for P^{32}. However, since Na^{22} emits a gamma-ray of about 1.3 Mev as well as annihilation radiation, these must also be considered. These radiations can only affect the measurements by the production of secondary electrons. Any secondaries produced in the walls of the vacuum chamber or the large screen are automatically taken into account in the correction factor. It may be noted in Table I that the effects of the surroundings are not very different for the two isotopes, indicating that the effects of the electro-magnetic radiations are certainly small. The effects of these radiations on the source supporting structures must also be small, because, for the atomic numbers involved, the cross section for the production of secondaries by photons of these energies is much less than that of charged particles. Thus any effects of these radiations may safely be included in the 3 percent allowed for the possible existence of low energy primaries and high energy secondaries. Accordingly the over-all precision in measuring the activity of Na^{22} by this technique may be estimated to be about 5 percent under the conditions of this experiment.

In comparing this technique with counter techniques, it may be noted that here particles are included of much lower energy than counters can reliably detect. In addition, counters will also include many of the high energy secondaries which this technique records. Thus the principal source of error in this technique is also a source of error of roughly the same magnitude for counter techniques. This is in addition to the difficulty of reliably establishing the other corrections required for counter measurements of activity. Given, then, a reliable determination of the importance of the low energy primaries and the high energy secondaries, this technique allows a precision limited only by the precision with which currents of the order of 10^{-13} amperes can be measured. Using the compensation technique described in this paper, this only requires increased precision in the compensating condenser calibration and the compensating voltmeter calibration in order to achieve a precision limited only by the observed internal consistency of the data (0.5 percent for P^{32} and Na^{22}). Thus this technique makes possible a considerable improvement in the precision of measurement of beta-ray activities.

The author is deeply indebted to Dr. G. Failla and Dr. H. H. Rossi, each of whom participated in many helpful discussions and had independently thought of using this technique. Many useful suggestions were also contributed by Mr. N. Baily.

Electronic Pile Simulator

P. R. BELL AND H. A. STRAUS*
*Oak Ridge National Laboratory,*** *Oak Ridge, Tennessee*

(Received April 18, 1950)

A device has been made that follows the same set of kinetic equations as a chain-reacting pile. The voltage output varies as a function of time as the neutron flux would vary in a pile. A potentiometer varies the effective multiplication factor and can be considered as a control rod. Five delayed neutron periods are simulated. A high precision electronic integrator is used, and the instrument is capable of an accuracy much better than one percent.

THE neutron flux in a graphite-uranium chain-reacting pile decreases or increases when a control rod or other absorber is moved into or out of the pile. The way in which the flux increases or decreases is of some interest as one might wish to keep the pile output constant by an automatic controller or one might wish to know the change in flux with time produced by an absorber. It is possible to make an analog computer or simulator that responds exactly as a pile does to changes in absorption. Such an instrument serves admirably for the design of controllers or for demonstration or training.

If one assumes that the neutrons produced by the fission process are slowed down without absorption and are absorbed only as thermal neutrons, then the number of thermal neutrons per cm^3 (n) is given by the relation

$$dn/dt=(\delta k_{\text{effective}}/kl^*)n-(\beta/l^*)n+e^{\tau\Delta}\sum_i \lambda_i C_i+S, \quad (1)$$

where

$l^*=l/ke^{\tau\Delta}=(1/ke^{\tau\Delta})\cdot(\lambda_a/v)$ = effective mean life of the neutrons from formation by fission to absorption or loss from pile by leakage.
$k=\nu\,\Sigma_f/\Sigma_{\text{total}}$ = number of neutrons per fission × (macroscopic cross section for fission/macroscopic total absorption cross section).
k = multiplication constant that pile lattice would have if it were of infinite extent.
τ = "Fermi age" of the neutrons, a measure of the net distance traveled by a neutron while being slowed down.
Δ = Laplacian representing the relative spatial distribution of the neutron flux. This is essentially a constant with time since the flux distribution is independent of the power level of the pile.
$\delta k_{\text{effective}}$ = reactivity of the pile $=(L^2\Delta-1+ke^{\tau\Delta})$.
L = diffusion length for thermal neutrons.
β = fraction of the fission neutrons coming from all delayed neutron emitters.
λ_i = decay constant of the ith kind of delayed neutron emitter.
C_i = concentration in atoms per cm^3 of the ith kind of delayed neutron emitter.
S = source in neutrons per cm^3 per second, other than those produced from neutron induced fission.

The first term on the right-hand side of Eq. (1) represents the effect of control rods or other absorbers upon the pile flux and is zero when the pile is in equilibrium at any value of neutron flux. The second term is inserted to correct for the fraction of the fission neutrons of each generation that does not appear instantaneously, and the third term represents the contribution of each of the delayed neutron emitters. The second and third terms must be equal when the pile is in a steady state at a constant flux. The fourth term represents the contribution of spontaneous fission, cosmic rays and other neutron sources that are not affected by adjusting the control rods of the pile.

The concentration of each delayed neutron emitter is a function of time depending on the past history of the pile. The rate of change of each delayed emitter is given by Eq. (2).

$$dC_i/dt=-\lambda_i C_i+(e^{-\tau\Delta}/l^*)\beta_i n. \quad (2)$$

Here β_i represents the fraction of the total fission neutrons formed from this particular delayed emitter. It is clear that the sum of these fractions β_i must be equal to the total fraction β.

The solution of differential equations of this type with variable coefficients can generally be accomplished by the use of a feed-back equation solver, which in principle is a very quick-operating trial and error method generally employing electrical circuits. In the electronic pile simulator the number of neutrons per cubic centimeter, n, is represented by a voltage and the other quantities involved in the equation are represented by other voltages or currents or by suitable circuit constants.

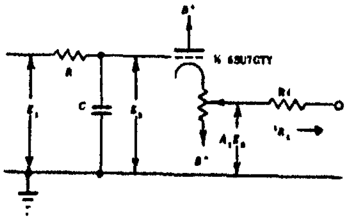

FIG. 1.

The circuit of Fig. 1 is used for the solution of Eq. (2). In this circuit

$$dE_2/dt=i/C=(E_1-E_2)/RC. \quad (3)$$

If $1/RC=\lambda_1$ and E_1 represents n, then

$$dE_2/dt=-\lambda_i E_2+\lambda_i n. \quad (4)$$

This equation is like Eq. (2) with

$$(e^{-\tau\Delta}\beta_i/l^*\lambda_i)E_2=C_i.^1 \quad (5)$$

---

* Now at Bendix Radio Corporation, Towson, Maryland.
** Contract W-35-058-eng. 71.

[1] The delayed neutron periods were taken from Table I, Bernstein, Preston, Wolfe, and Slattery, Phys. Rev. 71, 573 (1947).

The tube connected to E_2 is operated as a cathode follower. If the amplification factor (μ) of the tube is high and the load in the cathode circuit is a high resistance the gain (A) is nearly unity

$$A=1/[1+(1/gR_k)+1/\mu], \tag{6}$$

where R_k is the resistance of the load circuit measured from cathode to ground. In this instrument $A\approx 0.98$.

Potentiometers $R_{5,6,7,8,42}$ (Fig. 2) are located in the cathode circuits of the cathode followers and the gain at each potentiometer arm (A_i) includes the tube gain and the "gain" of the potentiometer. The internal resistance of the cathode follower and the potentiometer measured at the arm is so small that it can be neglected. To the arm of each potentiometer is attached the "adding" resistor R_i, and the far ends of these resistors are attached to point P which is essentially at a fixed potential. The current in each resistor is given by

$$i_{Ri}=(A_i/R_i)E_2=(A_il^*/R_i\beta_i)e^{\tau\Delta}\lambda_iC_i. \tag{7}$$

Thus if the voltage $E_1=n$, then the current given by this circuit at P is one of the elements of the sum in the third term of Eq. (1) with a scale factor $A_il^*/R_i\beta_i$. The first term in Eq. (1) can be represented very easily. Let us suppose a potentiometer is connected between a voltage representing n and a voltage representing $-n$. Then for the voltage E at the tap on the potentiometer we have

$$E=Dn, \tag{8}$$

where D is the linear scale of the potentiometer with zero at the center, $+1$ at the $+n$ end and -1 at the $-n$ end.

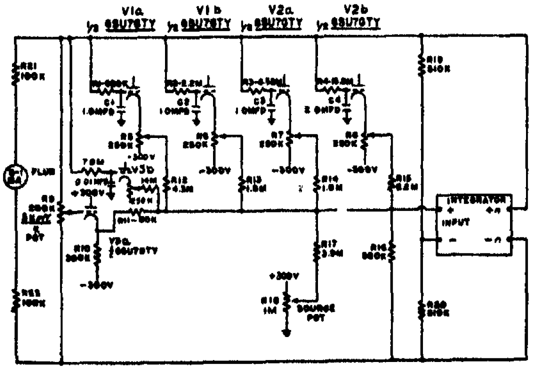

FIG. 2.

A cathode-follower circuit similar to that used in Fig. 1 is connected to the tap of the potentiometer and the current, i, in the output or adding resistor R_{11}, if the far end of this resistor is kept at a fixed potential, will be given by

$$i=(A_KD/R_{11})E$$
$$=[A_K/R_{11}(\delta k_{\text{eff. max.}}/kl^*)](\delta k_{\text{eff.}}/kl^*)n, \tag{9}$$

where A_K is the gain of the cathode follower and $(\delta k_{\text{eff.}}/kl^*)/(\delta k_{\text{eff. max.}}/kl^*)=D$. This current i represents

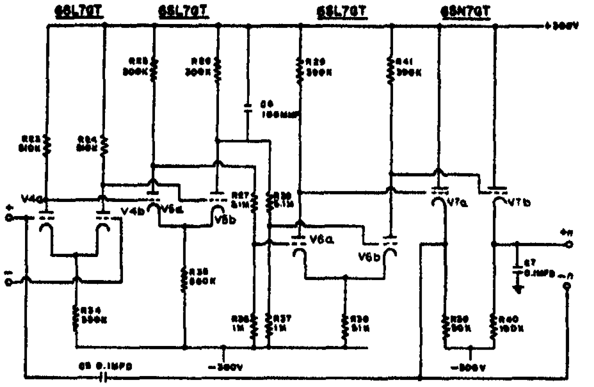

FIG. 3.

the first term in Eq. (1) with a term in brackets as a scale factor. In this instrument $(\delta k_{\text{eff. max.}}/k)$ was arranged to be ± 0.05.

The second term in Eq. (1) is obtained from a resistor (R_{16}, Fig. 2) connected to the voltage representing $-n$. The current in this resistor (if the opposite end is fixed in voltage) is

$$i=-n/R_{16}=-(l^*/R_{16}\beta)(\beta/l^*)n. \tag{10}$$

Nothing has been said, so far, about the fact that although the output of a cathode follower changes at a rate A times its input there is also a constant difference of voltage. This constant voltage difference is the bias required by the cathode-follower tube when its input is at its "zero input" or reference voltage. The reference voltage is obtained when the $+n$ and $-n$ points have no voltage difference. There are enough disposable values to allow one to arrange things so that the tubes are operating at all times on a satisfactory part of their characteristics. A potentiometer (source potentiometer) is included to represent a source of neutrons and compensates the residual constant voltage difference of the cathode followers which would by itself represent a source of neutrons. The potentiometers $R_{5,6,7,8,42}$ in the cathode follower circuits are adjusted so that the residual constant voltage difference term which must be corrected by the source potentiometer is quite small.

When the ends of the adding resistors like R_1 in Fig. 1, R_{11} and R_{14} (Fig. 2) are all connected together to a common point P there will be (if the point P is kept at a fixed voltage) a total current

$$i_{\text{total}}=[A_K/R_{11}(\delta k_{\text{eff. max.}}/kl^*)](\delta k_{\text{eff.}}/kl^*)n$$
$$+e^{\tau\Delta}\textstyle\sum_i(A_il^*/R_i\lambda_i)\lambda_iC_i-(l^*/R_{16}\beta)(\beta n/l^*)$$
$$+[(i_{\text{source}}+i_{\text{const}})/S]S, \tag{11}$$

where i_{const} is the current due to the several constant voltage differences in the cathode followers and i_{source} is the current contributed by R_{17}, the sum of these last two terms represents the source term in Eq. (1).

All that remains now is to connect point P to a circuit that will produce, as its output voltage, the time integral of the total current at P multiplied by an appropriate

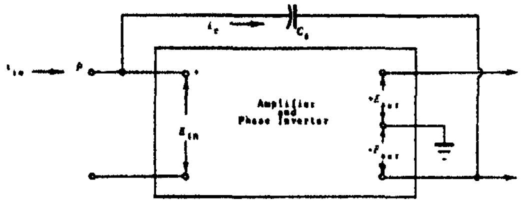

FIG. 4.

constant. This output voltage then would represent *n*. If a voltage changing equally but in the opposite direction is also produced, these voltages may then be connected to the parts of the circuit whose inputs are required to be *n* or $-n$. The whole instrument will then operate to give *n* as a function of time as required by the set of Eqs. (1) and (2). As long as the various elements of the circuit are operating in the range of voltages or currents in which their performance is satisfactory, the system approximates the relations we have assumed.

The integrator section of the instrument is the circuit whose output voltage is the time integral of its input current. The details of this section are shown in Fig. 3, and the operation may be more easily understood from the simplified diagram Fig. 4.

The point *P* is connected to a grid and one end of condenser C_6. This grid is in the negative grid region and the grid current is negligible so that the input current i_{in} at point *P* must be equal to the condenser current i_c but

$$\int i_c dt = C_6(E_{out} - E_{in}) = \int i_{in} dt. \tag{12}$$

If the voltage gain (*A*) of the amplifier in Fig. 4 is very great then E_{in} is very small compared with E_{out} and

$$\int i_{total} dt = \int i_{in} dt = C_6 E_{out} \tag{13}$$

is a good approximation.

The actual amplifier used (Fig. 3) is of the "differential" type in that it responds only to the difference in voltage between the two input grids. This effect is produced by the use of unbypassed cathode resistors.

The two nearly equal resistors, R_{19}, R_{20}, feed one of the input grids ($-$input) with one-half of the algebraic sum of the $+n$ and $-n$ output voltages, and only the difference between the voltage of this grid and the voltage at point *P* ($+$input) is amplified. This arrangement converts the circuit into a bridge and greatly reduces the effect of any errors in the phase-inverting action which produces $+n$ and $-n$; in addition if R_{19} is the right amount larger than R_{20} the effective gain of the integrator may be made infinite. A condenser C_7 is connected from the $+n$ output to ground to make the loading symmetrical.

It can be seen that the action of the integrator-amplifier opposes any change in the voltage difference between the $+$input and $-$input by supplying a current through the integrating condenser C_6. This keeps point *P* at a constant voltage relative to the algebraic sum of $+n$ and $-n$, that is, approximately constant with respect to ground as was assumed when considering the currents in the adding resistors.

Using Eqs. (13) and (11) we find

$$\begin{aligned}(C_6)dn/dt = {}& [A_K/R_{11}(\delta k_{\mathrm{eff.\,max.}}/kl^*)](\delta k_{\mathrm{eff.}}/kl^*)n \\ & + e^{r\Delta}\sum_i [A_i l^*/R_i\beta_i]\lambda_i C_i - (l^*/R_{16}\beta)(\beta n/l^*) \\ & + [(i_{source} + i_{const})/S]S. \end{aligned} \tag{14}$$

The quantities in the brackets are scale factors for each term. The condenser C_6 is 0.1 microfarad, which is the largest value for which the maximum integration current required can be supplied by tubes $V3_a$ and $V7_a$. The choice of C_6 fixes the value to which the other scale factors must be adjusted.

The errors in this instrument are mostly in the integrating circuit and these errors arise as follows:

Let us suppose that the amplifier of the integrator has an initial gain of 1000 and the resistor pair R_{19}–R_{20} is adjusted to supply just the amount of positive feedback required to make the effective gain infinite. If the differential gain of the amplifier falls to 500 at full output

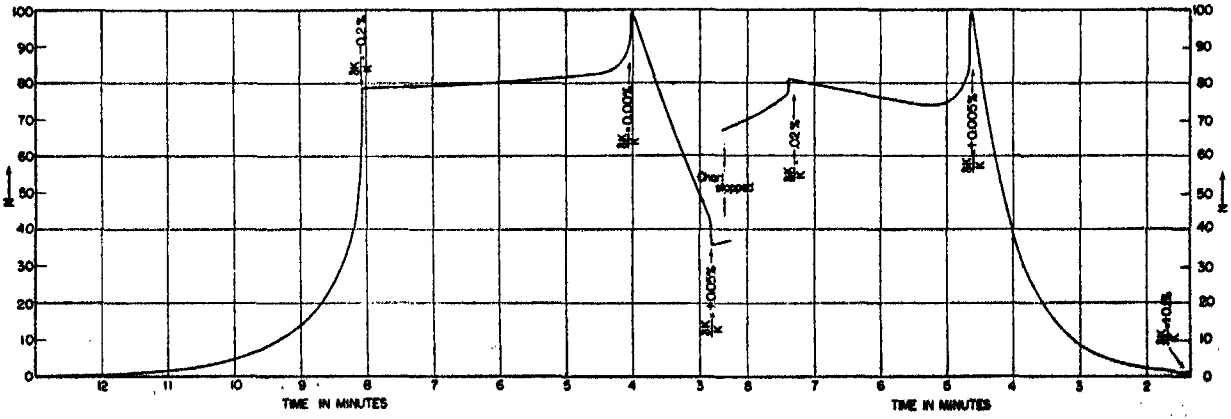

FIG. 5.

(100 volts), the signal required at the grids would be 0.2 volt, and the positive feedback would supply only 0.1 volt thus requiring the input signal to supply the remaining 0.1 volt. If the simulator output was rising initially with a 30 minute period due to a signal from the $\delta k_{\text{effective}}$ potentiometer of $\delta k/k_{\text{effective}}=0.005$ percent, the output would just cease rising when this amount of non-linearity had set in. Another kind of error due to the integrator circuit is drift or fluctuation of the output due to changes in contact potential in the first double triode. These fluctuations limit the range of n to about 5×10^3.

The last noticeable source of error is the variation in gain of the delayed neutron cathode followers. The current in these cathode followers varies about 30 percent from no output to full output. This change of current gives a variation of g of about 10 percent and results in a change of gain of about 0.03 percent. The effect due to the change of μ is still smaller. Since the total contribution of all the delayed neutron emitters is roughly 0.7 percent of the total neutrons, this small change in gain produces an error that has the same effect as a change in $\delta k_{\text{effective}}/k$ of 0.0002 percent.

The complete instrument must be adjusted experimentally to determine the exact setting of the source potentiometer, R_{18}, that represents zero source strength. It must be noted that this instrument, unlike the pile, is completely symmetrical with respect to the zero output point and may be caused to build up on either "positive" or "negative" neutrons depending on the source setting. In addition to the source zero the position of $\delta k_{\text{critical}}$ must be determined on the δk potentiometer. A satisfactory procedure is to set the δk potentiometer slightly more negative than the apparent position of $\delta k_{\text{critical}}$ and then slowly adjust the source potentiometer, allowing several minutes to elapse between each adjustment, until the n meter gives only an extremely small positive reading. The δk potentiometer should then be adjusted to cause the output to rise slowly (say 10–20 min. to reach full output) and the output plotted against time. If the δk potentiometer is at $\delta k_{\text{critical}}$ the output will rise linearly due to the small source; if the reactivity is positive the curve will bend upward; if the reactivity is negative the curve will bend downward. Slight readjustments can now be made until a very small change in the source potentiometer setting causes the output to rise or fall linearly with time. The setting on the source potentiometer is then zero source, and the setting on the δk potentiometer is $\delta k_{\text{critical}}$.

Figure 5 is a tracing made from a Brown recorder record of the output voltage n against time as the δk potentiometer, which represents the control rod of the pile, is moved as shown on the tracing. Note the transient effects whenever the control rod is moved. The output approaches a pure exponential curve as the transient dies away.

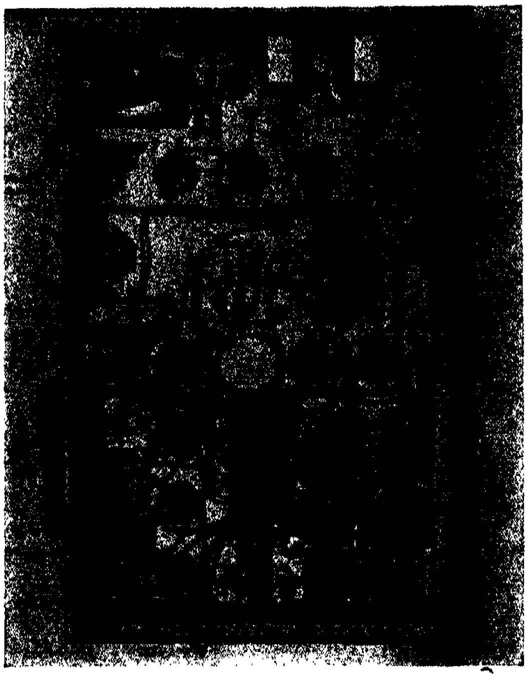

FIG. 6.

Figure 6 is a photograph of the bottom of the chassis of the simulator. The row of four tubes is the integrator section. All of the delayed neutron storage condensers except C_8 are invisible because they are above chassis. These condensers are Western Electric type D 161270 1 μf units chosen for their extremely low leakage and "soaking up" effect.

Anyone attempting the construction of an instrument of this type should place the leads with care, especially in the integrator section, and employ an oscilloscope to check the absence of high frequency parasitic oscillations. Condenser C_6 was added to suppress such an oscillation. When the δk potentiometer is mounted in a remote location it is necessary to shield separately the lead from the arm to prevent coupling between this lead and the $+n$ lead. Such coupling will produce oscillations at a high frequency.

We wish to acknowledge the valuable suggestions of F. H. Murray during the planning of this instrument.

An Infra-Red Microspectrometer for Biological Research

DARWIN L. WOOD*
Mendenhall Laboratory of Physics, Ohio State University, Columbus, Ohio

(Received May 15, 1950)

The apparatus herein described consists of a totally reflecting microscope of numerical aperture 0.6 coupled with a Perkin-Elmer Model 12C infra-red prism spectrometer. The combination makes possible the recording of infra-red spectra of individual cells of biological materials over the familiar range from 1 to 15μ, and has been particularly designed for the study of muscle fibers. The techniques for producing aspheric optics used in the microscope are discussed. Some preliminary performance data are given.

VARIOUS authors have described the optics of reflecting and reflecting-refracting microscopes.[1–6] Others have described the combination of microscope and infra-red spectrometer.[6–8] In all but one of these references (7), the microscope was either of low aperture or contained refracting elements which absorbed longer wave-lengths of the infra-red. It is the purpose of this paper to describe the relatively high aperture totally reflecting aspherical system built by the author.

The optical parts of the microspectrometer are shown in Fig. 1, with the elements in the same relative positions as in the photograph of Fig. 2. On the left in front is the source unit consisting of a self-starting Nernst filament N and a high aperture spherical mirror combination (M_1 and M_2) which fills the entrance pupil of the microscope condenser (M_5 and M_6) with radiation. From the condenser (M_5 and M_6) the radiation proceeds through the tissue specimen at S to the objective (M_7 and M_8), which forms an enlarged image of the tissue on the screen *Sc*. By properly positioning the specimen on the stage of the microscope, the desired portion of the specimen is selected to fall on the aperture of the screen *Sc* and the radiation passing through the aperture is focused on the slit of the spectrometer by the mirrors M_{10} and M_{11}. The mirrors M_3, M_4, M_9, and M_{11} are plane first surface mirrors folding the optical path into a convenient shape. It should be pointed out that the mirror combination M_1 and M_2 is merely a convenience, introduced to give a uniform illumination to the whole area of the image on the screen at *Sc*. Without this pair of mirrors only a small area of the magnified image (about the size of the source) will be illuminated. It makes little difference whether these mirrors are in the system or not as far as the amount of the energy received by the detector of the monochromator is concerned. The monochromator, as is evident from the photograph of Fig. 2, is that of the Perkin-Elmer Model 12*C*. The detecting system is the 7-cycle/sec. a.c. thermocouple system which is standard equipment on the Model 12*C*. The radiation interrupter can be seen just in front of the slit in Fig. 2. It is mounted in ball bearings in a brass block and is connected to the Perkin-Elmer synchronous rectifier camshaft by a flexible cable.

The whole auxiliary optical system for the microspectrometer is mounted on a heavy aluminum casting which fits over the standard spectrometer without disturbing the optical arrangement used in making macrospectra. Indeed, for use with d.c. operation where the radiation chopper is not needed, the auxiliary system can be installed without disturbing any part of the standard spectrometer. For the a.c. operation, it is necessary to remove the smaller housing of the spectrometer so that the synchronous rectifier camshaft can be reached with the flexible cable from the chopper. The microscope assembly, which is patterned to some extent after the ordinary light microscope, can be removed as a unit from the auxiliary optical system for use by itself.

The microscope optics are aspherical and follow the design of Burch.[1] The aspherical optics are necessary if the microscope is to have a reasonably large numerical aperture, as shown in Burch's paper. The objective and condenser form a symmetrical pair of effective numerical aperture 0.6 with a magnification of about 65× at the screen *Sc* of Fig. 1. Such high magnification is perhaps more than necessary, but it is very convenient when it comes to selecting the areas of the specimen to be examined. The mirror M_{10} provides some subsequent demagnification at the slit.

The microscope mirrors M_6 and M_7 are commercially available spherical segments, convex, 6 mm in diameter, and about 4.3 mm in radius of curvature. The mirrors M_5 and M_8 are aspherical, concave, 8 cm in diameter, and roughly 5 cm in radius of curvature. The large diameter of the concave mirrors is desirable to facilitate the aspherization. It causes no difficulty in practice, although it might offend the aesthetic sense of the conservative light microscopist.

Tests of the objective in visible light indicate that the resolving power is quite adequate for infra-red work. Using a stage micrometer ruled with lines 10μ apart, it was deduced that the objective would resolve lines 3 to 5μ apart. The image in visible light is quite good enough to select the portions of a piece of tissue for examination, and structures smaller in dimension than the wavelength of the radiation used for the examination are, of course, not observable.

To dispel the impression that aspherical objectives are prohibitively difficult to produce, some of the production techniques used by the author will be described. Let it be said at the outset that the aspherical mirror is not more difficult to figure than, for instance, an ellipsoid of the same depth of curve, and a focal ratio not far from unity. Furthermore, for the tolerances required for the infra-red, the figuring need not be particularly precise.

To start with, it was found that a local optometric supply house was equipped to supply glass blanks ground and polished to the spherical curve most nearly approximating the finished shape, so that the problem remaining was one of figuring these blanks. To do the figuring properly one needs first a good testing procedure, and second a polishing technique with which to change and control the shape of the surface.

The testing technique used in this work was a variation of the familiar Foucault knife edge test. A diagram of the arrangement as it was set up on an optical bench is shown in Fig. 3. A small, bright source of light about 1 mm in diameter is located at A. At B a standard 1.8-mm focal length microscope objective forms a greatly reduced image of the bright source A. The aspherical mirror under test is assembled in its proper position in the reflecting microscope objective housing, and located at C, "looking" at the reduced image of the source produced by the refracting objective at B. The refracting objective must have sufficient aperture to fill the large concave mirror of the reflecting objective with light. Then at D a knife edge is arranged with a screw adjustment so that it can be moved gradually across the enlarged image produced by the reflecting objective C when focused on the virtual source formed at B. The telescope F receives light from the small convex mirror of the reflecting objective, and is focused on the surface of the large concave mirror which is being tested. The telescope shows a bright field in its eyepiece which is to go dark all at once when the knife edge is moved across the ray bundle at D. The telescope has sufficient magnification to enlarge the field of the exit pupil of the reflecting objective up to the point where the various areas of the large convex mirror can be conveniently examined. As the correction of the objective improves, the contrast of the knife edge shadow pattern can be increased by placing a pinhole in a piece of aluminum foil in front of the 1-mm diameter hole at A to diminish the size of the virtual source at B.

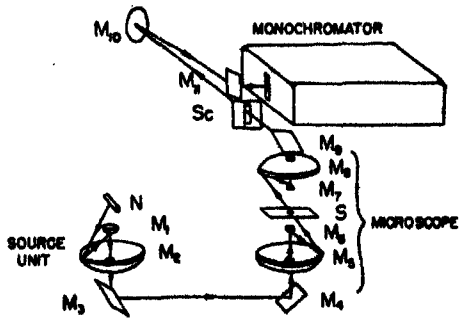

FIG. 1.

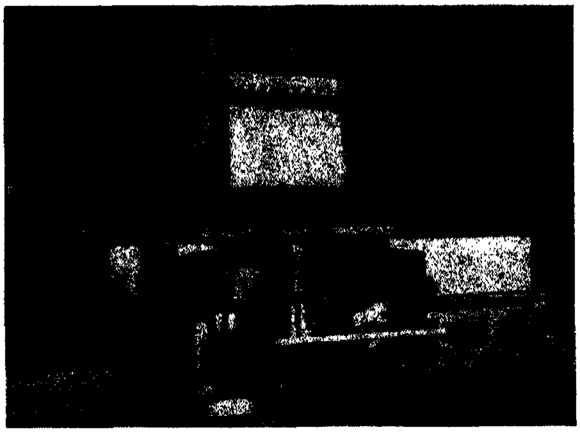

FIG. 2.

To supplement the knife edge test an eyepiece may be introduced at E, and some information about the objective may be obtained through the so-called eyepiece test. Both tests worked well with the convex mirror aluminized but the large concave mirror not coated.

The polishing technique actually involved more than just polishing, since the aspherical surface was so far from a sphere. It was found convenient to do some grinding before the surface could be brought in by polishing with rouge. The grinding and polishing operations were carried out on a rotating spindle such as commonly used by the producers of ophthalmic lenses. The only necessary deviation from ordinary optical shop practice was the use of the flexible lap in both grinding and polishing. The laps were of two kinds: a metal one for grinding, and a pitch lap for polishing. The metal lap

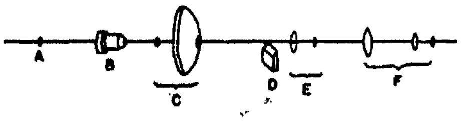

FIG. 3.

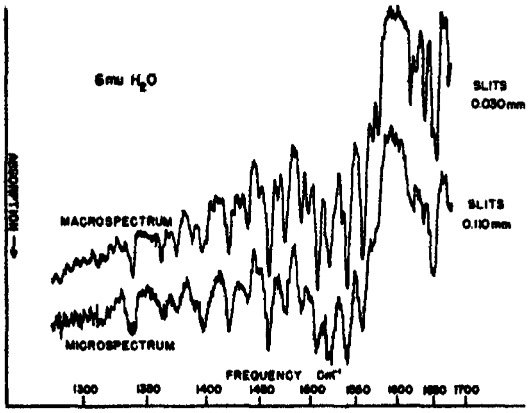

FIG. 4.

was made by casting Woods metal between the glass surface to be aspherized and a cast iron spherical form of a suitable curvature. A second cast iron spherical lap was then covered with a piece of sponge rubber about 0.125 in. thick and the cast Woods metal lap was waxed to the sponge rubber with beeswax. The metal was cut into facets about ½ in. sq. with a jeweler's saw, and the appropriate facets removed to grind down the "high" zones of the mirror. An obvious variation of this procedure came after one aspheric surface had been finished. This was to cast the Woods metal against the aspheric surface and use the rigid aspheric lap thus produced to grind in the asphericity on the second mirror. By this means it was possible to eliminate the metal flexible lap grinding step, and proceed directly to the polishing steps.

The pitch polishing lap was made in much the same way as the metal grinding lap. The pitch layer was applied directly to the sponge rubber layer on the cast iron base. Hard pitch was used, and it was formed against the surface to be polished in the usual manner. When the lap was cold, it was struck with a hammer, and a multitude of facets was thus produced. By painting the lap with a thin coating of beeswax the scratches from the hard pitch were minimized. The lap was cut down where the test showed the mirror surface to be low, and it was not disturbed where the test showed it to be high. With this lap, then, the shape of the surface was worked until the knife edge test showed sufficient correction. For the last few stages of the figuring the mirror was worked with the spindle stationary.

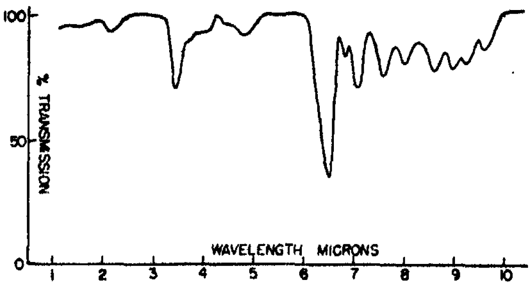

FIG. 5. Frog muscle single fiber absorption spectrum.

Typical results with the microspectrometer are indicated in Figs. 4 and 5. In Fig. 4 is shown a microspectrum of the 6μ-atmospheric water band and a macrospectrum of the same part of the same band recorded with the spectrometer in its standard form. It will be quickly seen that there is a loss in resolution because of the larger slit widths required by the microscope in the optical path. The microspectra require slits almost four times as large as those for ordinary macrospectra. The microspectrometer will be useful, none the less, over the same range as the macrospectrometer in spite of the diminished resolution.

In Fig. 5 is shown a composite microspectrum of single live frog muscle fibers supported between fluorite plates. The excessive interference of the aqueous medium and the cellular water has been partially compensated for by measuring the percent transmissions relative to the Ringer's solution just next to the muscle fiber in the preparation. It is expected that considerable information on the contractile mechanism of muscle will become available from further studies of the microspectra of muscle fibers, and muscle extractives.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 8 AUGUST, 1950

Modification of the Apparatus Used for the Baldes Thermoelectric Method of Measuring Osmotic Pressure*

V. Everett Kinsey
Howe Laboratory of Ophthalmology, Harvard Medical School, Boston, Massachusetts

(Received April 28, 1950)

The apparatus employed with the Baldes method for determining osmotic pressure has been modified by substituting a breaker-type d.c.-a.c. amplifier for a sensitive galvanometer, thereby permitting its use under conditions where galvanometers are impractical. Precise temperature control of the water bath in which the thermoelements are immersed has been shown to be unnecessary provided the bath is stirred vigorously. A switch made from one block of electrolytically pure copper provides a satisfactory current-reversing mechanism with low interfering contact potentials arising from non-thermostated portions of the circuit.

BALDES[1] has devised an excellent method for determining osmotic pressure which is applicable to quantities of fluids of the order of several microliters. More widespread application of this method has probably been lacking because of the complexity of the apparatus required. The present paper is concerned with several modifications of this apparatus which, while maintaining the accuracy of the method, offer advantages which permit measurement of osmotic pressure to be made more easily and under a wider variety of laboratory conditions.

The apparatus, as described in detail by Baldes, consists of a double thermocouple enclosed in a small water-tight chamber, the inside walls of which are lined with filter paper moistened with a solution having an osmotic pressure approximately the same as that of the solution to be determined. The chamber is immersed in a water bath the temperature of which Baldes maintained constant to 0.001°C. Leads from the thermocouples connect with a galvanometer having a sensitivity of 10^{-9} ampere through a double-throw, double-pole switch.

The two features of the method which involve the most elaborate components of the apparatus are the measurement of extremely small voltages set up by the thermocouples and the maintenance of the temperature of the water bath to within 0.001°C. A third complication is concerned with possible spurious electromotive forces arising from contact potentials in the non-thermostated double-pole, double-throw switch.

AMPLIFIER

Because the Howe Laboratory is located close to heavy city traffic it was not possible to use a sensitive galvanometer to measure the voltages without taking elaborate precautions to damp the instrument. The latter would require excessive space and expensive equipment. Direct current amplifiers are frequently unsatisfactory when great amplification is required. However, a satisfactory substitute for the galvanometer was found in a breaker-type d.c.-a.c. amplifier (Perkin-Elmer Corporation, Model 53). This instrument operates satisfactorily in a range between 0.1 and 300 microvolts and is designed to change d.c. into a.c. current by mechanical means, amplify the current in this form, and reconvert it to d.c. whence it can be measured on any common indicating instrument such as a milliameter. The sensitivity of the amplifier approaches the theoretical limit imposed by thermal agitation in the input circuit, and is particularly suited for amplification of thermal e.m.f. when both voltage and impedance are low.

Despite these desirable features, when the instrument was set for medium amplification it did not give satisfactory results when employed with the thermocouple elements because of oscillation of the needle on the milliameter. The oscillations were presumably due to the effect of slight contact noise in the room. Insertion of a capacitance (2000 mfd, 6 working volts) in parallel with the milliameter, however, completely eliminated this difficulty. In practice the gain was set so that 0.5 microvolt corresponded to full-scale deflection (1 milliampere) on the milliameter. Increased amplification could be obtained by advancing the gain but much of the advantage is offset by variations in voltage arising apparently from contact potentials from non-thermostatted parts of the circuit. The breaker-type d.c.-a.c. amplifier has been in use over a period of two years and is satisfactory except for the occasional need of replacing amplifier tubes and bias cells.

THERMOSTAT

The second modification of the apparatus involves the need for controlling the temperature constant to 0.001°C. Initially, temperature control was accomplished by constructing a copper water bath 18 inches on a side. The four sides and bottom of the tank were surrounded with one inch of cork and a five-eighths inch plywood box. The tank was then sunk in an ordinary laboratory bench and the top covered with a one-fourth inch Lucite plate. Stirring was accomplished with a one-twentieth horsepower electric motor using a two inch, three-bladed propellor. The temperature was controlled by means of a thermoregulator consisting of a twenty-foot glass helix filled with mercury, feeding into a

[1] E. J. Baldes, J. Sci. Inst. 11, 223 (1934).

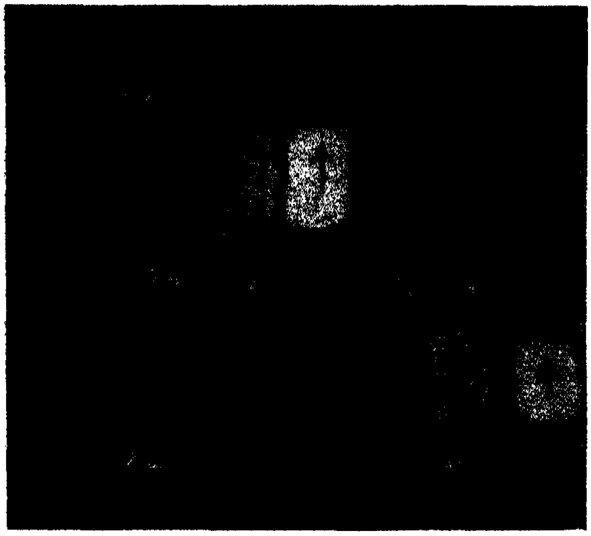

Fig. 1.

capillary. Consideration of the problems involved in controlling temperature, however, suggests that if the temperature were maintained constant to within 0.001°C over all parts of the surface of the brass jacket surrounding the thermocouples, no further precautions would be necessary. This could be accomplished presumably by stirring the bath vigorously even though the temperature of the water in the bath may vary considerably from moment to moment.

To test this idea, the water was permitted to assume the temperature of the room, stirring was continued as before, but the thermoregulator was disconnected. Measurements were made using 150 millimolar solution of NaCl on one couple and 145 millimolar solution of NaCl on the other. The difference in concentration amounting to a 5.0 millimolar solution gave rise to a reading of 0.15 milliampere (0.073 microvolt) and the greatest variation between replicate readings was ±0.015 milliampere.† This variation was no greater than that obtained when the temperature of the water bath was maintained constant to 0.001°C. To eliminate the possibility that temperature conditions might have been unusually favorable on the day in which the experiments were performed, for example, with respect to draughts, a more critical test was arranged by elevating the temperature of the bath to 32°C, or about 8° above room temperature, and another series of measurements was made (without any temperature regulation). Under these circumstances the temperature of the water in the bath fell at a rate of 0.02° per minute during the four-hour period in which measurements were made. The maximum variation in replicate determinations was the same as those obtained under the conditions prevailing during the two preceding experiments despite a change of temperature approximately five times that which would introduce a serious error had it given rise to temperature differences of this magnitude on the two sides of the brass jacket surrounding the couples. These results indicate that with adequate stirring a water bath may be used without the necessity of providing especially constant temperature control, thus permitting the use of sturdy, relatively cheap, and readily adjustable thermoregulators.

SWITCH

A third modification of the apparatus as originally described by Baldes arose from inability to procure a double-pole reversing switch which did not produce high contact potentials. At the suggestion of Dr. Ernst Bárány of Uppsala, Sweden, who had experienced a similar difficulty, a reversing switch was constructed by sawing a one-half inch block of electrolytically pure copper into several segments (Fig. 1). The copper was obtained from a local electric utility company. The switch is closed by inserting two additional blocks of copper from the same block between the center and lateral blocks of copper and reversal is made by changing the position of the blocks. The ends of the blocks to be inserted are insulated from the heat of the hand with adhesive tape, and all the edges which make electrical contact are cleaned frequently with emery paper. It is thought that contact potentials arising from the non-thermostated switch are minimized by use of metal of essentially similar composition.

ACKNOWLEDGMENT

Dr. Elek Ludvigh suggested substituting the d.c.-a.c. amplifier for the galvanometer.

---

† Incidentally, this represents a maximum variation in individual readings of ±0.5 millimole in 150 millimoles or less than 1 percent.

Laboratory and Shop Notes

The Temperature Coefficient of Resistance of Tin Oxide-Coated Electrically Conducting Glass between 1° and 300°K*

D. N. Lyon and T. H. Geballe
Chemical Laboratory, University of California, Berkeley, California

May 8, 1950

THE development, by Corning and other groups, of electrically conducting coated glass suggests that some of the problems of calorimetry in the temperature region below 10° K might be minimized if such conducting coatings could be produced with a temperature coefficient of resistance such as to make them suitable for secondary thermometers. A suitable reference thermometer should of course be reproducible during the course of an experiment, relatively insensitive to magnetic fields, independent of the measuring current, and should have as small an adsorptive capacity for helium gas as possible. A glass sample container, with a suitable heater-thermometer coating essentially an integral part of the surface might prove useful down to temperatures below which it is impossible to maintain thermal equilibrium between a sample and container (~0.2° K).

We have recently measured the properties of a number of coated conducting glass samples and although it is not yet certain that a coating satisfactory for precision thermometry can be developed, we believe the results are sufficiently promising and interesting to report here.

The samples tested were made and supplied to us by Corning Glass Works through the courtesy of Mr. W. W. Shaver. The samples were in the form of flat plates of Pyrex Brand 7740 glass, approximately 2.5 cm wide, 15 cm long and 0.4 cm thick. The coatings are produced by an incompletely disclosed process which yields a film of controllable resistivity, consisting nominally of stannic oxide with added small amounts of certain other metallic salts, on one surface of the glass. Fired silver contacts were provided at each end, to which copper lead wires were fastened. The samples were placed in a Dewar and immersed directly in baths of various refrigerants.

Samples with the following approximate surface resistivities at 295° K were tested:

No. 1—	10.5 ohms/cm square	No. 7—	670 ohms/cm square
2—	170	8—	740
3—	280	9—	1530
4—	290	10—	1470
5—	450	11—	13,000.
6—	370		

Curves of resistance *versus* temperature for samples No. 2 through 11 are shown in Fig. 1. Sample No. 1 showed practically no change in resistance with temperature below 77° K, and about a 2 percent increase in resistance between 77 and 297° K, and is not included in the figure.

Above ~14° K, those samples with appreciable temperature coefficients exhibited severe lag in the approach to final resistance following a change in temperature. When samples No. 3 to 8 were cooled from 295° K to 90° K over a period of 45 minutes and then placed directly in liquid N_2, all samples required some 20 hours to reach an equilibrium resistance. The approach to equilibrium was approximately exponential with time; the total change in resistance, between the value some 15 minutes after placing in liquid N_2 and the equilibrium value, was roughly proportional to the temperature coefficient of the sample and approximately equal to the change which would be produced by a temperature change of 0.5°. The effects persisted, although much less severe, to 4.2° K below which, if present, they were masked by instability of the bath temperatures. Upon rewarming to room temperature, all samples returned to the initial resistance at 295° K to within deviations corresponding to ± 0.2° K.

Between 297 and 77° K, all samples can be approximated by expressions of the form $R=aT^n$. Below 77° K, more elaborate expressions are required, although for sample No. 3 the expression

$$R_{\text{No. }3}=46640T^{-0.4927},$$

based upon the observations at 20.4 and 1.25° K, reproduces the measurements at 2.60 and 4.22° K to within 0.005° K, deviating at 13.95° K by 0.33° K.

The change in resistance produced by a magnetic field applied parallel to the direction of current flow was measured for a few of the samples and is shown in Table I. Although small, the effect at 20.4 and 13.95° K appeared beyond the limits of error to be opposite in sign to the effect at and below 4.2° K. Within the accuracy of the measurements, the increase in resistance of sample No. 3 was proportional to H^2 up to 9000 oersteds at 4.2° K, but at 1.25° K, the increase was less rapid that $\propto H^2$.

TABLE I. Isothermal change in resistance of Corning E-C glass samples with parallel magnetic field.

		Sample No.					
		No. 3		No. 6		No. 7	
T, °K	H_{oersteds}	R Ω	ΔR Ω	R Ω	ΔR Ω	R Ω	ΔR Ω
20.4	0	10557		21748			
	7350		−0.9		−2.1		
13.95	0	12874		28811			
	7600		−2.3		−7.1		
4.25	0	22850		76335		323450	
	6200		+5.0		+62		+200
	7150		+7.5		+81		+265
	9000		+12.5		+134		+440
1.25	0	41700					
	6200		+221				
	7150		+278				
	9100		+406				

The following data were obtained in the few tests made of conformity to Ohm's law. The accuracy of the circuits used for the larger currents (normally used for determination of energy input during calorimetry) was about 3 ohms in 25,000. The effect noticed on sample No. 3 is in the direction which would be produced due to heating slightly above bath temperature,

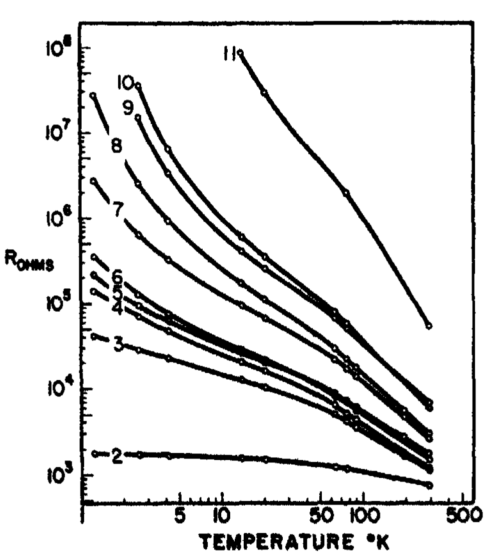

FIG. 1. Resistance *vs.* temperature for Corning electrically conducting coated glass.

TABLE II. Tests for dependence of resistance upon measuring current.

Sample No.	Temperature °K	Approximate current amp.	Resistance ohms
3	4.215	3.4×10^{-6}	22,960
		2.8×10^{-4}	22,918
		3.4×10^{-6}	22,964
	1.253	2.4×10^{-6}	41,660
		1.6×10^{-4}	41,585
		2.4×10^{-6}	41,655
5	4.215	1.8×10^{-6}	63,150
		1.0×10^{-4}	62,960
		1.8×10^{-6}	63,160
8	77.3	1.8×10^{-6}	22,998
		2.8×10^{-4}	23,000
		1.8×10^{-6}	23,008
9	77.3	2.3×10^{-6}	59,090
		1.1×10^{-4}	59,130
		2.3×10^{-6}	59,100

+0.015° at 4.215° K and +0.004° at 1.25° K. For sample No. 5 the effect at 4.215° K corresponds to +0.003° K. For sample No. 9 at 77° K, the effect is in the opposite direction to that produced by a slight heating of the sample and probably represents a real deviation from Ohm's law. The resistances of samples Nos. 8 and 9 were too large at helium temperatures to permit accurate tests. (See Table II.)

We believe these few data to be sufficiently promising to warrant further study of resistances comparable to samples Nos. 2, 3, 4 and 5.

Improving Differential Amplifier Rejection Ratios*

RICHARD MCFEE
Heart Station, University Hospital, Ann Arbor, Michigan

March 20, 1950

A LARGE number of circuits having the differential amplifier property are known, but of these only a few have combined simple construction and operation with stable, high rejection ratios. The most important differential amplifiers are shown in Fig. 1.[1] The purpose of this note is to describe for two of these circuits some simple modifications which result theoretically in infinite rejection ratios and experimentally in rejection ratios about fifty times as great as those of the unmodified circuits. By using adjustable potentiometers in these modified circuits, their rejection ratios may be made as large as desired.

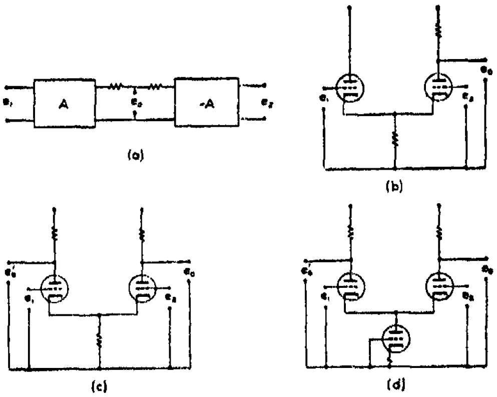

FIG. 1. Basic differential amplifier circuits.

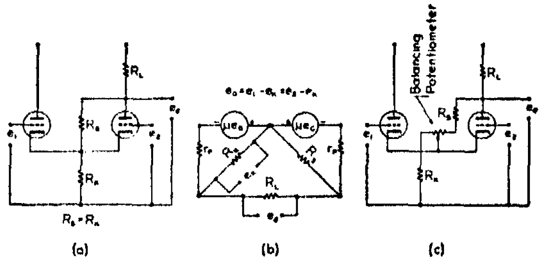
Modification A: The first modification is shown in Fig. 2 and is obtained from the circuit of Fig. 1(b) by adding the resistor R_s. Several factors act to make the output of a modified circuit insensitive to the common-mode component of the input. There is degeneration due to cathode-follower action which reduces the effective grid voltage resulting from the common-mode component to about two percent of its actual value, and there is complete cancellation of the amplified residual e_g at the output, as can be seen from the equivalent circuit. Thus, the common-mode gain is zero, and the rejection ratio infinite. This property of the circuit is dependent only upon tube balance and equality of the cathode and shunt resistors; it is independent of the impedance of the load and the linearity of the tube characteristics.

Because tubes and resistors are in reality never precisely matched, the common-mode gain will not be exactly zero. Experimental tests indicate that using ±1 percent tolerance resistors and randomly selected 6SL7's rejection ratios from 2000 to 4000 may be expected. Of course when the d.c. plate voltages of the tubes are not the same it is necessary to change either R_s or R_k slightly to compensate for the resulting unbalance in tube gains and plate resistances, but this correction need not be variable. If a very high rejection ratio is desired, a balancing potentiometer may be added as is shown in Fig. 2(c).



(a) (b) (c)

FIG. 2. Modification A. (a) Circuit. (b) Equivalent circuit. (c) Circuit with balancing potentiometer.

The gain of the circuit is

$$\frac{e_0}{(e_1-e_2)}=\frac{\mu R_T}{r_p+R_T},\quad R_T=\frac{R_kR_L}{2R_k+R_L}. \tag{1}$$

In the actual design of the circuit it is desirable to choose R_k and R_L so that the gain is maximum for a given tube voltage, current and plate supply voltage. It can be shown that this will occur when the d.c. voltage across the cathode resistor is one-half the total supply voltage. This condition completely determines the values of the resistors.

It is sometimes useful, in designing the circuit for use without a balancing potentiometer, to be able to calculate the common-mode gain resulting from unbalances in tube gains. An approximate equation for this is

$$\frac{e_0}{\frac{1}{2}(e_1+e_2)}=2\frac{\mu_1-\mu_2}{\mu_1+\mu_2}. \tag{2}$$

Similar equations showing the effect of mismatches in tube plate resistances and circuit resistances have been worked out.

Modification B: The second modification[2] is shown in Fig. 3 and is obtained from the circuit of Fig. 1(c) by adding the two pairs of resistors R_1 and R_2 and the resistor R_c. Zero common-mode gain results partly from cathode-follower degeneration and partly from the cancellation of the amplified residual by the bucking resistors R_2 connected from the cathode to the output. Complete cancellation occurs when

$$\frac{R_2}{R_1}=\frac{R_L}{2R_k}. \tag{3}$$

The magnitude of R_c does not affect the differential action of the circuit. It is determined by the desired tube voltages and currents, the values of the other resistors, and the plate-supply voltage.

With ±1 percent tolerance resistors and 6SL7's, rejection ratios from 2000 to 5000 are found. When an even higher rejection is desired, a balancing potentiometer may be located as is shown in Fig. 3(c).

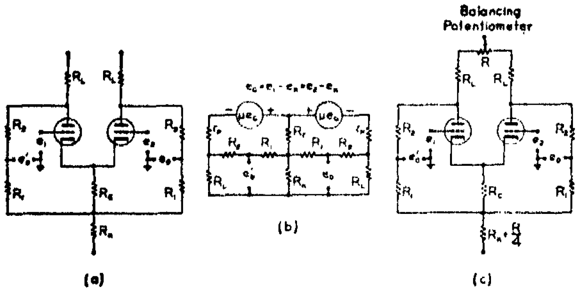


FIG. 3. Modification B. (a) Circuit. (b) Equivalent circuit. (c) Circuit with balancing potentiometer.

An equation for the gain is

$$\frac{e_0}{(e_1-e_2)}=\frac{R_1}{R_1+R_2}\frac{\mu R_T}{r_p+R_T},\quad R_T=\frac{(R_1+R_2)R_L}{R_1+R_2+R_L}. \tag{4}$$

An approximate value for the common-mode gain resulting from unbalance in tube amplification factors may be found using Eq. (2).

This circuit may be used as a differential d.c. amplifier, but it is advantageous to do so only when one stage of amplification is required, or when a single-ended output is needed. It might be noted that when $R_1=R_2$, the output is at the d.c. level of a center-tap on the plate power supply, which can be grounded. In this case the output is not affected by equal changes in the tube characteristic or emission, or by variations in the plate voltage.

Both of these circuits may be used as multipliers. Large variations of the common-mode voltage will not affect the output directly but will vary the differential gain if the tubes are nonlinear, and this variation of gain is easily used to obtain multiplication. They may also be used as simple balanced modulators.

The author is indebted to Dr. Samuel Seely of the Syracuse University Electrical Engineering Department for help in checking the equations.

Voltage Stabilizer for 200 Kv Acceleration

J. T. DEWAN
Atomic Energy Project, National Research Council of Canada, Chalk River, Ontario, Canada

May 8, 1950

IN recent experiments with the resolved beam from a 200 kv positive ion accelerator[1] it was necessary to prevent the beam from wandering more than 0.5 mm on a target placed 100 cm from the exit face of the 90° resolving magnet. This required the accelerating voltage to be held constant to 0.1 percent despite fluctuations of 1 percent in the a.c. supply voltage.

A stabilization ratio of 40 is achieved by the method shown schematically in Fig. 1. This method is an extension of the common degenerative stabilizer[2] and is somewhat similar to that used by Parratt and Trischka[3] for stabilizing voltages up to 50 kv. Regulation is effected by a series tube capable of handling variations of several thousand volts. This is controlled by a feed-back amplifier which receives as its error signal the difference between the voltage across a small portion of the 250 megohm bleeder resistance and a stable balancing voltage. The over-all voltage constancy depends on the stability of the bleeder chain which is a precision wire-wound resistance[4] guaranteed to 0.1 percent. Power is supplied to the stabilizer from a 500 c.p.s. generator which feeds the ion source and focusing supply at the d.c. level designated G in Fig. 1.

Essentials of the regulating circuit are shown in Fig. 2, all supply voltages being referred to the cathode of the stabilizer tube. A small fraction of any output voltage variation appears across R_1, is amplified in two stages directly coupled through Type 5651 high stability neon tubes, and the amplified voltage applied to the grid of a Type 4E27 series regulating tube. As the accelerator voltage is raised from 0 to 200 kv the voltage across R_1 increases from 0 to 160 volts. Consequently a stable adjustable bucking voltage is applied, via the 6AC7 cathode follower, to allow operation of the first amplifier grid at the correct d.c. level. The magnitude of the balancing voltage is controlled by a helical potentiometer which is operated through selsyn motors from the main control panel. The stabilizer is brought into proper operation at any given accelerating voltage by simply adjusting the potentiometer until the electrostatic voltmeter across the 4E27 tube indicates 3 to 4 kv. Fluctuations in the meter up to several kv in magnitude then represent the input voltage variations which are being canceled by the stabilizer tube. In order to protect this tube and the meter from overvoltage a 6H6 diode clamp is placed at the grid of the tube. This prevents the grid being driven negative by more than 105 volts and therefore prevents the plate voltage from rising above 7 to 8 kv. The exact voltage at which the plate clamps depends on the plate current which, however, varies only between 0 and 1 ma.

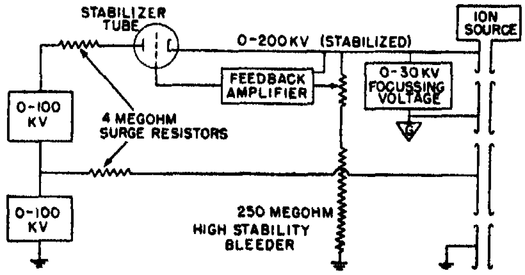

FIG. 1. Schematic diagram of the method of stabilization.

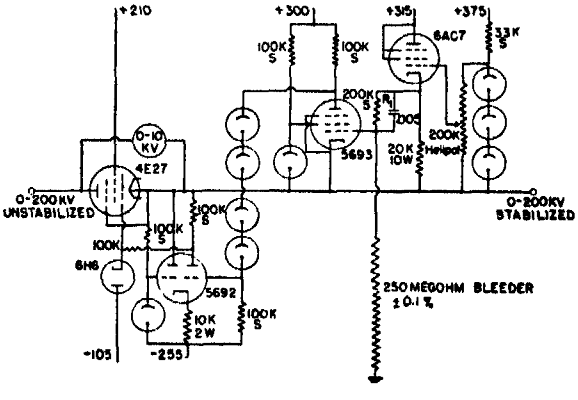

FIG. 2. Details of the stabilizer circuit. All neon tubes are Type 5651 and all resistances marked S are Nobleloy high stability 1-watt resistors.

Theoretically the stabilizer should reduce input voltage variations by a factor approximately equal to $\mu\beta G$ where μ is the amplification factor of the 4E27 tube (150), β is the feed-back factor (1/1250) and G is the gain of the amplifier (500). Thus the stabilization ratio should be 60 but in practice it is about 40. The reduction, inconsequent in this application, is caused by pick-up of stray radiation from the r-f ion source in the feed-back amplifier. With regulation, the output impedance of the accelerator is 10^8 ohms but variations in current at any given voltage are less than 10^{-4} ampere; hence fluctuations due to the high output impedance are only a few volts.

In order that the accelerator voltage should drift less than 25 volts (0.1 percent at 25 kv) over a period of about an hour it is necessary to ensure that any spurious amplifier drift referred to the 5693 grid be less than 20 millivolts. This is effected (a) by the use of iron wire ballast tubes to maintain the 5693 filament current constant, (b) by the use of high stability neon tubes to provide the bucking voltage, (c) by regulating all power supply voltages with ordinary VR tubes, and (d) by using high stability resistors wherever necessary. A final test showed the drift to be 10 millivolts in one hour.

When installed in the accelerator the circuit admirably fulfilled all requirements for regulation and simplicity of operation. Used in conjunction with a constant current supply for the beam deflecting magnet, a target spot results in which the only small fluctuations detectable may be ascribed directly to ion source variations.

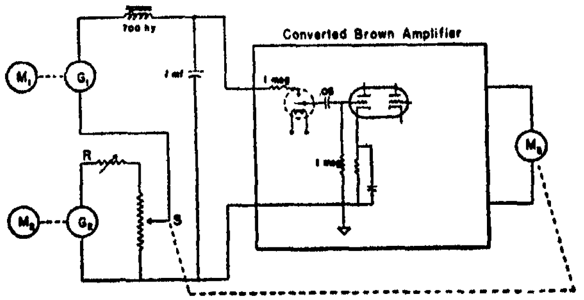
A Mass Indicator

V. J. Caldecourt
The Dow Chemical Company, Midland, Michigan
May 29, 1950

MASS spectrometers which scan by varying the magnetic field require a calibrated field measuring device to indicate the mass of the ions being recorded. The field can be measured conveniently by measuring the voltage output of a small solenoid and commutator rotated in the field by a sychronous motor. This voltage output depends on the motor speed and, if the indicating device draws current, on the commutator contact resistance.

The method shown in Fig. 1 minimizes both of these variables. To eliminate the motor speed effect, the output of the field generator of the mass spectrometer is compared to the voltage output of a permanent magnet generator driven by a second sychronous motor. Separate motor drives were used to avoid the problem of magnetically shielding the permanent magnet generator from the variable magnetic field of the mass spectrometer. The indicator actually shows the ratio of the permanent magnet field to the field of the spectrometer.

The effects of varying commutator contact resistance are negligible because the indicator is a self-balancing potentiometer with high input impedance. The modification of the Brown amplifier to attain this involves removing the input transformer and wiring the input to the first grid as shown. Since the slide wire voltage is high, no trouble from a.c. pick-up is encountered.



M_1, M_2—Bodine Synchronous Motors 1800 r.p.m. 1/150 hp. Type NSY-12
M_3—Brown Balance Motor
G_1—Field Generator
G_2—P.M. Generator, Elinco Type PM-2
S—Slide Wire 20,000 Ω
R—2000 Ω

FIG. 1. Mass indicator.

The mass indicator used here has a ten turn, drum-type linear slide wire, *S*, of six inch diameter with a resistance of 20,000 ohms. It is coupled to a tape scale of 35 mm film nearly ten feet long. This gives 1 cm spacing between mass 200 and 201, and the readings are steady to ½ mm. The indicator is standardized daily by adjusting *R* with the spectrometer set on a known peak.

An uncertainty results from the hysteresis effects in the spectrometer magnet in the instrument here. The flip coil is in a region of nearly uniform field and therefore is affected differently than are the ions which pass through the fringing fields as well as the uniform field between the pole faces. Probably a position could be found for the flip coil so that it also would be subject to some fringe effects, thus giving a better mass indication. In the present setup this effect causes an uncertainty of 0.2–0.3 of a mass unit if the scanning range is changed by a large factor. On running samples over the same scanning range and having standardized in that range, the indicator is accurate to one-tenth of a mass unit for the high masses and slightly better than that for the low masses.

Packless Valve Flow Regulator

Walter Rose*
Gulf Research and Development Company, Pittsburgh, Pennsylvania
May 15, 1950

THIS note describes a valve which has been found convenient to employ when low flow rates are to be controlled and when valve-stem leakage is to be avoided. Although the valve is operatable at pressures above or below atmospheric, it is implicit in the following discussion that the control of flow rate depends on maintenance of a constant pressure drop across the valve as well as on the valve plunger position determining the resistance to flow offered by the valve.

The principles of construction and operation of the valve are indicated by Fig. 1, where it is seen that the flowing fluid is directed through the porous element, *C*, fabricated from unglazed porcelain, fritted glass, sintered metal or the like. Thus, the fluid path is through entry port, *A*; thence through a portion of hole *B* drilled in the porous element; thence through a portion of the porous body, *C*; and thence out through exit port, *D*. Hole *B* opens into mercury reservoir *E*, and the position of piston, *F*, determines how much mercury will be contained in drilled hole, *B*. Obviously, if mercury completely fills the hole, no flow will occur between ports *A* and *D* unless the pressure drop between *A* and *D* is sufficient to cause the mercury to enter the pores of the porous element *C*. This critical pressure drop which must not be exceeded for the proper shut-off operation of the valve is known as the displacement pressure, and is given approximately by:

$$\text{p.s.i. displacement pressure} = \frac{2\gamma \cos\theta}{r} \times 1.45 \times 10^{-5}$$

where γ is the interfacial tension in dynes/cm between mercury and the fluid flowing through the valve, θ is the contact angle, and r is the radius in centimeters of the larger pores in the porous element, *C*. Thus, in flowing air through a valve with the porous element fabricated from 10^{-4} cm pore radius material (e.g., filtration grade porcelain) it is not difficult to achieve the positive shut-off of the valve with pressure differences between *A* and *D* of 100 p.s.i.

The operation of the valve involves changing the piston position until the mercury column position in *B* limits in the desired manner the surface area of hole *B* available to flow. Thus, for a given piston position the flow rate which obtains will be proportional to the pressure drop from *A* to *D*, to the viscosity of the flowing fluid, to the mean pressure of the fluid in *C* if the fluid is a gas, to the geometry of that portion of *C* available to flow, and to the permeability characteristics of *C*. One is enabled, therefore, to calibrate piston position *versus* flow rate for given conditions of

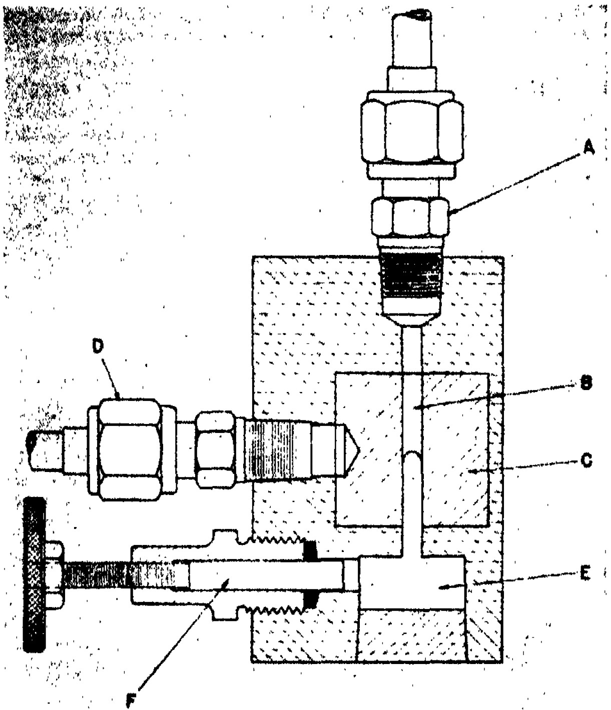


FIG. 1.

fluid viscosities and fluid pressures. It has been found possible to regulate flow rates as low as 10^{-8} cc/sec. employing filtration grade porcelain as the porous element *C*.

The valve units are comprised of porous elements molded in plastic with subsequent machining to provide for the port and piston entries. The mercury column effectively prevents fluid loss through the piston packing. When liquids are being flowed the system is evacuated initially to provide for a complete saturation of the porous element *C*. In this connection, there would be advantage in a valve assembly which would permit interchange of porous elements *C* to facilitate alternating from gas to liquid flow, as well as enlarge on the range of flow rates which could be achieved, since the flow rate is so much dependent on the permeability characteristics of the porous elements. On the other hand, no way has been found to avoid the requirement that the valve be operated in the vertical position indicated by Fig. 1, since it is necessary to prevent mercury spillage.

New Instruments

W. A. Wildhack: Associate Editor
in Charge of this Section
National Bureau of Standards, Washington, D. C.

These descriptions are based on information supplied by the manufacturer and in some cases from independent sources. THE REVIEW *assumes no responsibility for their correctness.*

Spectrograph and Excitation Unit

A single instrument combining a large Littrow spectrograph and equipment for arc and spark excitation of spectra is available from *Optica*, Milan, Italy. The autocollimating spectrograph Model B3 has a working range from 2000 to 10,000A, obtained with quartz and glass optics easily interchangeable by means of a special revolving system. The quartz system has a working field ranging from 2000 to 3800A with reciprocal linear dispersion of 5.0A/mm at 3000A. The glass system covers the range from 3600 to 10,000A with 8.0A/mm at 5000A. The camera accommodates a 9 by 24-cm photographic plate and may be modified later to carry a film holder. Linear and wave-length scales are provided for each working range. The plate holder can be adjusted vertically by means of a lever and provision for automatic raising of the holder is available. The prism, lens, and photographic camera are automatically adjusted to the positions required for the different ranges of spectra by turning a drum. The wave-length range and central wave-length of the plate are read on a scale. The apparatus is enclosed in a metal cabinet approximately 3 meters long, which accommodates also the optical bench, arc and spark excitation equipment and a control panel.

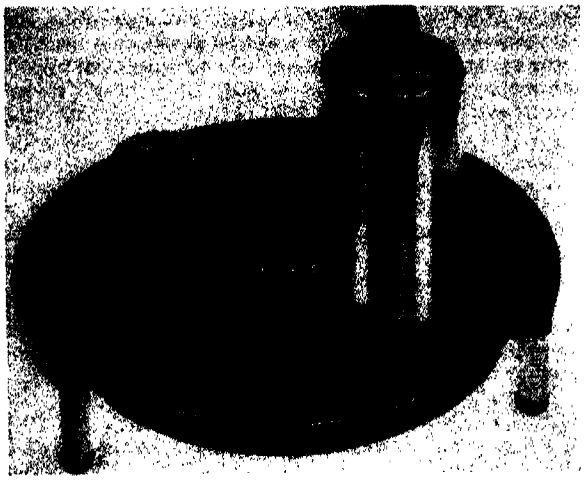
The excitation equipment built into this instrument is also available as a separate unit. It consists of a Fuessner-type spark generator and an arc generator providing continuous and interrupted arc current. The standard model of the spark generator is equipped with 0.012 μf capacitance and a larger model with 0.024 μf capacitance. The input voltage is controlled by an adjustable transformer and the capacitance and inductance in the discharge circuit are selected by lever switches operated from the control panel. The 200-volt d.c. arc may be varied from 2 to 15 amperes, the current being obtained from a thermionic rectifier tube. The 200-volt interrupted arc is operated by a thyratron tube to supply current that may be varied from 2 to 40 amperes peak for each single impulse. The duration of each impulse is 0.001 to 0.01 second, the interval between impulses is 0.02 second, and the series of impulses can be adjusted from 1 to 200.

Optica also builds a medium quartz spectrograph, Model B2, and various accessories for spectrographic analysis and research in spectroscopy.—OPTICA S. P. A., *Via Calatafimi, 7–9, Milano, Italy.*

Gas Flow Counter

The Model 200 Gas Flow Counter is a windowless or internal-sample type Geiger counter. Samples are placed in the counting chamber by means of the circular style sample holder. Self-quenching counting gas mixture continuously flows through this chamber, through the pre-flush position chamber, and out the glass bubbler.

The Model 200 is made of stainless steel with a Teflon insulator and a platinum anode. Simple assembly and disassembly makes cleaning and thorough decontamination fast and easy. The large gas sealing surfaces are hand-lapped flat. The counting chamber is easily removable and interchangeable with other chambers. The sample holder has three positions: while one sample is being loaded, another is being pre-flushed, and a third is being counted. Because these operations are performed simultaneously rather than in sequence, the time required for the over-all counting operation is considerably less than that for single-position, straight-slide style flow counters.



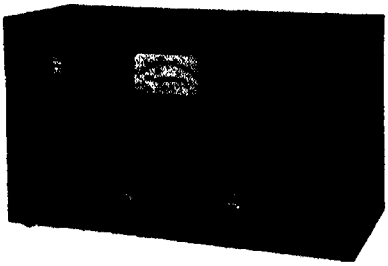
Samples up to 1⅜ in. diameter and ⅜ in. deep may be accomodated. Special stainless steel adapters will be provided to order for all smaller samples. The 1⅜ in. inside diameter of the standard counting chamber is designed to give full geometry with the maximum sample size. Special interchangeable chambers with any smaller inside diameters down to 11/16 in. will be provided upon request. By selecting a counting chamber with an inside diameter equal to your sample size, you will get the lowest background count possible without losing full geometry. The background counts without additional shielding will range approximately from 12 counts per minute with an 11/16 in. chamber to 30 counts per minute with a standard 1⅜ in. chamber. The plateau will depend upon the size counting chamber and the particular gas mixture being used. In general there will be at least 200 volts with a slope of less than 3 percent per hundred volts in the range around 1400 volts.—RESEARCH EQUIPMENT AND SERVICE, *1155 East 61st Street, Chicago 37, Illinois.*

New Stabilized D.C. Indicating Amplifier

Multi-purpose Stabilized D.C. Indicating Amplifiers just announced by Leeds and Northrup Company are useful for low level d.c. measurements as direct-reading microvoltmeters or micromicroammeters; as recorder preamplifiers to extend the range of standard Speedomax Recorders; and as high sensitivity, short-period null detectors in place of galvanometers. Amplifiers are supplied either as voltage or current type, with choice of zero-left or zero-center built-in 4-inch indicating meter.

Both gain and zero point are so highly stabilized by a combination of a.c. amplification and d.c. null-balance feedback that trimmer controls are unnecessary. Without impairing performance, the voltage amplifier can be used with sources up to 10,000 ohms resistance, and the current type with sources of 100,000 ohms and higher.

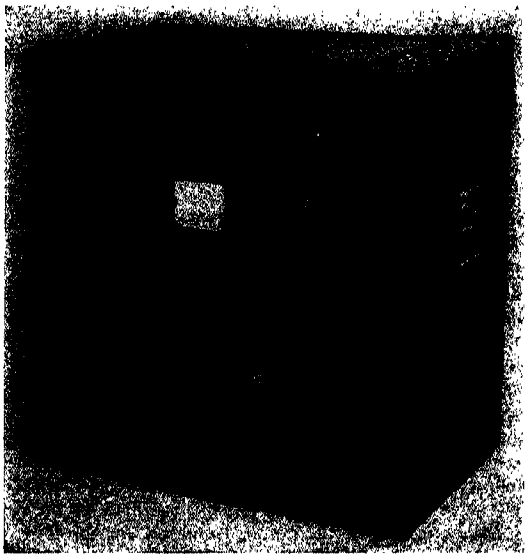
Basic range of the voltage amplifier is 0 to 50 or −25 to +25 microvolts, with scale multipliers of 1, 2, 4, 10, 20, and 40; of the current amplifier, is 0 to 1000 or −500 to +500 micromicroamperes, with multipliers of 1, 2, 5, 10, 20, 50, 100, 200, 500, 1000, and 2000. Response time of both models is 2 to 3 seconds. Output at recorder connector for full-scale input on any range is 10 millivolts at output impedance of 500 ohms.



For convenience in null balance measurements, the indicating meter can be switched to non-linear response. This type of response retains full sensitivity where needed, in the region of the zero point, but gradually decreases sensitivity toward the ends of the scale, to prevent large unbalance inputs from sending the meter off scale.—LEEDS AND NORTHRUP COMPANY, *4934 Stenton Avenue, Philadelphia 44, Pennsylvania.*

Dew-Point Indicators

Three new types of dew-point indicators, designated as Types D-1, D-2, and D-3, are used for determining the moisture content of air. These instruments measure the dew point or frost point of air by indicating temperatures of a small mirror surface. The temperature is controlled automatically in a manner such that a thin film of dew or frost of constant thickness is maintained on the mirror surface at all times.



These dew-point indicators find wide application in scientific and engineering work. The Tower Unit, Type D-1, is designed for installation at airports or remote locations, such as in weather towers. It can be left unattended and is built to operate indefinitely. The Aircraft Unit, Type D-2, is made in two sections to

Dew-point indicator specifications.

	Type D-1	Type D-2	Type D-3
Response	5°C/sec.	5°C/sec.	5°C/sec.
Range	−30°C to +−40°C	−80°C to +−40°C	−80°C to +−40°C
Operation time	Indefinitely	8 hr./filling	8 hr./filling
Application	Airport and remote locations	Aircraft	Indoors
Power	110 v 60 c.p.s.	110 v 60 c.p.s.	110 v 60 c.p.s.
Weight	142 lb.	72 lb.	103 lb.
Height	23″	21″	23″
Width	21″	10″	21″
Depth	13″	15″	15″

facilitate installation in aircraft and airborne equipment. It is designed to operate for 8 hours without refilling. Laboratory Unit, Type D-3, illustrated, is most suitable for laboratory use or indoor locations and is built to operate for an 8-hour period without refilling with coolant.

Specifications on the three types of dew-point indicators are as shown in the table.

Pressuregraph

The new Electro Pressuregraph has been tested and used by leading manufacturers and universities in the design and maintenance of internal combustion engines, compressors, injection pumps, and pipe lines and also in the measurement of hydraulic, gas, or explosion pressures, and the displacement of moving bodies. It accurately measures and records dynamic and static pressure variations in either gaseous or hydraulic media. Extreme versatility is made possible by its excellent frequency response and by its wide range, obtained through the use of interchangeable diaphragms. Particularly wide acceptance has been found in the Diesel and gasoline field, where its ease of installation and operation make it a cost-saving instrument in the study of intake, exhaust, and firing pressures.

The equipment consists of (1) an electronic pick-up, which is connected to the region where the pressure is to be studied; (2) an associated electronic circuit and power supply; (3) a cathode-ray oscilloscope, on whose screen the pressure-*versus*-time characteristic is presented. When used with the Syncro-Marker the Electro Pressuregraph provides three information channels on the same diagram: (a) the pressure curve which shows the pressure being measured; (b) a predetermined reference point that can be set at any angular position such as top dead-center; and (c) a choice of time or angular markers (time markers are spaced 1/60 or 1/1000 of a second; angular markers are spaced 5°).

The Pressuregraph is based on a system of carrier modulation. Carrier voltage is made to vary according to the pressure applied to the diaphragm. A 100-kilocycle carrier provides sufficiently high frequency to reproduce any pressure variations encountered in most applications. It is said to produce fullscale deflections for any pressure or vacuum from a few ounces to over 10,000 p.s.i., and to offer a wide frequency response of static to over 20,000 c.p.s. Installation is simple, requiring only a threaded hole into which the pick-up is screwed.

The Electro Syncro-Marker and Angular-Sync are designed to broaden and amplify the usefulness of the Pressuregraph by performing three important functions: 1. It makes possible quick, thorough examination of any particular portion of pressure cycles while the engine under study is in operation, and it synchronizes the horizontal time base sweep of the cathode-ray oscilloscope with rotation of the engine, making trace of the pressure phenomenon appear stationary on the screen. The synchronizer head may be rotated to trip the sweep at any position through 360°. 2. It produces 5 degree, millisecond, and reference marker signals directly on the pressure diagram. 3. It provides an identification pulse, once each revolution, which can be adjusted to coincide with that of the top or bottom dead-center, or of any other point in the rotation. This pulse may be shifted over the calibrated scale for measuring angular distances on the diagram.

The Syncro-Marker contains a 1000-cycle oscillator for generating the primary signal, electronic circuits for shaping the identification and marking signals, and for mixing these signals with the Pressuregraph output and power supply.

The Angular-Sync is a magneto-mechanical device whose shaft is coupled to that of the engine. It generates the pulse and marking signal and synchronizes the oscillograph picture with variations in the speed of the engine.—Electro Products Laboratories, Inc., *4501 North Ravenswood Avenue, Chicago 40, Illinois.*

Exposure Photometer

The SEI Exposure Photometer is a portable photometer that can be used for accurately measuring either reflected or transmitted light. No larger than a flashlight, and just about as easy to use, it makes it possible to obtain scientifically correct answers to all exposure problems. It is as valuable at the darkroom enlarging easel for determining printing exposures as it is in the studio or on location.

To the photographer and the television cameraman, the SEI Photometer offers two distinct advantages over the conventional type of exposure meter—it can be used to measure the brightness of pinpoint areas on a subject *from camera position*, and it can be used to measure brightness ranges up to one million to one. With it, a subject literally can be analyzed in terms of the reflected light as the lens sees it, and readings can be made of the deepest shadows as well as the brightest highlights.

In use, any portion of a subject—which may be only a few feet away or as much as 100 feet away from the camera—whose illumination is to be measured, is viewed through the photometer's focusable telescopic eyepiece. A dark spot is seen superimposed on the scene. The user then turns a knurled ring on the photometer's base until the brilliance of the dot, which is illuminated by a calibrated battery-powered bulb, is adjusted to match the portion of the scene or subject being measured. When the dot blends in and disappears, shutter speeds and *f*-stop openings can be read directly from scales on the photometer's main barrel.

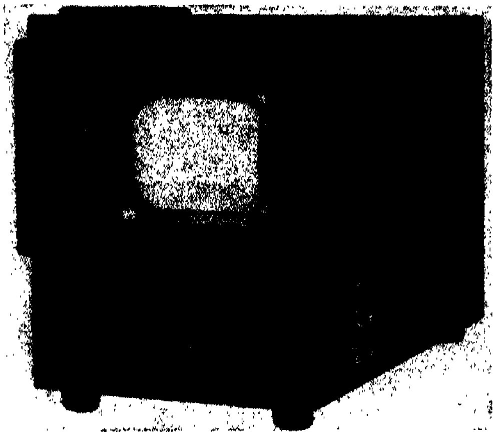
Calibration, to compensate for battery and lamp wear, is accomplished just as easily. The light from the comparison lamp, which illuminates the dot, also illuminates a photoelectric cell connected to a microammeter mounted in the top of the photometer. Before the exposure readings, a rheostat control in the photometer's base is adjusted until the needle of the microammeter points to a central standard mark. This ability to calibrate the photometer quickly and easily eliminates the possibility of errors caused by uncontrollable variables.

The SEI Exposure Photometer is made by Salford Electrical Instruments, Ltd., England, and is now distributed exclusively in the United States by the Zoomar Corporation.—The Zoomar Corporation, *381 Fourth Avenue, New York 16, New York.*

Analascope

This new instrument provides a convenient, dependable means for measuring and continuously showing any phenomena that can be translated into electrical impulses. Heretofore, devices to measure these functions had to be custom built by researchers at considerable expense and loss of time which could be more profitably applied to their own projects.

Its possibilities as a tool of general utility in the laboratory can be appreciated from the fact that one moment it can serve as a *p*H meter which measures to 0.001 *p*H, and the next moment it can serve as an electrocardiograph, a pressure indicator, a strain analyzer, or, in fact, an instrument for measuring any phenomena converted into electrical impulses, whether static, rapidly fluctuating, or of high or low impedance.

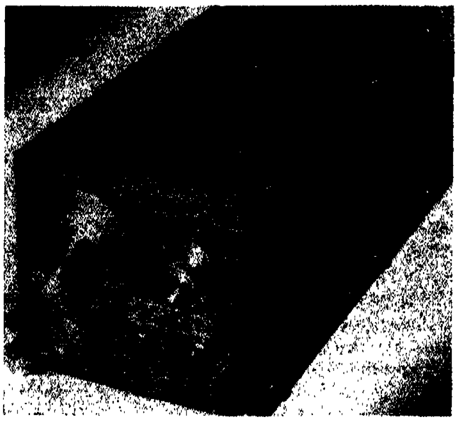


Results are displayed on the long persistence screen of a 5-in. cathode-ray tube which is an extremely flexible, indestructible indicator. It allows continuous observation of non-recurrent phenomena at sweep speeds of from 0.01 to 5 seconds. A two decade precision potentiometer calibrated with a self-contained standard cell provides direct measurements from 0.001 *p*H to 15 *p*H and 0.1 millivolt to 1.5 volts. An input attenuator of 1000 megohms provides overlapping ranges of 1 micromicroampere to 10 milliamperes and 1 millivolt to 100 volts per centimeter deflection.—Analytical Measurements, Inc., *585 Main Street, Chatham, New Jersey.*

Variable Electronic Filter

The Model 300 Variable Electronic Filter has the unusual specification of a continuously variable cut-off within the frequency range of 20 cycles per second to 200 kc. With an attenuation rate of 18 db per octave it is analogous in performance characteristics to the Constant-K inductance capacitance filter.

A range switch selects the type of section desired—high pass or low pass—as well as four decade frequency ranges. Several filters can be cascaded so that attenuation rates of 36, 54, etc. db per octave can be realized. Sections can be combined to make a variable band-pass filter.



Light in weight, compact in construction, and including a regulated power supply, the Model 300 Variable Electronic Filter has many uses in the movie, radio broadcasting, television, and sound recording industries. Its low noise level and versatility make it an ideal research instrument for noise analysis or acoustic measurements in the automotive, aircraft, machine tool industry or for general laboratory use in university, commercial and government laboratories.—Spencer-Kennedy Laboratories, Inc., Department SI, *186 Massachusetts Avenue, Cambridge 39, Massachusetts.*

Manufacturers' Literature

New Materials

Forest K. Harris: Associate Editor
in Charge of this Section
National Bureau of Standards, Washington, D. C.

Heat-Resistant Steel Castings

16–25–6 is a heat-resistant alloy containing chromium, nickel, and molybdenum, patented and trademarked by the Timken Roller Bearing Company, which has now been adapted to sand or centrifugal casting processes. Originally developed as a wrought material, the alloy has high creep resistance and rupture strength at temperatures as high as 1200–1500°F, and provides satisfactory corrosion resistance at these elevated temperatures. To keep the alloy austenitic and to assure good welding properties, the carbon content is kept to 0.12 percent or less. Comparative data on the wrought form of this alloy show a rupture time of 1000 hours under 10,000 p.s.i. stress at 1500°F, whereas the corresponding time was seven hours for 18–8 stainless steel. Exact data of a comparable nature have not been developed or the cast form of the alloy. It is of interest to note that critical materials such as columbium, cobalt, or tungsten are not used in this alloy.—Lebanon Steel Foundry, *Lebanon, Pennsylvania.*

Coated Tubing

Dekoron tubing is a low cost, corrosion-proof metal instrument tubing with a 1/32-inch coating of extruded thermoplastic. It is planned for use in laboratories and plants where there is a corrosive atmosphere. The plastic coating is stated to be unaffected by moisture, salt air, oils, acids, and alkalies. The plastic coating can be used to color-code the line. The tubing can be bent as easily as ordinary copper tubing and is available in ¼- and ⅜-inch diameters. Literature and sample lengths of tubing are available from the maker.—Samuel Moore and Company, *Mantua, Ohio.*

Coaxial Cable

Coaxitube consists of an inner conductor, a dielectric and a seamless outer tube forming an efficient coaxial cable. The components are continuous and the cable remains coaxial even when formed into intricate shapes. The dielectric can be of any commercially available material to give required electrical performance. The cable can also be used as a thermocouple, being available with an inner conductor of Copnic, Constantan or Advance wire, a suitable insulator, and a seamless copper outer conductor. Outside diameter can be controlled from 0.023 to 0.100 in. or larger.—Precision Tube Company, *3824 Terrace Street, Philadelphia 28, Pennsylvania.*

Glass Bearings

Industrial Glass Bearings are available in which glass is fused in a thickness of 5–15 mils on cast iron or low carbon steel to form an integral porcelain-enameled bearing surface. The bearing is installed with a sleeve of synthetic rubber ⅛–¼ inch in thickness, depending on service conditions. This sleeve presses over the shaft and rides in the bearing. It will operate satisfactorily with most liquids as the lubricant but should not be run dry. Custom-built bearings are available for shafts up to 12 inches in diameter to operate at speeds up to 4500 r.p.m.—Farley M. Caldwell, *1105 Richwood Avenue, Cincinnati 26, Onio.*

Coated Safety Lenses

Tuf-Cote is a preparation for coating safety lenses to make them more resistant to welding splatter and emery pitting. Its effectiveness is derived from its resilience which cushions the impact of particles striking against lens surfaces, and keeps them free from pits and scratches for a substantially longer period than is the case with untreated lenses. The process involves the patented application of a clear solution, resulting in a coating which is stated not to produce distortion, not to discolor or peel, and to afford the same degree of vision available in untreated lenses. Lenses may be recoated indefinitely so long as their surfaces are undamaged, and the coating may be applied to both surfaces of the lens. While the process is applied largely to safety glasses it may be applied successfully to prescription lenses of any curvature from −15 to +15 diopters. Lenses treated with Tuf-Cote will be available at all Bausch and Lomb sales and service divisions and affiliated offices. —Bausch & Lomb Optical Company, *635 St. Paul Street, Rochester 2, New York.*

Fluoro Carbons

Halocarbons, now in quantity production, are stabilized low polymers of chlorotrifluoroethylene in the form of oils, greases, and waxes. These products contain only carbon, fluorine, and chlorine and are inert toward corrosive agents including acids, alkalies, salts, and oxidizing agents, wet or dry. They are unaffected by prolonged heating in air at 480°F.

The presence of unstable structures and of hydrogen in the molecules of ordinary lubricants and plastics causes their decomposition by corrosive chemicals and by air at high temperatures. By synthesizing compounds containing only carbon, fluorine, and chlorine, products are obtained that are in many ways more inert than graphite itself. In addition to the well-known fluorinated refrigerants and the high melting point fluorinated plastics the present line of oils, greases, and waxes completes the range of fluorinated analogs of hydrocarbons available for industrial use. They make available a number of lubricants and coatings which are not attacked by corrosive products, and their resistance to oxidation at high temperatures permits their use, with or without inert bodying agents, as bearing lubricants in high temperature installations. Laboratory uses include inert stopcock greases, sealing cements, diffusion-pump oils, and manometer liquids. In the field of plastics their use as softeners of fluorocarbon plastics in molding and coating operations is of interest. Their use yields a molding mix which can be readily melted and formed without the decomposition usually experienced in fabricating the pure plastic. —Halocarbon Products Corporation, *2012 88 Street, North Bergen, New Jersey.*

Chemical Developments

Sterox CD is a re-wetting agent developed to increase the absorbency of paper toweling and tissues. Industrial toweling is usually strengthened with materials that reduce its absorbency. This is restored by the re-wetting agent. It may also be added to soft household toweling to prevent loss of absorbency with age and to improve moisture pick-up. This chemical, used in minute amounts as an additive, is stated to be odorless and harmless.

OS-16 is a hydraulic fluid with a favorable combination of properties. Chemically it is an ester base compound, containing no halogenated hydrocarbons, salts or water. It is non-toxic, flame-resistant and has excellent lubricating qualities. During a three-month test period it was used in a heavy-duty, hydraulically operated, coal-cutting machine on a 24-hour day, three-day week schedule. The operating pressure was 1500 p.s.i. At the conclusion of the test the machine was disassembled, and examination showed no evidences of wear in pumps and all other parts which were in contact with the hydraulic fluid. This fluid generally requires the use of special hose, packing and gasket materials. Its viscosity is 11.05 c.s. at 100°F and 2.65 c.s. at 210°F. Its flash point is 435°F.—Monsanto Chemical Company, Organic Chemicals Division, *St. Louis 4, Missouri.*

Static Eliminator

The Model B Neutra-Stat eliminator was designed to dissipate static charges from materials being weighed on delicate analytical balances. It employs polonium to irradiate the balance inclosure with alpha-particles which ionize the air and discharge all nearby surfaces. The unit can also be carried in the hand and passed over a charged object or area to remove any static charge.—E. Machlett and Son, *220 East 23 Street, New York 10, New York.*

A Machine for Synthesizing Two-Dimensional Fourier Series in the Determination of Crystal Structures*

H. SHIMIZU, P. J. ELSEY, AND D. MCLACHLAN, JR.
Department of Metallurgy and the Engineering Experiment Station, University of Utah, Salt Lake City, Utah

(Received February 6, 1950)

An electromechanical analog machine is described which performs a two-dimensional Fourier synthesis for use primarily in x-ray crystal structure calculations,

$$\rho(xy)=\sum_h\sum_k F_{hk0}\cos 2\pi(hx+ky).$$

The analog to a term in this summation is obtained through the use of a pair of selsyns as a synchro-variable transformer somewhat similar to its use in servomechanisms. $\rho(xy)_{hk}$ is represented by the output voltage, F_{hk0} by the input voltage, and $2\pi hx$ and $2\pi ky$ are the angles of rotation of the primary and secondary rotors respectively. A system of crossed shaft and cascading gear trains turns the rotors to the appropriate angles for each selection of point (x, y) in the unit cell. The present machine handles h and k values up through 8, but provision is made for future extension through 16. Computations are shown for two known structures to indicate the results obtainable with the machine.

INTRODUCTION

Although any machine capable of synthesizing two-dimensional Fourier series may be applied to a variety of problems, such as heat flow and vibrations in thin membranes, the present machine is to be described on the basis of its utility in Fourier projections as applied in the study of crystal structures using x-ray data. It may be well to state that the data are obtained in the form of diffraction spots from the x-ray film of the moving film types of camera, such as the Weissenberg camera. From a so-called zero layer line x-ray picture the positions of the spots enable the investigator to assign two indices, h and k, to each spot, and from the intensity of each spot an amplitude factor or coefficient, F_{hk0}, is deduced. The solution of the structure of a crystal in two dimensions implies the computation of the electronic density (that is, the number of electrons per square angstrom) over the entire area of unit of projection. The computation is accomplished by introducing the x-ray data (in the form of h, k, and F_{hk0}) into a Fourier equation of the type

$$\rho(xy)=\sum_h\sum_k F_{hk0}e^{2\pi i(hx+ky)}. \tag{1}$$

In the case of centro-symmetric structures, this equation is of the form

$$\rho(xy)=\sum_h\sum_k F_{hk0}\cos 2\pi(hx+ky). \tag{2}$$

Although the machine under discussion is in the process of being extended to utilize h and k values up through 16, in its present state it is capable of handling only h and k values up through 8. Equation (2) indicates the computation which the machine performs.

Some of the principles of this machine were presented by Dan McLachlan as part of a paper before the American Society for X-Ray and Electron Diffraction at Lake George, New York, June 11, 1946, at which time a scheme was shown for mechanically coupling Maxwell's[1] variometers so that use of them may be extended to two dimensions. The present machine makes use of selsyns† instead of variometers because of their availability, small size, low cost, and adequacy of magnetic shielding.

PRINCIPLES OF THE MACHINE

In its original form, Maxwell's variometer consists of a long stationary primary coil within which are mounted

---

† Selsyn is one of the trade names which has come into common usage for synchros or self-synchronous repeaters. Other trade names are Autosyn, Teletorque, Diehlsyn, etc.

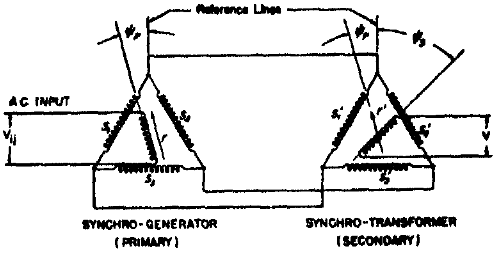

FIG. 2. The synchro-transformer system.

two identical secondary coils, one free to rotate (the rotor) and the other fixed (the stator). The output of the secondary rotor generates a potential which is a sinusoidal function of the angle of rotation while the secondary stator produces a constant potential equal to the amplitude of the rotor potential. These secondary rotor and stator coils are connected in series with each other and with those of additional variometers for the higher harmonics to obtain a one-dimensional Fourier summation of the type

$$V=\sum_{i=1}^{n} kV_i'(1+\cos i\varphi), \tag{3}$$

where V is the total output voltage, k is the inductive coefficient, V_i' is the input voltage to the primary coil of the ith variometer, and φ is the angle of rotation of the first variometer. The proposal made at Lake George extended the use of variometers to a two-dimensional synthesis of the type

$$V=\sum_i\sum_j kV_{ij}'[1+\cos(i\varphi_p+j\varphi_s)], \tag{4}$$

where i and j are integers taking values 0, 1, 2, 3, $\cdots$ with the exception $ij=00$ and where φ_p and φ_s are the angles of rotation of the first primary coils and first secondary rotor coils respectively. To accomplish this synthesis it is necessary that the primary coil also rotate about the same axis but independently of the secondary rotor. A system of parallel shafts emerging from two gear trains, one set perpendicular to the other, controls the rotations of the coils. Thus in Fig. 1(a) the variometers are mounted at the intersections of the shafts with the vertical shafts turning the primary coils to the angle $i\varphi_p$ and the horizontal shafts turning the secondary coils $j\varphi_s$.

The net shown in Fig. 1 is not new, having been suggested by Robertson[2] in connection with a machine for synthesizing two-dimensional Fourier series wherein pistons were driven sinusoidally into cylinders containing oil and the summation accomplished by measuring the total oil displaced.

In the present machine, a pair of selsyns is used in place of each variometer, see Fig. 1(b). Selsyns are essentially two-pole three-phase alternating current generators or synchronous motors and for most purposes used in pairs. Their conventional use is in remote positioning or indicating in which case the a.c. input is applied to the rotors of both selsyns, the generator whose rotor is driven and the motor whose rotor follows in synchronism. A second common use for selsyns is as synchro-control transformers used in conjunction with servomechanisms in which case the a.c. input is applied only to the rotor of the first selsyn or generator. Any voltage produced in the rotor of the second selsyn or transformer represents an error and is amplified and fed into a servo-motor which turns the transformer rotor shaft and other mechanisms to correct the error. For the purpose of the calculator, however (see Fig. 2), the selsyns are used in a third manner (as a synchro-variable transformer) in which the rotors of the generator and transformer are driven independently while a given voltage V_{ij}' (Eq. (4)) is applied to the generator rotor and the output voltage is measured. With the generator rotor in the position indicated in Fig. 2 a magnetic field r is induced in the direction of the poles of the rotor. This field causes currents in coils s_1, s_2, and s_3 of the generator which are transmitted to coils s_1', s_2',

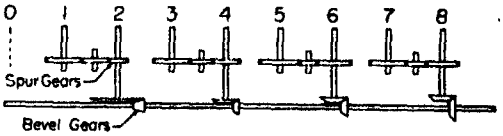

FIG. 3. The gear train.

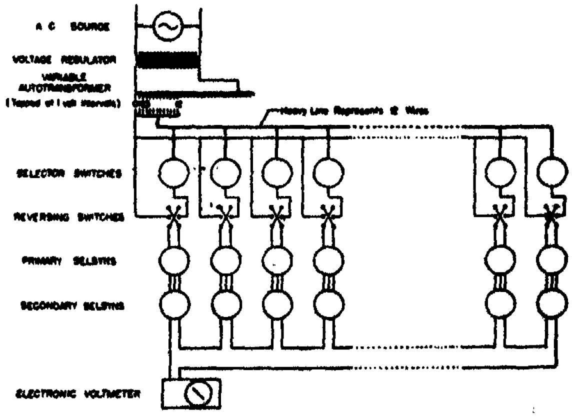

FIG. 4. The electrical circuit.

---

[2] J. M. Robertson, Phil. Mag. 13, 413 (1932).

and s_3' of the transformer which in turn induce a field r' in a direction corresponding to the field r of the generator. When the poles of the transformer rotor are in the direction parallel to r' the output is a maximum and when perpendicular the output is zero. At any position of the rotors the output voltage varies according to the equation

$$V_{ij}=kV_{ij}'\cos(i\varphi_p+j\varphi_s), \tag{5}$$

where symbols are as previously defined. This equation is directly analogous to a term of Eq. (2),

$$\rho(xy)_{hk}=F_{hko}\cos 2\pi(hx+ky), \tag{6}$$

where the output V_{ij} represents the electronic density $\rho(xy)$ due to the hk term, kV_{ij}' represents the structure factor F_{hko}, and where i, j, φ_p, and φ_s are analogous respectively to h, k, $2\pi x$, and $2\pi y$.

As mentioned for the proposed use of the variometers, a network of shafts (Fig. 1(b)) is placed so that the vertical shafts turn the primary rotors $2\pi hx$ radians and the horizontal shafts turn the secondary rotors $2\pi ky$ radians corresponding to the h and k values of each selsyn pair. For example the pair in the dotted circle of Fig. 1(b) would achieve the angle $2\pi(4x+3y)$. If separate potentials proportional to F_{hko} are applied to the primary rotors of the respective h, k selsyn pairs and if the output potentials of all the transformers are summed in series, the resulting potential will be proportional to the summation in Eq. (2). Thus through proper calibration of the voltmeter, the electronic density, $\rho(xy)$, may be obtained directly for any desired point, x, y.

Again the use of selsyns as variable transformers is not new. Booth[8] states that the use of selsyns was con-

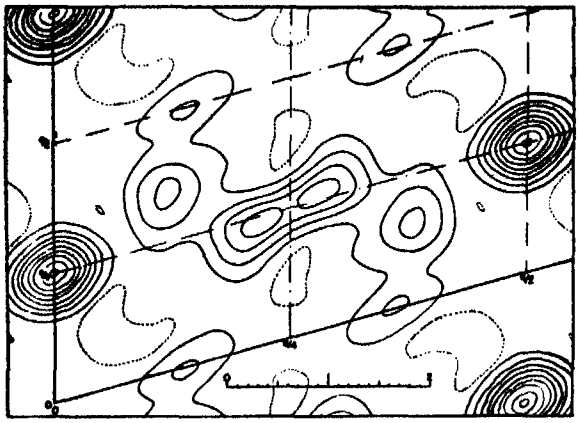

FIG. 6. The *b*-axis projection of diopside.

sidered in connection with his machine but the high cost precluded their use. Also Pepinsky[4] describes the use of selsyns in synchronizing sweep frequencies on the screen of the cathode-ray tube of his machine.

CONSTRUCTION OF THE MACHINE

The most important parts of the mechanical system of the calculator are the two nearly identical gear trains, GT_h and GT_k (Fig. 1(b)), one on the primary rack and the other on the secondary rack. The arrangement of gears is shown diagrammatically in Fig. 3 with numbers assigned to indicate ratios of shaft rotations with respect to each other. For example, all primary selsyn rotors of column 1 (Fig. 1(b)) rotate 1 revolution while those of column 2 rotate 2 revolutions, etc. All the rotors of the secondary selsyns of row 1 rotate 1 revolution and those of row 2 rotate 2 revolutions, etc. The main drive shaft of each gear train is turned manually from the instrument and control table (see Fig. 5) as a consequence of selecting positions x, y in the unit cell.

The crossed shaft arrangement as shown in Fig. 1(b) requires a separate series of selsyns for each value of h and of k in Eq. (2), the h or primary series being arranged vertically and the k or secondary series arranged horizontally in the machine. To provide this, the selsyns for each series are mounted along an angle-iron and connected by miter gears to a common shaft running the length of the angle-iron. The angle-irons are mounted in their respective positions in the primary or secondary rack and the shafts of each series of selsyns connected to their respective gear train shafts. These connections are made by means of multijaw couplers to facilitate assembly and adjustments and to provide for independent removal of each angle iron carrying its series of selsyns.

The primary and secondary racks were constructed in two separate frameworks. Cord-end plugs and sockets were used for electrical connections from the front to the primary rack and also between the primary and secondary racks, thus permitting independent removal and insertion of the entire racks. The plugs and sockets also facilitate testing and checking individual selsyns.

Figure 4 shows the basic electrical circuit for the machine. The a.c. voltage supply is held constant by means of a voltage regulator. Voltages from 0 to 12 in approximately one-volt steps, representing the structure factor coefficients, F_{hk0}, are applied to the primary rotor by means of 12 point single pole rotary switches on the data panel. The voltages are obtained from 12 taps on a variable autotransformer. The input to this transformer is through the slide contact to permit adjustment of the voltages. The input to each primary rotor can be reversed by means of a d.p.d.t. switch. The resulting 180° phase shift provides for the negative values of F_{hk0}. The "off" position of the d.p.d.t. switch serves as the "zero" which was not provided by the rotary selector switch.

The secondary selsyn rotors are connected in series so that the total voltage is the algebraic sum of all the rotor voltages. Because of the high impedance in the secondary circuit an electronic voltmeter is used to measure the output voltage.

OPERATION OF THE MACHINE

The appearance and dimensions of the machine are shown in Fig. 5. The structure factor data are applied to the machine through the rotary switches which are shown in the dotted circle insert to the panel. To the right of each rotary switch are the d.p.d.t. switches for the selection of signs and also for the "zero" structure factor not provided by the rotary swtiches. The (hk) values are marked below each rotary switch to aid the operator when setting up the machine for calculation. The structure factor values are applied as one of twelve values from a simple conversion table letting the largest F_{hk0} value assume the twelfth position of the rotary switches.

When the data have been applied and machine turned on, the voltage representing the electronic density value is read on the voltmeter V for each position (xy) which in turn is selected by knobs X' and Y' and indicated by dials X and Y of Fig. 5. These

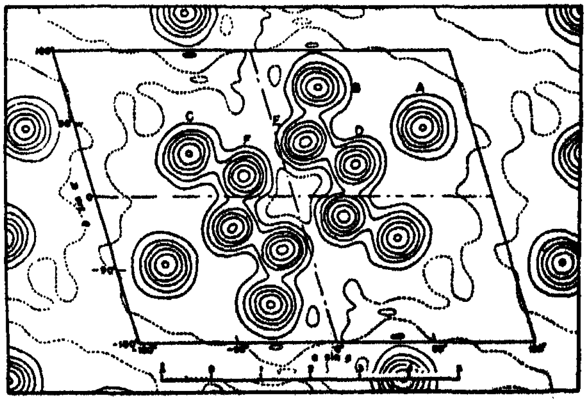

FIG. 7. The *c*-axis projection of hexamethylbenzene.

---

[4] R. Pepinsky, J. App. Phys. 18, 601 (1947).

instruments and control knobs are located on the instrument and control table as shown in the dotted rectangle inset. The dials are divided into 60 parts as a result of traversing the unit cell in 60 increments. This restriction of cell positioning may be removed at any time by disengaging a ratchet in each of the gear trains. The knob rotates a 1/4 turn for a movement of one division of the dial needle. The knobs turn the main gear train shafts directly by means of flexible shafting.

To ascertain the usefulness and accuracy of the machine, calculations were made on two known structures using the data of the original investigators. The first was that of one of the projections of diopside determined by Bragg.[5] The contour map obtained by use of the machine in a *b*-axis projection shown in Fig. 6 is in very close agreement with that of Bragg's. Although numerical comparison, point for point, cannot be made (since Bragg used intervals of 1/48 unit cell dimensions instead of 1/60), interpolation reveals satisfactory operation of the machine. As in the original work, a contour interval of 40 was used.

The second test was made on hexamethylbenzene based on the data of Brockway and Robertson.[6] Since the machine handles only Miller indices up through 8, there were two structure factor values that could not be included. However, these were of minor magnitude and the effect of omitting them is considered negligible. Figure 7 shows the *c*-axis projection of hexamethylbenzene obtained through the machine. The lines were drawn at equal density intervals from uncalibrated results, but the interval may be taken as approximately 60 with the values for the dotted lines being about 30. The carbon atom positions taken from this map are tabulated and compared with Brockway and Robertson's values in Table I.

FACTORS AFFECTING ACCURACY

The accuracy of the machine is dependent upon (a) backlash in the gears, (b) the accuracy with which the structure factors can be applied, and (c) the uniformity in the construction of the selsyns for their use as variable transformers. In adjusting the gear spacings the decrease in backlash must be weighed against the tightness of meshing to obtain optimum operating conditions. The use of only twelve discrete voltages rather than a continuous one has its effect on accuracy, but if the twelfth point of the rotary switch is used for the highest value of the structure factors, the error for the others with respect to this value is one-half of one-twelfth or about 4 percent. This is of sufficient accuracy for most structure calculations, the degree of accuracy in locating the positions of the atoms being of a much higher order. To offset the non-uniformity in the construction of individual selsyns, an attempt is made to match the selsyns to obtain equality of transformer characteristics from one pair of selsyns to another. The variations resulting from fluctuations in the line voltage are eliminated by the voltage regulator in the power supply.

TABLE I. Position of carbon atoms in hexamethylbenzene.

Atom	Brockway and Robertson x/a	y/b	Machine x/a	y/b	Difference x/a	y/b
A	0.371	0.234	0.371	0.233		−0.001
B	0.144	0.379	0.142	0.375	−0.002	−0.004
C	−0.227	0.1455	−0.226	0.147	0.001	0.0015
D	0.1775	0.111	0.178	0.113	0.0005	0.002
E	0.685	0.180	0.683	0.182	−0.002	0.002
F	−0.108	0.169	−0.110	0.070	−0.002	0.001

Since many structures require F_{hk0} values where *h* and *k* exceed eight, it is planned to extend the machine to receive values to 16 and also provide for one of the Miller indices to be negative. Also since the speed of the present machine is limited to the rate at which a person can write down the answers, a means for automatic recording of contour intervals is being developed.

ACKNOWLEDGMENTS

The authors wish to express their gratitude for a grant from The University of Utah Research Fund which made this work possible, to Dean C. J. Christensen of the College of Mines and Mineral Industries and to Dr. J. R. Lewis, Head of the Department of Metallurgy, for their continued encouragement and valuable suggestions, to Dr. J. Hugh Hamilton, Director of Utah Engineering Experiment Station, for use of tools and machine shop facilities, and to Mr. Hardy Felt for his ready assistance and suggestions.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 9 SEPTEMBER, 1950

The Scintillation Efficiency of Anthracene for Low Energy Electrons

W. J. RAMLER AND M. S. FREEDMAN
Argonne National Laboratory, Chicago, Illinois

(Received January 11, 1950)

The efficiency of an anthracene scintillation counter used as the detector in a double magnetic lens beta-ray spectrometer for electrons in the range 0–20 kev has been determined. Monoenergetic electrons generated by an electron gun were focused on the anthracene crystal, the beam being concurrently monitored by an electron collector and electrometer. The results are shown in Fig. 4.

THE comparative efficiency for low energy electrons of a scintillation counter employing a thin anthracene crystal as scintillator has been determined. The scintillation counter has been used for over a year as the detector in the double lens β-ray spectrometer constructed in this laboratory.[1] Recent investigations of very low energy spectra[2] have shown that β's were being counted at energies as low as 500 ev. The primary purpose of the experiments described here was to obtain the relative efficiency as a function of β-energy in the experimental arrangement used in the spectrometer, which efficiency may then be applied to obtain corrected β-energy distributions.

EXPERIMENTAL PROCEDURE

The experiment was performed by counting scintillations induced in the anthracene counter by a monoenergetic electron beam and simultaneously monitoring the beam intensity with an electron collector and vibrating reed electrometer. The apparatus is shown in Fig. 1, and enlarged views of the collector and crystal in Fig. 2, and of the electron gun in Fig. 3. An electron beam is furnished by the electron gun driven by a 30-kv voltage supply, the gun being mounted in the source position in the double lens spectrometer. The gun consists of a tungsten hairpin filament shielded by a highly polished platinum cup, and a conical polished brass anode. All insulation is fused quartz. It was found that zinc vapor was evolved from a brass filament shield, which led to breakdown in a short time for accelerating voltages greater than 10 kv. At a pressure of 5×10^{-6} mm Hg, accelerating potentials of over 25 kv could be maintained with negligible field emission.

The most intense part of the electron beam is projected along the axis of the spectrometer where it is intercepted by baffles. Because of the defocusing actions of the conical electrostatic lens anode and of space charge, a small fraction of the beam diverges sufficiently to be focused by the spectrometer at the adjustable ring focus baffle, B_2. Baffle B_2 is set to a very narrow annulus, so that light from the incandescent gun filament is effectively shielded from the scintillation counter.

The focused beam impinges on the electron collector, and a fraction ($\sim$1 percent) passes through the central hole onto the anthracene crystal. The angle at which the beam enters the central hole is such that it cannot touch the wall, so no secondary electrons can reach the crystal. Secondary electrons produced in the collector tubes are recollected with an observed efficiency of >85 percent (probably greater than 98 percent) over the range 0–20 kev of primary electron energy.

The thin anthracene single crystal (0.1 mm) was grown by sublimation in a helium atmosphere, and the 1-mm thick crystal was cleaved from a large single

crystal grown from the melt. Both crystals were clear blue-white and showed only faintly the bands due to naphthacene fluorescence with either ultraviolet or x-ray excitation.[3] The crystals are cemented to the Lucite light pipe, which is shaped hemispherically[4] to collect photons ejected tangentially to the crystal surface. Photons are piped with a geometrical efficiency of ~10 percent to the 1P21 photo-multiplier, which is maintained at −196°C in a Dewar, and shielded from the magnetic field of the lens coil. Since Lucite fluoresces well at −196°C[5] and so enhances the background count due to cosmic rays, the last few inches of the light guide inside the Dewar consists of an aluminum foil cylinder. With 1200 v on the photo-multiplier, well up on the plateau for pulses due to single photo-electrons from the photo-cathode, the background is about 40 c/m. With the gun filament on, the stray light increased the background to a few hundred counts per minute.

Amplified pulses from the 1P21 are recorded by a logarithmic counting rate meter and chart recorder as is the output of the vibrating reed electrometer. As the current through the spectrometer lens coils is controlled by a motor driven potentiometer, the current may be swept continuously through the range corresponding to the energy being emitted by the gun, and the profiles of the "line" received on both scintillation counter and electron collector may be simultaneously recorded. This is necessary as it is difficult to ensure extremely steady emission from the tungsten filament. Furthermore it ensures against a change in the spatial distribution of the gun emission pattern appearing as an altered ratio of the electron current on the collector to that on the crystal, because the pattern is swept across both by the varying magnetic field. The emission is adjusted to give counting rates in the range 5000 to 35,000 c/m and collector currents of 10^{-14} to 10^{-12} amp. At all energies investigated the lines were sharp, indicating clean separation from low energy scattered electrons in the beam.

RESULTS

The relative counting efficiency, defined as the ratio of the peak counting rate to peak collector current, as a function of electron energy is shown in Fig. 4. Curve *A* is for a "thick" crystal (1 mm) which was somewhat "frosted" on its surface due to partial evaporation of the anthracene in the vacuum.[6] Curve *B* is for a thin (0.1 mm) clear single crystal. The curves are normalized to 100 percent counting efficiency at the horizontal asymptote. Data were not obtained for curve *B* for energies below 1.5 kev because of the more rapid drop in efficiency.

It was anticipated that the frosted surface of the thick crystal would result in light losses for the lower energy electrons. The higher efficiency of the thicker crystal at very low energies is thus as yet unexplained, as is the very rapid drop off in efficiency at low energy for both. It appears that the specific efficiency of the anthracene for the production of ~3-ev fluorescence photons (photons/kev) is sensitive to primary electron energy in the region of a few kilovolts.

That the sharp drop in efficiency of production of photons is due to an insensitive surface layer on the crystal seems ruled out because the surface is continually renewed by the evaporation of the anthracene. Contamination of the crystal surface from residual vapors such as silicone diffusion pump oil in the vacuum system is eliminated as the cause since there is no progressive lessening of the efficiency with time.

The data of curve *A* are shown on a log-log scale in Fig. 5. Where the efficiency is low there is only a small probability that more than one photo-electron will be ejected from the photo-cathode, so the efficiency will be closely proportional to the number of photons generated per incident electron. It may be seen from Fig. 5 that the curve is asymptotic to the relation:

Number of photons = constant $(\text{volts})^{3.8}$. Similar relations have been observed[7] for some inorganic phosphors, such as zinc orthosilicate, zinc sulfide, and calcium tungstate, with values for the exponential factor of 2.0, 2.8, and 2.0, respectively. If this relation is

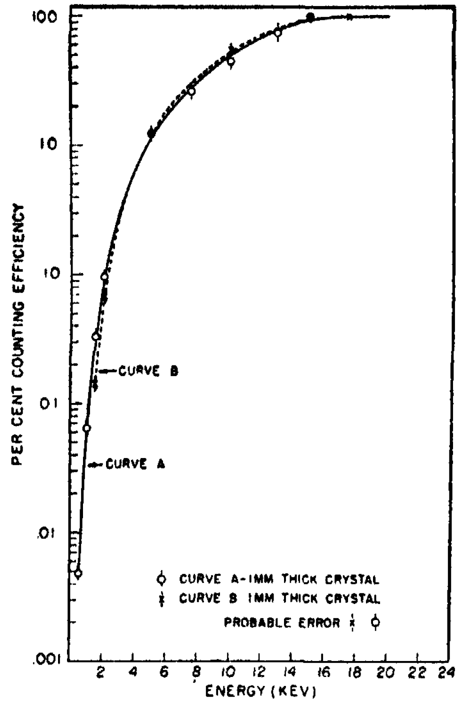

FIG. 4. Relative counting efficiency.

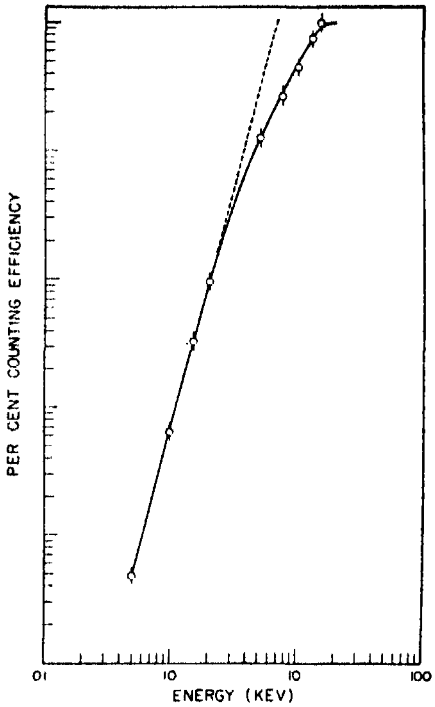

FIG. 5.

assumed to hold for energies somewhat higher than 15 kev, it follows that the counting efficiency curve will change only slightly with changes in the light-gathering efficiency, because of the rapid variation of light emission with energy.

From estimates of the light-gathering efficiency and the value of the photo-electron yield of the photomultiplier (supplied by the manufacturer) the efficiency of anthracene to electron energies in excess of 15 kev is simply calculated as ~5 percent; i.e., ~5 percent of the energy loss appears as fluorescence, or 60 ev per photon. This value compares with a value of 3 percent for energetic deuterons given by Wouters,[8] and with 64 ev per photon for electrons in naphthalene by Kallmann.[9]

We have observed that scintillation pulses generated by 5-Mev α-particles in anthracene have amplitudes about equal to those produced by 0.5-Mev electrons. It is notable that both α's and very low energy electrons have higher rates of energy loss than do energetic β's. Kallmann[9] assigns an efficiency of 960 ev per photon for α-particles in naphthalene.

The reproducible counting efficiency of 100 percent above 50 kv, with usable efficiency to below 2 kev, combined with the convenience of the scintillation counter technique makes it an attractive alternative for Geiger counters in the beta-spectrometer. If a low energy cut-off of ~50 kev is acceptable in a particular experiment, the pulse height discrimination may be raised to correspond, with the advantage that the background count is reduced essentially to zero. We have observed that if too thin anthracene crystals are used (~0.1 mm), the counting efficiency for high energy beta-rays is less than 100 percent. This result is consistent with calculations of the energy loss of energetic β's in such thicknesses based on a simple model.[10] No loss in high energy counting efficiency with 1-mm thick crystals has been found.

The low energy ends of some β-spectra have also been observed using KI (Tl) single crystals as fluorescers. Poorer low energy sensitivity than anthracene was found. In addition, KI (Tl) gives rise to spurious "single electron" counts because of the release of trapped electrons.[11] The gross efficiency of diphenyl acetylene[12] for low energy β's has also been compared with that of anthracene by D. W. Engelkemeir of this laboratory; anthracene was superior.

We are indebted to Dr. T. B. Novey of this laboratory who prepared the anthracene crystals, and to Bernard Smaller for his contributions to the adaptation of the scintillation counter for use in the beta-spectrometer.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 9 SEPTEMBER, 1950

Fabrication of a High Power Resonant Wave-Guide Window

E. V. EDWARDS AND K. GAROFF
Signal Corps Engineering Laboratories, Fort Monmouth, New Jersey

(Received May 17, 1950)

The inability of present wave-guide pre-TR and TR tube windows to withstand high transmitter power necessitates improved window design if 3000-megacycle radar systems are to continue using the conventional band pass TR protective device. The fabrication of a glass window with a loaded Q of four is described and operational tests at high line power are discussed. This construction permits the TR tube parts to be brazed in a hydrogen furnace and a more rigorous pumping schedule to be followed. A flow chart of the window processing operations and pictures of the window and pre-TR tube are included.

1. INTRODUCTION

THE band pass type of TR tube consists of a gas-filled section of wave guide containing two or three resonant gaps and closed at both ends by resonant windows. A pre-TR is a similar gas-filled tube except that it is only a quarter of a wave-length long and has no gaps. The high power from the pulsed transmitter ionizes the gas between the gaps and across the back of the window, most of the power being dissipated at the window. The heat generated in the discharge across the window reaches very high levels because of the required presence of a de-ionizing gas in the tube. It has been known for some time that window burnout would limit the maximum transmitter power handling capabilities of TR tubes now in use.[1]

The development of band pass TR tubes for high power therefore requires an improved window. An accepted method of reducing the power dissipated at the window is to increase the loaded Q of the window.[1] An additional requirement of high power TR tubes is that they be hard soldered and baked at 400°C instead of the present practice of soft soldering the windows to the tube body.[1,2] The window must therefore be capable of resisting the high brazing temperatures of the hydrogen furnace.

Before entering into the discussion of the glass window, it should be noted that the possibilities of a ceramic window have not been ignored. The techniques for bonding rectangular shaped ceramic to metal are now being investigated at this laboratory.

2. DESIGN OF A RESONANT WINDOW (Loaded $Q=4$)

The wave-guide type of TR tube described in the previous paragraph has a band pass frequency response to signal levels below the ionization potential of the gas. The band width of this response depends on the loaded Q of the resonant elements and therefore limits the increase in window loaded Q that can be tolerated. With these considerations in mind, a value of 4 was assigned as a design parameter for the loaded Q of the window. The dimensions were determined empirically for such a window to resonate at the desired frequency and fit into standard rectangular wave guide $1\frac{1}{2}\times 3\times 0.080$ inches. The Kovar of the cup is 0.060 inches thick and the glass thickness at the center of the finished window is 0.078 ± 0.001 inches. Figures 1 and 2 show views of a window made to these specifications and Fig. 3 is a pre-TR tube with the windows brazed to the tube body.

3. WINDOW PROCESSING

A flow chart has been included to show the step by step procedure for processing the window. However, some elaboration on the skeleton of the flow chart may prove helpful. It should be noted that the procedure outlined is the result of a number of attempts which will not be described here for lack of space.

Spraying the powdered glass takes some practice if an even coating of the desired thickness is to be obtained. A small DeVilbiss gun under 20 pounds pressure of tank nitrogen with the work 8 to 12 inches from the gun gives the most satisfactory results. The first coat is light and wet and permitted to dry only partially before the next coat is added. The 705*FN* powdered glass should be used as soon as possible after it is ball milled and sized, in order to minimize the moisture adsorbed by the glass. The mixture must be stirred after every minute of spraying to maintain a uniform density of the sprayed material. Methyl alcohol was found to be a very poor substitute for ethyl alcohol as a carrier for the powdered glass. However, Sylvania has reported favorably on the use of Innis Speidon and Company's Isco Algin No. 117 as a binder. The strength of the final seal is greatly improved by glazing the front of the Kovar cup as well as the edges of the iris. The glazing period is measured from the time that the furnace and the Kovar cup became the same color.

Electric motor-brush carbon is best suited for molding the glass during the sealing operation. The carbons are grooved on the surfaces that contact the softened glass to permit trapped air to escape without forming bubbles in the glass. A weight of 175 grams is placed on the carbon to bring the glass to the desired thickness in the firing time specified. This thickness is fairly critical, a 0.002-inch variation shifts the resonant frequency of the window by 30 megacycles. If required a small amount of glass can be removed by an ammonium bifluoride solution, although this has not been necessary in the 25 or more windows processed thus far.

4. RESULTS OF TESTS ON WINDOW

These windows have proved their ability to withstand extreme processing and operational temperatures. The former is indicated during the assembly of the pre-TR of Fig. 3 where the temperature required for brazing window to tube body is 800°C. The windows and the tube body are not preheated but pushed directly into the hot hydrogen furnace. None of the windows that were processed leaked as a consequence of the thermal shock from such treatment. In addition, some windows have withstood reheating to this temperature as many as 14 times in TR tubes that were being rebrazed. For operational tests, pre-TR tubes were used since they are simpler to construct although the window is subjected to the same gas discharge conditions as in the TR tube.

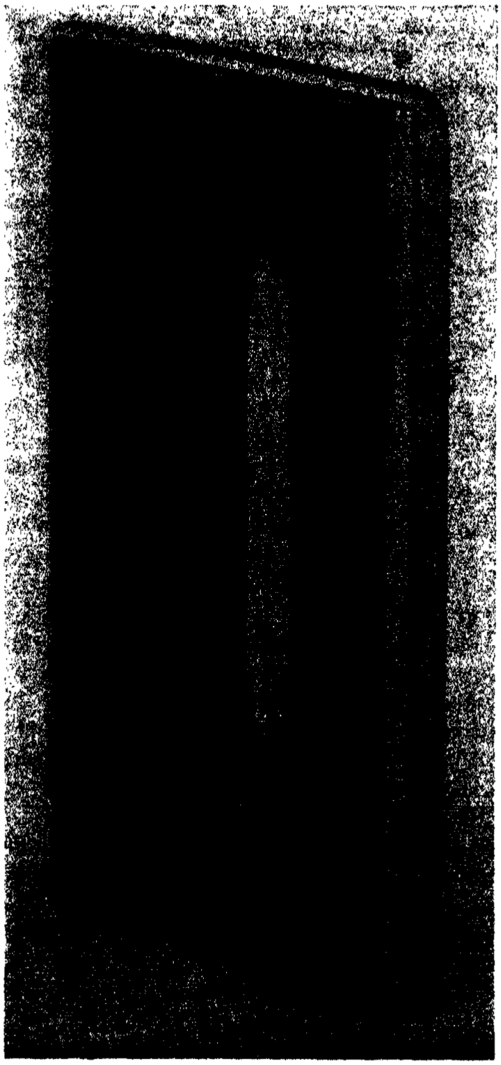

FIG. 1. 3000 mc r-f window, $Q_L = 4$. Interior view. Complete unit showing sprayed powdered glass fused to inner surfaces.

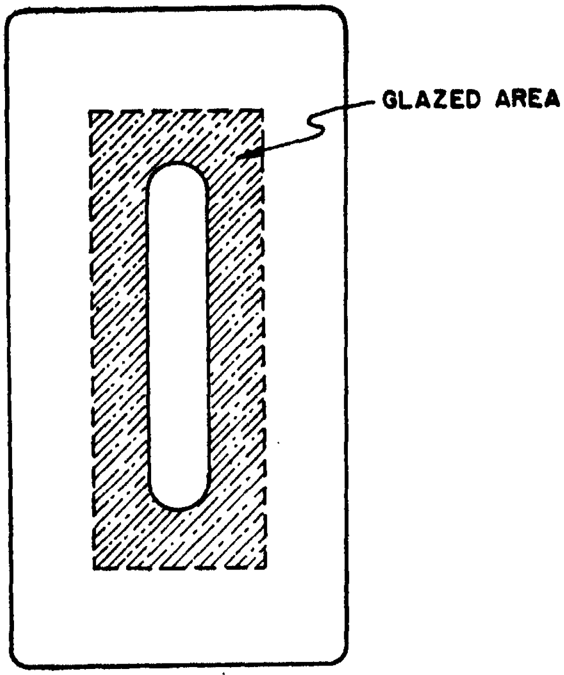

FIG. 2. 3000 mc r-f window, $Q_L = 4$. Exterior front view. Complete unit showing glass to metal type of seal.

Since tubes filled only with a de-ionizing gas will generate the hottest discharge, three pre-TR's with such gas were subjected to high peak transmitter powers. The temperature of the window as measured by a thermocouple was 160°C under these conditions with no window failure. This should be compared with the results obtained with the pre-TR tubes having a window loaded Q of unity, where the window was sucked in or cracked at about half the power used here, depending on the partial pressure of the de-ionizing gas.

5. CONCLUSION

Windows with a loaded Q of unity now being used in TR and pre-TR tubes will not be satisfactory at high transmitter power. The use of a higher Q window processed as reported, solves one of the major problems in the path of the development of conventional band pass pre-TR and TR tubes that will operate at very high power levels. The sources of r-f power available at this Laboratory at the present time cannot feed sufficient power into the pre-TR discharge to damage the high Q window.

WINDOW PROCESSING FLOW CHART

Preparation of Kovar Cup

1. Cut sheet Kovar to size and anneal in H_2 at 900°C for one-half hour.
2. Draw Kovar into rectangular cup approximately 0.400 in. deep.
3. Anneal cup at 900°C for one-half hour in H_2 furnace.

4. Mill the lip of the cup for mounting to wave-guide body and cut out the iris. Round the edges of the iris to avoid sharp corners.

5. Degrease the cup and then sandblast the inside of the cup and a narrow margin around the iris on the outside of the cup.

6. Degrease and anneal in H_2 furnace for one-half hour at 900°C.

7. Spray powdered 705*FN* glass uniformly around the inside of the cup as well as around the sandblasted margin on the front of the cup. (200 mesh 705*FN* glass—one part glass to three parts ethyl alcohol by volume.)

8. Dry thoroughly under infra-red lamp but avoid intense heat.

9. Remove powdered glass from any parts of cup where it will interfere with brazing the window to the tube body.

10. Glaze the sprayed glass in an air furnace at 940°C, keeping the cup in the furnace for two minutes after it reaches this temperature.

11. Remove the glazed cup from the furnace and cool to room temperature in a place free from drafts.

Processing the Glass Blank

1. Press 707*DG* glass cane into a ¾×2×0.100 inch blank.

2. Shape blank on the grinding wheel to 0.250×1.718 ×0.070 inches.

3. Bevel the edges on one face of the blank to permit insertion into glazed iris.

4. Clean blank with soap-water, rinse in potassium dichromate solution then distilled water and dry under infra-red lamp.

5. Examine blank for cracks, flaws or large air bubbles.

Sealing Glass Blank to Kovar

1. With the glass blank set in the iris, place the Kovar blank cup side down on a carbon block and place another carbon block, weighted by 175 grams, on the face of the window.

2. Keep in air furnace at 940°C for three minutes after work has reached temperature, then remove and allow it to cool to room temperature in draft-free place.

3. Remove oxide with "Oakite," polish with aluminum oxide and electroplate with a high conductivity metal.

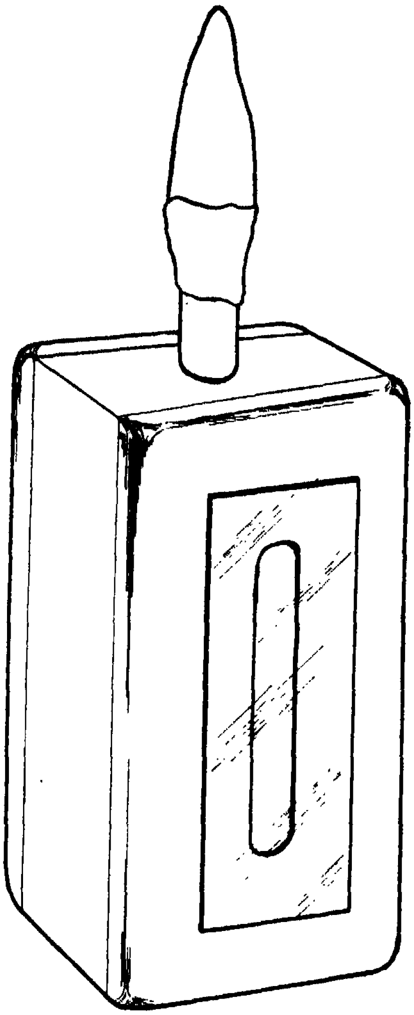

FIG. 3. 3000 mc pre-TR tube. Application of r-f windows in hard-soldered construction over-all ¾ view. Complete unit showing typical assembly and use of a window.

Erratum: Regulated Low Voltage Power Supply

[Rev. Sci. Inst. 21, 570 (1950)]

A. K. SOLOMON
Biophysical Laboratory, Harvard University, Cambridge, Massachusetts

THE lead from pin 5 of the uppermost VR 75 tube should be connected to the regulated output voltage of 225 volts, in lieu of the *incorrect* connection as indicated in Fig. 1 to the grids of the 6AS7 and plate of the 6AK5 tubes.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 9 SEPTEMBER, 1950

An Improved Resolving Time Measuring Device*

B. W. ROBERTS, JR., K. E. PERRY, AND R. G. FLUHARTY
Department of Physics and the Radioactivity Center of the Laboratory for Nuclear Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts

(Received January 23, 1950)

A circuit for measuring resolving times has been developed utilizing the scheme of Curran and Rae with the addition of a delayed pulse of variable width. Any random event initiates a delayed pulse which is fed into coincidence with subsequent pulses giving rise to a sharp increase in the coincidence rate at a delay time close to the resolving time. A theory is given which predicts observed curve shapes and data is given for several counters to illustrate the operation under different counting rates and overvoltages.

INTRODUCTION

THE resolving time, ρ, of a counter or circuit is a parameter needed to obtain accurate counting results. It will be defined as the dead-time of a counter or circuit plus that part of the recovery time[1] needed for the pulse height to reach operating size.

Among the more direct methods of measuring resolving times of counters observing random events are: (1) the direct timed-sweep oscilloscope method[1] in which a pulse initiates the horizontal sweep and then records the subsequent pulse on the oscilloscope, (2) the standard two-source method and (3) the coincidence methods.

Curran and Rae[2] devised a coincidence circuit which utilized a variable width square pulse initiated by any random pulse from the counter tube. The square pulse was then differentiated, giving rise to a narrow pulse delayed a time equal to the time-width of the square pulse. This delayed pulse was fed into a mixing circuit with subsequent random pulses where coincidences were observed. A plot of the delay time against the observed coincidences gave a curve with a rise in the region of the resolving time.

A National Bureau of Standards circuit[3] used for dead-time measurements "selects, in effect, pairs of pulses with a time separation less than a selected value determined by the setting of the multivibrator controls, and one count is recorded for each pair received." A plot of counting rate *versus* gating time is then interpreted for the dead-time.

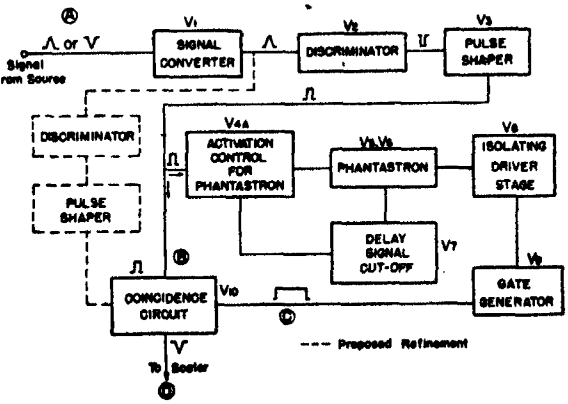

FIG. 1. Block diagram of coincidence circuit.

A British report[4] describes an electronic method where the "electronic gate is initiated by fully recovered pulses, and this automatically sets itself to the time of recovery to a pre-set amplitude. The time is then displayed on a calibrated meter." This is essentially a coincidence method with an involved circuit for directly recording the resolving time on a meter.

An interesting indirect method for measuring the resolving times of x-ray counters was devised by Pepinsky and co-workers.[5] An x-ray tube is pulsed into conduction by two sets of ½ micro-second, 1000 cycle triggers which are continuously phasable with respect to each other. The sets of x-ray pulses produce two Geiger pulse contours on the oscilloscope screen, and by reducing the time separation (phase difference) until the second pulse contour disappears, the dead-time can be directly determined. Measurements made by this technique checked favorably with those taken by Alexander[6] using the oscilloscope method.

Among the above methods, there are various limitations. The oscilloscope method requires photographic recording for best results. The two-source method does not give consistent results for mixed β- and γ-sources,[7] γ-sources and x-ray sources;[8] and a large number of counts is required to reduce statistical errors. This is objectionable both in regard to counter lifetimes and to the laboratory time required for measurement.

The British gate circuit is complicated by the large number of electronic elements. The Pepinsky method requires a pulsed x-ray source which is not always available. And the circuit of Curran and Rae requires large counting rates or long observation times to get significant results because of the narrowness of the pulses mixed for coincidences.

In an effort to increase the efficiency and accuracy of measuring resolving times a circuit has been designed using the basic scheme of Curran and Rae but utilizing a variable-width delayed pulse.

DESCRIPTION OF CIRCUIT OPERATION

A block diagram of this improved instrument is shown in Fig. 1 and the schematic in Fig. 3. Idealized wave forms at various points of the circuit are detailed in Fig. 2 to clarify the following text.

A positive or negative signal is received from the counter preamplifier, or other source, and is fed through the signal converter where the correct polarity is selected by a panel switch.

The initiating pulse (curve *a*, Fig. 2), being large enough to overcome the discriminator bias on V_2 (Fig. 3), triggers the pulse shaping multivibrator V_3. The shaped pulse (*b*, Fig. 2) is impressed on the grid of V_{4A}, the phantastron activation control; and on the first grid of V_{10}, the output coincidence tube; but since there is no opening gate on the third grid of V_{10} no pulse appears on the output plate. The phantastron circuit is triggered by the plate of V_{4A} through the isolating diode. The operation of the phantastron circuit (V_5, V_6) has been given by Close and Lebenbaum.[9]

A wide negative gate appears on the cathode of V_{4B} (curve *c*, Fig. 2) and another of the same duration on the cathode of V_6 (curve *d*) which faithfully reproduces the linear fall of the V_6 plate. The gate widths are determined by the quiescent d.c. voltage on the plate of V_6, which is controlled through diode V_{8B} by the linear voltage divider potentiometer which is calibrated in micro-minutes. R_1C_1 also determines the phantastron gate width; C_2 being switched in for the higher range.

V_7 constitutes a blocking tube or signal cut off which inactivates V_{4A} during the delay time and for several hundred micro-seconds thereafter. This prevents the phantastron from being triggered before it has fully recovered to its quiescent state. If this were not done the delay time would not be reliable. Curves *e* and *f* of Fig. 3 show this action. It can be seen that the cathode of V_{4A} is driven strongly positive, thus holding it far beyond cut-off until, after the recovery of the phantastron, it decays back nearly to its original voltage.

At the end of the phantastron delay a positive pulse is applied to the grid of V_8 (curve *g*), the isolating driver stage (there is a negative pulse at the beginning of the delay but since V_8 is nearly at cut-off this has no effect), causing it to trigger the gate generator multivibrator V_9 which delivers the opening gate to grid three of coincidence tube V_{10}. In V_9 it is seen that in the left triode the grid is returned through a large resistor to 75 volts positive bias so that it is held at zero bias by drawing grid current. The left-hand plate being only a few volts above ground, the right-hand triode, with cathode at plus 75 volts, is cut off. The trigger pulse cuts off the left triode, causing the circuit to flip and the plate, along with grid three of V_{10}, to go plus 75 volts (curve *h*). The plate of V_{10}, which was originally cut off by the fact that the third grid was more negative than the cathode, will, during this gating interval, conduct if a positive subsequent pulse is applied to the first grid (curve *j*).

Five dotted pulses are shown on curves *a* and *b* (Fig. 2). These represent alternative random pulses which may occur after the initiating pulse. Number 1 is too early for the particular delay setting and is not detected. Pulses 2 and 3 represent the extremes that will be detected within the coincidence gate. Pulse 4 occurs after the end of the gate but the phantastron driver is still cut off so that a new cycle is not initiated. Pulse 5 occurs just after the phantastron is ready to receive a pulse so that it initiates another delay cycle.

Thus when the delay time is less than the effective resolving time, no coincidences can occur. As the delay time is increased, a sudden rise will be observed in n_c, the coincidence rate, when the resolving time is reached. n_c is largely determined by three parameters: t the time of delay, T the delayed pulse width, and ρ the resolving time of the circuit.

THEORY

In operation of the device two extremes of counters or circuits can be encountered. The actual case will be intermediate. The first to be considered is the paralyzable type such as a pure gas non-self-quenching

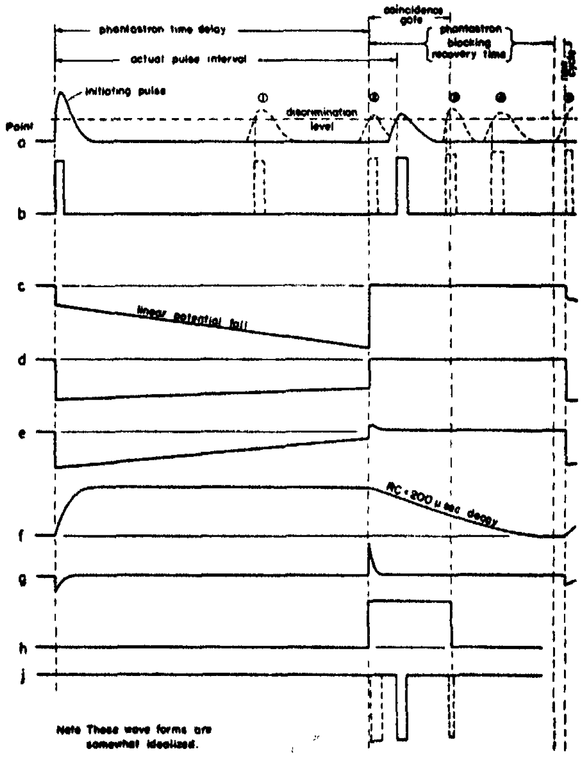

FIG. 2. Plot of time relation of pulses in circuit of Fig. 3.

---

[9] R. N. Close and M. T. Lebenbaum, Electronics 21, 100 (1948).

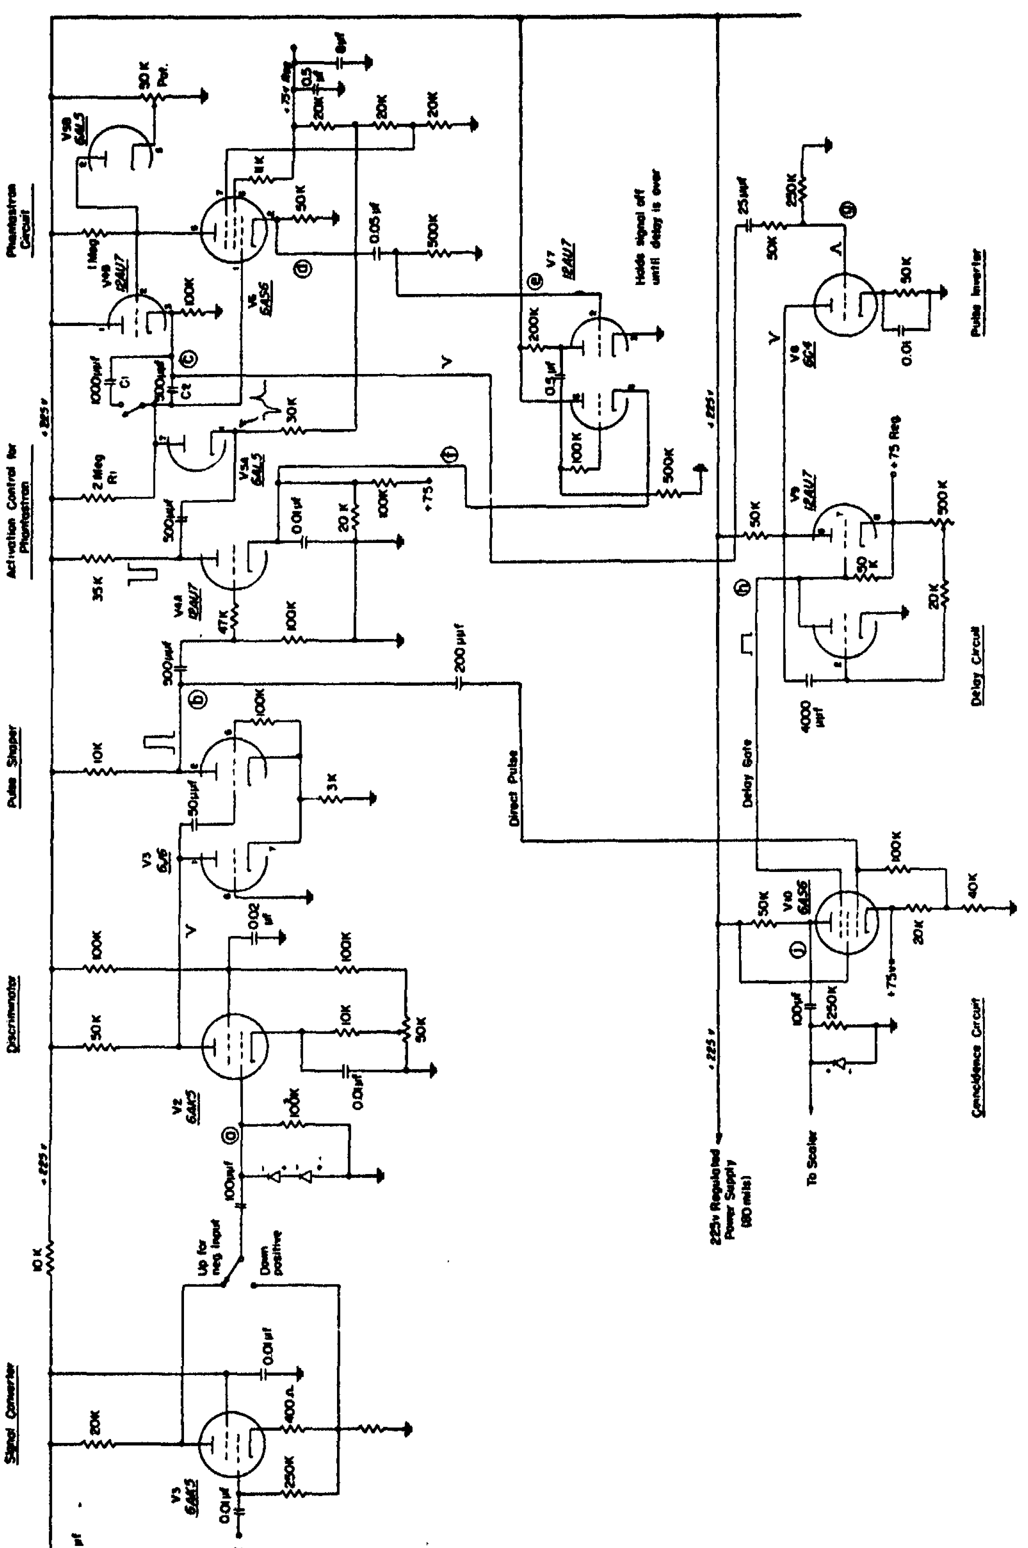

Fig. 3. Circuit design schematic of the coincidence-resolving time device.

counter where the preamplifier time constant is greater than ρ. This circuit will give a counting rate n_1 from n_0 true random events:

$$n_1=n_0e^{-n_0\rho}. \tag{1}$$

From these n_1 observed pulses, n_2 wide delayed pulses are derived. Since the delay circuit is dead during a delay time t (plus the phantastron blocking recovery time which is neglected here), the counting rate n_2 will be reduced since the circuit is inactive for a fraction of time n_2t. Thus the circuit is sensitive for a fraction of time $1-n_2t$ which is also equal to the ratio n_2/n_1. This gives for the delayed pulse rate:

$$n_2=n_1/(1+n_1t). \tag{2}$$

n_1 and n_2 are mixed in the coincidence circuit giving rise to a rate n_c. If n_1 and n_2 are assumed to consist of random events (which is untrue in both cases due to the loss of very short intervals in the distributions) the observed n_c will be:

$$n_c=n_1n_2(dt_1+dt_2), \tag{3}$$

where dt_1 and dt_2 are the pulse widths of n_1 and n_2 respectively.

Substitution of Eq. (2) in (3) and the use of Eq. (1) after replacing dt_2 by T gives:

$$n_c=\frac{n_0^2e^{-2n_0\rho}}{1+n_0te^{-n_0\rho}}(dt_1+T)\quad t\geqslant\rho, \tag{4}$$

which is a maximum when $t=\rho$ as shown in Fig. 4. In the limiting case as n_0 goes to ∞, n_c approaches zero. When $n_0\rho\ll 1$, the exponentials can be expanded and after dropping the second-order terms and permitting t to equal ρ we have:

$$n_c\approx\frac{n_0^2}{(1+3n_0\rho)}(dt_1+T). \tag{5}$$

This shows that the maximum value of n_c becomes proportional to n_0^2 as $n_0\rho$ approaches zero.

From $t=0$ to $t=\rho-T$, n_c must equal zero since no coincidences can occur. Then a sharp rise is observed as the delay pulse of width T moves across $t=\rho$, i.e. into the region where n_1 pulses can occur. This rise may be approximated for low values of n_0 by:

$$n_c=n_c(\max)\left(\frac{t-\rho+T}{T}\right)\quad \rho-T<t<\rho, \tag{6}$$

where $n_c(\max)$ is the value of n_c in Eq. (4) when $t=\rho$. Finally for the region of $\rho<t<\infty$, Eq. (4) applies. This region is described by a nearly constant relationship between n_c and t when $n_0\rho$ is very small and a $1/(1+n_0te^{-n_0\rho})$ decrease when $n_0\rho$ is large. Figure 4 shows several plots of n_c *versus* t and illustrates the expected curve shapes for low and high counting rates.

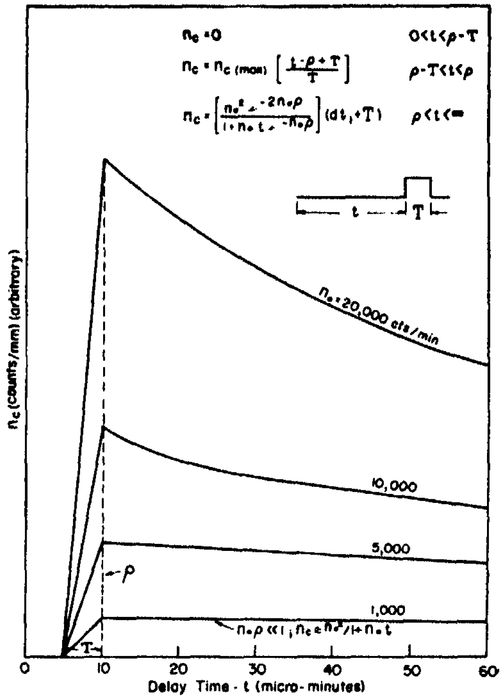

FIG. 4. Predicted coincidence curve for paralyzable apparatus.

The ordinate is arbitrary for each curve in order to plot simultaneously since $n_c(\max)$ for $n_0=1000$ counts/min. is 1/400 the value for $n_0=20{,}000$ counts/min. n_c is also directly dependent upon the value of T used in the measurement.

The non-paralyzable apparatus on the other extreme which is typified by a self-quenching counter with a very sensitive preamplifier gives rise to an equation

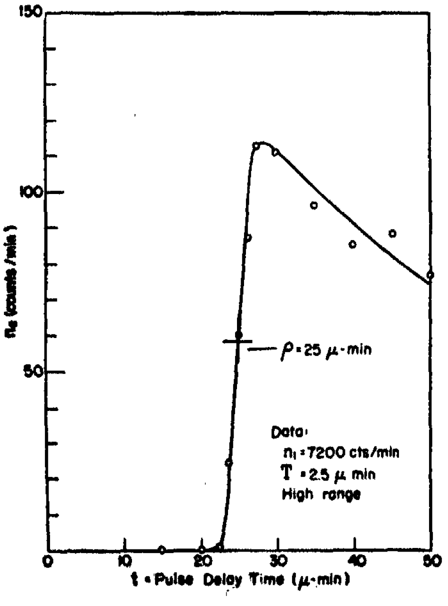

FIG. 5. Plot of n_c *versus* t for multivibrator-quenched circuit.

TABLE I. n_c and ρ as a function of pulse width T.

T micro-minutes	Rise width micro-minutes	ρ micro-minutes	n_c(max) Exper. counts/min.	n_c(max) Theory counts/min.
0.3	8.3	17.4	144	146
1.5	9.8	17.5	460	730
2.5	10.1	17.5	990	1200
3.5	9.7	16.0	1670	1700
5.0	10.1	15.6	2430	2430

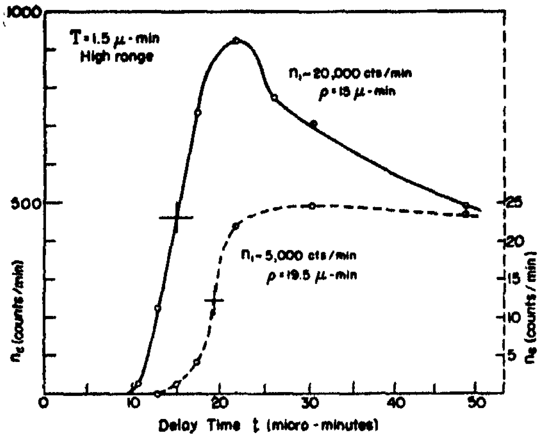

FIG. 6. Plot showing ρ as a function of counting rate.

for the coincidence rate similar to Eq. (4).

$$n_c' = \frac{n_0^2(dt_1+T)}{(1+n_0\rho)[1+n_0(t+\rho)]} \qquad t>\rho. \tag{7}$$

OPERATION

The delay time and pulse width were calibrated against the fixed time intervals on a precision synchroscope with internal calibration with intervals of about $\frac{1}{5}$ micro-minute. The delay time t had a range from 3 to 50 micro-minutes and the pulse width T varied from 0.3 to 20 micro-minutes. The input pulse height *versus* discriminator setting was found for both the scaler and coincidence circuit.

To measure ρ it is best to have the counter in an environment identical to that of normal usage to avoid effects such as counter sensitivity to light that may affect the counting rate. The counter is attached to the pre-amplifier and the prescribed operating voltage applied. A source is placed to give the desired counting rate n_1. By changing a switch the counter pulses enter directly into the scaler and a quick measure of n_1 can be made if desired. The pulses from the counter and the pre-amplifier are then fed into the coincidence circuit. The discriminator bias is adjusted to eliminate noise and other disturbances arising in the circuit for G-M counters, and the bias may usually be adjusted to maximum value for circuit resolving times since the pulses are full size and large. Next, the delayed pulse width T is adjusted to a value that gives a useful n_c. That is, an n_c value that may be quickly observed and plotted. For ρ up to 15 micro-minutes and n_1 approximately 6000 counts/min. a pulse width up to 2.5 micro-minutes was found applicable. For ρ above this range a 5 micro-minute pulse width may be used. There are two overlapping ranges of delay time. With these adjustments completed, t is varied from high to low until the abrupt drop in n_c is observed. This region is then scanned at small intervals of t over the n_c drop. A plot of n_c *versus* t is made and the half-maximum point on the curve is taken as the effective resolving time.

DISCUSSION OF MEASUREMENTS

The first determinations of resolving time were made on a high resistance multivibrator quenching pre-amplifier which had been carefully measured by the two-source method and found to be 25 micro-minutes. Figure 5 shows a plot of n_c *versus* t made at $n_1=7200$ counts/min. and $T=2.5$ micro-min. The expected abrupt rise is found and an approximately linear decrease follows. Using the half-maximum point on the plot gives 25 micro-minutes for the effective resolving time of the pre-amplifier circuit. The rise covers 5 micro-minutes which is twice that predicted since the theory gives the rise width as T. This extra width may be due to several factors, including non-ideal pulse forms in the circuit and the probable occurrence of G-M multiples in the rise region.

To observe the effects of pulse width, T, on n_c

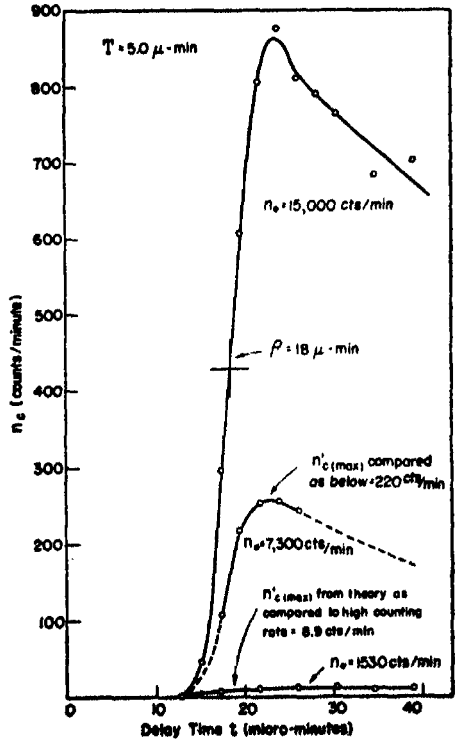

FIG. 7. Plot of n_c *versus* t to show experimental agreement with theory (multivibrator-quenched circuit in conjunction with a mica end-window x-ray counter).

and ρ, a series of measurements with a high pressure (69-cm Hg argon, 1-cm alcohol) mica end-window G-M counter were taken. A classical non-quenching pre-amplifier was used (1 megohm). From the plots the half-maxima were taken as ρ and the rise width was measured as the intercepts on a straight line along the rise from $n_c=0$ to n_c a maximum. These data are given in Table I. The pulse width does not affect ρ until a value of $T=3.5$ micro-minutes is obtained where a decrease is observed. The rise width does not show conclusive change. The maximum values of n_c are given to show the wide range obtainable with the variable pulse width T. A rough linear comparison between T and n_c is given in the last column where the n_c for $T=5$ micro-minutes was taken as the comparison point.

Figure 6 shows the effect of counting rate on ρ for a high pressure G-M counter with a classical pre-amplifier. An increase in counting rate of four times or more gives a decrease of about 20 percent. This decrease has been observed by Muehlhause and Friedman.[10] The plot also illustrates the theory roughly in that a more rapid decrease is observed for the higher counting rate after the maximum value of n_c.

In Fig. 7, three plots of n_c *versus* t are shown with their respective counting rates. The curve with $n_0=15{,}000$ counts/min. rises linearly in accord with Eq. (8) and then falls sharply. The fall is more rapid than that shown in Fig. 4 for $n_0=20{,}000$ counts/min. because the experimental ρ is nearly twice that of the theoretical curve. For the low counting rate the curve is horizontal within the dispersion of the points due to statistical error. Theoretical maximum values of n_c are shown for the two lower curves as referred to the top curve.

An interesting check was made on the variation of ρ with overvoltage on a high pressure counter (69-cm Hg argon, 1-cm alcohol) with a mica end-window. A very high fixed counting rate n_0 was used throughout with $T=0.3$ micro-minutes. The discriminator bias was reduced for the 50-volt reading due to the decrease of input pulse height (nearly a linear function of overvoltage). Figure 8 shows four plots at specified voltages above minimum operating voltage. A marked decrease of ρ is observed with increasing overvoltage. This effect has been observed and reported by Hartog.[11]

DISCUSSION AND CONCLUSION

By the addition of a wide delayed pulse to the scheme devised by Curran and Rae,[2] a flexible instrument has been designed to measure resolving times in the 3 to 50 micro-minute range. It is believed that the principle can be extended to the 10 micro-second region. The flexibility lies directly with the wide delayed pulse which permits arbitrarily large coincidence counting rates to be observed between a delayed pulse and subsequent pulses. This coincidence counting rate may be made large to the point that a rough resolving time can be read directly from a calibrated pulse delay dial.

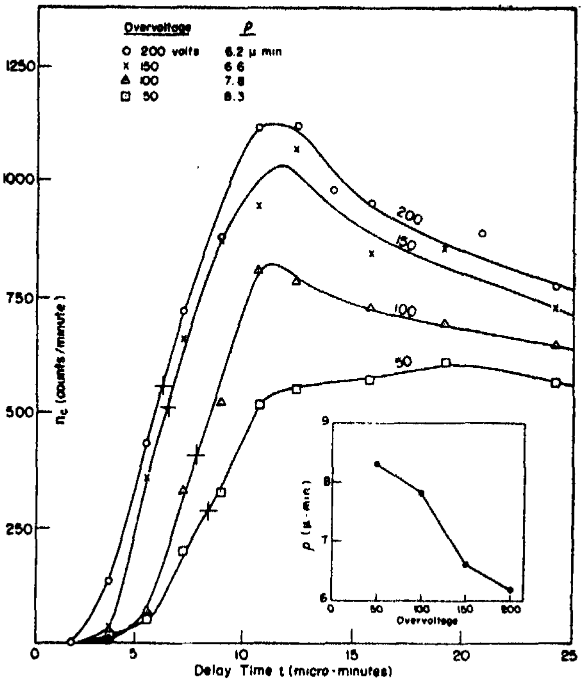

FIG. 8. Plot of n_c *versus* t for several over-voltage values.

A comparison of the observed resolving times with those measured by the two-source method indicates that the half-maximum of the coincidence curve is the best effective value of the resolving time. This contrasts with the rough theory which gives the curve maximum for the resolving time. This may be due to the neglect in the theory of small interval losses, the phantastron blocking recovery time, and the statistical nature of resolving time. Also the n_1 and n_2 pulse shapes found experimentally are not those assumed for the theory. These irregular pulse shapes would tend to make the n_c rise wider than indicated by the theory. The occurrence of G-M multiples would also disturb the curve in this manner. It is believed that a better comparison of resolving times could be made using the timed-sweep oscilloscope method.

The measured resolving time is determined both by the dead-time of the counter and by the pulse size discrimination level of the instrument for detection of the subsequent pulses. It is also true that the dead-time of the counter after any initiating (of the phantastron delay) pulse is affected by the size of this initiating pulse. That is, if the phantastron delay is initiated by one of the smaller pulses which may occur under the recovery envelope then the dead-time and the measured resolving time will be smaller. This effect can occur occasionally at high counting rates in the present instrument.

Thus it is seen that there are two functions of the discrimination level which are inseparable; the resolving time as determined by the level of selection of the subsequent pulses, and the minimum possible dead-time determined by the pulse size necessary for the delay initiation. The latter effect is not too important except at very high counting rates. In order to separate the two functions it has been suggested that a separate identical discriminator be employed as shown in Fig. 1. By this scheme the phantastron could be triggered only by full size pulses and the detection level of the subsequent pulses could be selected without the possibility of affecting the dead-time.

A 500-Kilovolt Linear Accelerator Using Selenium Rectifiers

WAYNE R. ARNOLD[*]
State University of Iowa, Iowa City, Iowa

(Received June 16, 1950)

A 500-kilovolt generator for use on a linear accelerator is described. This voltage is obtained by using selenium rectifiers and one microfarad condensers in 22 stages of voltage doublers. The maximum input is nine kilovolts r.m.s. at 750 cycles, and the maximum peak inverse voltage across each rectifier and each condenser is 25 kilovolts. The measured regulation is 25 kv/ma, the measured ripple (peak to peak voltage) is less than 1200 volts/ma; both independent of output voltage. The maximum load is 2.5 ma.

INTRODUCTION

THE voltage multiplier circuit usually used to give voltages of 500 kilovolts or less is a two- or three-stage multiplier using hot filament x-ray tube rectifiers. Such circuits require the use of condensers and rectifiers which must be rated at one-half to one-third of the total output voltage. They also require batteries, generators, or high voltage insulation transformers to heat the rectifier filaments. The machine described here uses selenium dry disk rectifiers so the filament heating problem does not arise. It is then convenient to use a greater number of stages of multiplication; more stages with the same output voltage results in a reduced voltage across each component. Although for a given load there is a limit to the number of stages of multiplication that can be used, proper choice of condensers and input frequency make this limitation relatively unimportant.

ELECTRICAL CIRCUIT AND COMPONENTS

The circuit used is shown in Fig. 1, and is essentially the same as used by Cockcroft and Walton[1] and by Bouwers and Kuntke.[2] The 44 condensers, used in 22 stages, are Westinghouse Inerteen Type FP rated at one microfarad and 25 kv and are all identical. Each of the selenium rectifier assemblies consists of five General Electric type 6RS5K72 selenium rectifiers placed in series to form a 25-kilovolt rectifier. These rectifiers are rated at 2.5 ma maximum and are the limiting factor on the output current. The transformer is a special 750-cycle transformer with a 250-volt primary and a 10,000-volt secondary insulated for 50 kv. This transformer is supplied through a Variac by a 750-cycle, 10-kva alternator. The 750-cycle frequency was used because this alternator was available. Lower frequencies could be used if a higher ripple voltage would not be objectionable.

The paper by Bouwers and Kuntke[2] gives an analysis of the circuit of Fig. 1, based on the assumption of perfect rectifiers and condensers. Their result, where n is the number of stages of doublers, C is the capacity of the individual condensers, i is the current drain, f is the frequency of the a.c. supply voltage, E is the peak input voltage, and V the output voltage, is

$$V=2nE-i[2n^3/3+n^2/2-n/6]/fC.$$

The terms in n^2 and n (in the bracket) may be neglected for large n. For this machine $n=22$, $C=10^{-6}$, $f=750$, $E=12.5$ kv; so for maximum input we have

$$V=550\text{ kv}-9.5i\text{ kv},$$

where i is in milliamperes.

By taking the derivative of V with respect to n, we find that the maximum voltage output (for 2.5-ma load, one-microfarad condensers, and a frequency of 750 cycles) would be obtained for n equal to 61 stages.

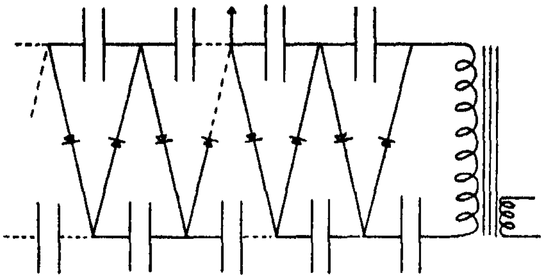

FIG. 1. Voltage multiplier circuit. The circuit below the arrow represents the usual quadrupler or two-stage multiplier.

The same theory gives

$$v=i[n^2/2+n/2]/fC$$

for the peak to peak value of the ripple. At full load on this machine the theory thus predicts a ripple of 840 volts (peak to peak). Either ripple or voltage drop under load could be minimized by using different values of capacity in the different sections, but the advantage over having all capacitors identical is negligible.

500-volt and 50-kilovolt scale models were built to check the applicability of this theory and to aid in the design of the 500-kilovolt machine. The behavior of both models was adequately explained by the theory so construction was started on the main machine.

MECHANICAL CONSTRUCTION

The manner in which the machine was assembled may be seen in the photograph of Fig. 2. The 44 condensers are arranged in four stacks of 11 condensers each. Each condenser is housed in an aluminum cylinder 18 inches in diameter, 3/16-inch wall, and nine inches high. The case of the condenser is connected by means of a strap soldered to the corona shield on which it rests, while the single insulated terminal is connected by means of an aluminum tube to the corona shield in the adjoining stack. The selenium rectifier assemblies attach to the aluminum tubes by means of fuse clips. These rectifier assemblies have five of the G.E. five kv units, inside of a one-half-inch I.D. Textolite tube, compressed by a spring. On top of each aluminum cylinder is a 26-inch disk of Textolite insulation, one-half inch thick, which in turn is covered by the 28-inch diameter corona shield. This shield forms the base for the next condenser in the stack. One of each pair of stacks has a 4¾-inch spacer at the bottom so that the condenser lead from one stack will be level with the corona shield on the adjoining stack. All four stacks are insulated from the floor to allow a voltage to be applied which will compensate for drifts in the high voltage. Mechanically the stacks were quite stable and no provision was made to prevent sideways slip. This allows a rather rapid change of components if necessary. Supported atop the four stacks is a large tank 30 inches high and with outside dimensions 84 by 90 inches, giving an over-all height of 12 feet for the machine. The main purpose of this tank is to prevent corona, but it provides more than adequate room for the voltage supplies for the ion source of the linear accelerator. This tank contains a 110-volt a.c. generator run by means of the long belt seen in Fig. 2. All wiring in the room is run through conduit for shielding.

The accelerating tube of the linear accelerator is seen at the right in Fig. 2, and consists of 23 re-entrant spinnings separated by 2½-inch porcelain insulators. Each stage of the voltage multiplier provides a constant voltage point which was connected by means of Yard-ohm (500 ohm/inch) inside of ⅜-inch Neoprene tubing to an accelerator tube spinning. This insures that the potential difference between adjacent spinnings is 1/22 of the total voltage. The extra spinning is used for focusing.

These tie lines necessitated a separate column at the edge of the accelerator tube platform. This column spaces the lines and prevents them from exerting sideways force on the accelerator tube. The column is made of Textolite tubing, six inches in diameter, with aluminum rings inside and out. In addition to the tie lines, this column also supports two three-inch copper tubes which run from the high voltage tank to the sphere atop the accelerator tube. One of these tubes is used as a vacuum pumping line for the ion source, and the other carries the wires supplying voltages for the ion source and focusing gap.

The ion source used on the accelerator tube is an Allison type source[3] modified so as to be more compact

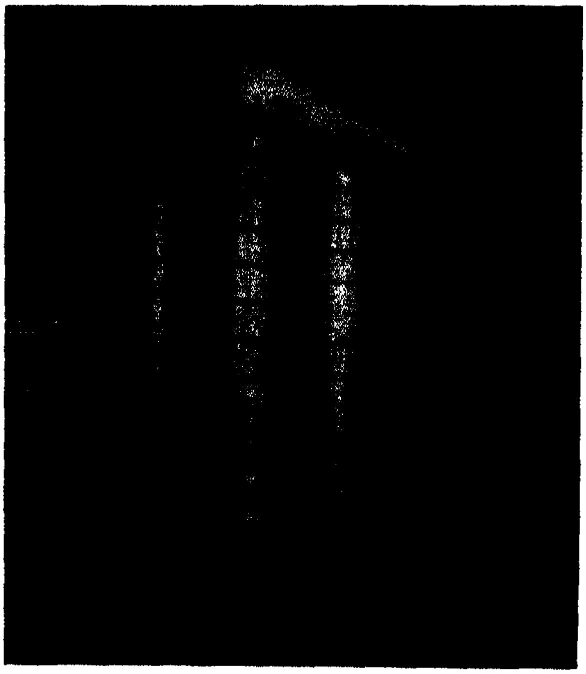

FIG. 2. The Iowa Generator. The accelerating tube is on the platform to the right.

and having a second probe orifice to allow differential pumping.

PERFORMANCE TESTS

The performance of this generator under load was measured by means of a resistance load, since the maximum total beam current was less than 1 ma. Several $\frac{1}{8}$-inch diameter Saran tubes were run from bottles of distilled water in the large tank on top to grounded bottles on the floor, and the water allowed to syphon out of the upper bottles. Moving water was used to prevent overheating in the Saran tubing. The resistance of the water was varied by adding small amounts of NaCl. The high voltage was measured by running a beam down the accelerating tube and finding the magnetic field necessary to deflect the protons through 90°. The current was measured by a meter in the line joining the bottom of the high voltage generator to ground. The curves obtained are shown in Fig. 3. Zero load points were not obtained since the beam with which the voltage was measured drew 0.5 ma. The curves show a voltage drop under load of about 25 kv/ma, or about 2.5 times the drop predicted for perfect rectifiers. The relatively large forward resistance of the selenium rectifiers also shows up in the lower output voltage obtained for a given a.c. input voltage. This effect is relatively unimportant as the voltages are uniformly lower across all components and in practice this is compensated by merely increasing the input voltage. A curve was not obtained for maximum output voltage because the resistivity of the distilled water was too low. The machine has, however, been run at 500 kv with a 0.5-ma beam load.

The ripple was measured by placing a known resistor in series with one of the Saran tubes. The a.c. component across this resistor was measured by an oscilloscope. It was necessary to shield the resistance and oscilloscope to prevent electrical pick-up from the sharply peaked current which flows in the transformer secondary. Since this pick-up was not completely eliminated the ripple measurement is only an upper limit to the true value. The ripple measured by this method was 1200 volts peak to peak per milliampere of load. This is about 3.5 times the theoretical ripple to be expected if the rectifiers and condensers were perfect.

The over-all efficiency was measured at 350 kilovolts and a 0.5-ma load and found to be 70 percent. (The current measured was the return current and not the beam current.)

The time constant for the high voltage to fall to $1/e$ of its original value with no load and zero input is 240 seconds.

OPERATIONAL PERFORMANCE

All difficulties with corona and arc-over have been experienced at the accelerating tube and the adjoining Textolite column. Because there are no surge resistors in this machine, the arc-overs are rather violent. All wiring in the room is in conduit and only very minor damage has been caused by electrical pick-up from these surges. The most damage that has occurred was when one of the straps joining a condenser case to a corona shield came loose during a surge. Photographs taken of the arc-over showed that it took place down the Textolite column next to the accelerator tube, and experience showed that it occurred only after 30 to 40 minutes of operation at voltages above 200 kv. A flattened sphere was placed on top of the column but had no effect. Recently corona shields having an outside diameter of 12 inches were placed around the outside of the column and these appear to have eliminated the arc-over completely. These shields were added after the photograph of Fig. 2 was taken. Research was done previous to the addition of these shields by limiting the length of a run to 20 minutes and discharging the machine completely between runs. Such a procedure was possible because the beam was steady almost immediately after voltage was reached.

The machine has been in operation since July of 1949, but it was not until the spring of 1950 that trouble was experienced with the 26-inch Textolite disks used for insulation in the condenser stacks. Six of these disks have punctured so far. As much as ten minutes before one of these disks breaks down a fluctuation of about 5 to 10 kilovolts is usually noticed in the high voltage, indicating that a leakage path is set up through the Textolite prior to puncturing. These Textolites are being replaced with annealed plate glass (Herculite) three-eighth-inch thick, with one-sixteenth-inch rubber gaskets to distribute the load. No difficulty has been experienced as yet with the glass disks in the machine. There seems to be no connection between the arc-overs and the failure of the Textolite disks.

Difficulties with the selenium rectifiers have been limited to gaps opening up within individual rectifiers. This does not introduce fluctuations of more than a few hundred volts in the output voltage, but does produce a 750-cycle arc across the gap which may be picked up by high gain detection apparatus. This difficulty is due to the manner in which the five-kv rectifier units are manufactured. The individual buttons are $\frac{9}{32}$-inch in diameter and are slid into a Textolite tube of only slightly larger diameter and then compressed with a small spring. The buttons tend to bind inside of the tube and expansion and contraction with temperature occasionally results in an imperfect contact between adjoining buttons. The offending rectifier may be easily found by use of an ohm-meter and corrected by tapping the end of the unit on the bench.

The use of a large number of accelerating gaps in the accelerator tube with each spinning connected to a constant voltage point on the power supply, has resulted in a beam that is well focused and which does not fluctuate nearly as much when the machine is first brought up to voltage as do beams in tubes where corona gaps are used as voltage dividers.

Resolved beams have been obtained with 30 microamps in mass one and 100 microamps in mass 2. The limitation on the beam current appears to be in the size of the second probe button which it used to effect the differential pumping. It should be possible to overcome this limitation with a new design, and allow full use of the maximum current available in the high voltage supply. To date the maximum load that has been placed on the machine by the beam and the return electron current is less than 1 ma.

Because of the small contribution of each stage to the total output, repair of an offending component may be postponed by merely shorting out the particular stage involved. This was done, for example, for the stage involved in the open condenser strap.

CONCLUSIONS

The difficulties that have been experienced with this machine are of such a nature that it should be possible to correct them without any major changes in design. The elimination of corona gaps for voltage dividers appears to be a definite advantage in obtaining stable operating conditions. By proper design of the ion source one should be able to obtain resolved beams on the order of three to five hundred microamperes without undue ripple. By reversing the polarity of the rectifiers, this machine could be used to accelerate electrons and thereby produce rather high x-ray intensities.

ACKNOWLEDGMENTS

This machine was built under the direction of Professor James A. Jacobs. Mr. George Carson helped keep costs down by securing many of the components, in particular the condensers, from war surplus. Mr. Joseph Zijacek did most of the labor involved in the construction, and Mr. Russell K. Soderquist helped in obtaining the data on the performance of the machine.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 9 SEPTEMBER, 1950

An Electronic A.C. Differential Voltmeter

L. A. Rosenthal and H. S. Zablocki
Rutgers University, New Brunswick, New Jersey

(Received June 8, 1950)

An electronic a.c. differential voltmeter capable of giving a direct reading of the percentage change in voltage in the region of ± 10 percent for voltage levels from 1.5 to 150 volts and frequencies between 20 and 200,000 cycles, is presented. The instrument is stable in operation, and simple in design. Experimental observations and circuit details are included.

INTRODUCTION

THE need frequently arises for a voltmeter capable of measuring changes in voltage about a given reference level. If the changes are in excess of ±10 percent, they can generally be read directly on a conventional instrument. However, for small changes the accuracy becomes poor and, if this region is to be expanded, a differential voltmeter capable of reading variations of less than ±10 percent is highly desirable. In addition, the differential voltmeter must have the other necessary characteristics of vacuum tube voltmeters, outstanding of which are insensitivity to line voltage variations, aging effects, and independence to input frequency. It is also desirable that the instrument be phase sensitive to avoid ambiguity in the change measured.

The aforementioned characteristics are obtainable in the electronic differential voltmeter to be described. The instrument consists of a non-linear Thyrite[1] bridge as the differential a.c. voltage detector in an amplifier circuit that has been stabilized by a large amount of feedback.

NON-LINEAR BRIDGES

A non-linear bridge can be defined as a bridge containing one or more elements which are non-linear. The

---

[1] Thyrite is the General Electric trade name for silicon carbide non-ohmic resistors. Bulletin GEA-4138B.

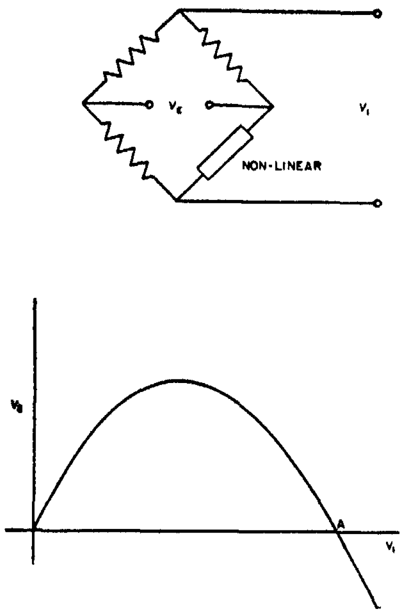

FIG. 1. Typical bridge characteristic for the indicated non-linear bridge.

element may have a resistance which varies with average power and temperature, or a resistance that varies with the instantaneous voltage applied. The former group includes lamps, barretters, and thermistors whereas the latter group includes elements such as Thyrite. If a bridge characteristic is obtained relating the error voltage as a function of the applied voltage, a curve typical to that of Fig. 1 is obtained. The point A corresponds to the balance point at which the power dissipated in, or voltage across, the non-linear element results in the critical resistance necessary to balance the bridge.[2,3] The region about A is generally linear for approximately ±20 percent of the balance voltage. For elements which are power sensitive, the voltages indicated can be a.c.[4]

There are several disadvantages in using power sensitive elements in a differential bridge. They are sensitive to ambient temperature changes, slow in response, and require an a.c. type[4] detector which is not phase sensitive. Mechanical shock may change the thermal characteristics and the balance point of the bridge. There is also a minimum balance voltage which increases at the lower frequencies due to harmonics generated by the non-linear element. A Thyrite bridge appears to be generally superior since the response is rapid, the temperature sensitivity is considerably less, and the elements are physically rugged.

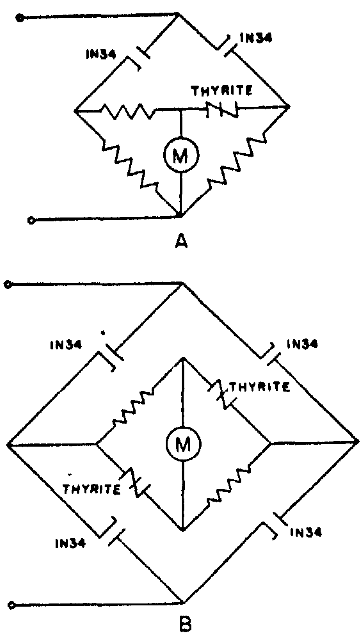

FIG. 2. Two non-linear bridge combinations. A. Half-wave single Thyrite bridge. B. Full-wave double Thyrite bridge.

The non-linear volt-ampere characteristic of Thyrite[5,6] is closely represented by

$$V = KI^n,$$

where K is a geometry constant and "n" is an exponent that generally falls between 0.2 and 0.4.

It can be shown that a non-linear symmetrical bridge, at the balance point, will have a slope,

$$s = (n-1)/2(n+1),$$

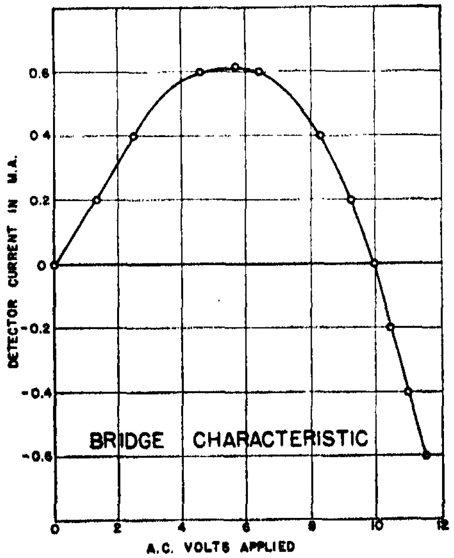

FIG. 3. Voltmeter bridge characteristics for the bridge of Fig. 2B.

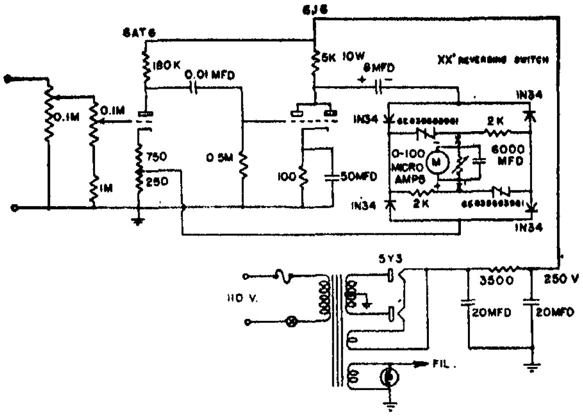

FIG. 4. Differential voltmeter circuit. Component values are as indicated.

for one Thyrite element, or if two identical elements in diagonal arms are used then,

$$s=(n-1)/(n+1).$$

If the voltage across a bridge at balance is V_A, then for a change in V_A the current that would flow through a detector is approximately

$$s\Delta V_A/(R_B+R_D),$$

where R_B is the internal bridge impedance and R_D is the detector impedance. Since the balance voltage is fixed by the operating resistance, the detector current can be calibrated as a percent change in V_A. It is apparent that operating the bridge at higher initial balance voltages will result in a greater sensitivity percentage-wise. However, Thyrite resistance decreases with increasing voltage and the entire bridge impedance will decrease, thus rapidly increasing the power requirements of the driving source. A compromise must be made between sensitivity and driving power requirements.

If instead of applying d.c., as in the foregoing analysis, the applied voltage is half or full wave rectified a.c., similar characteristics would be obtained. Figure 2 (A and B) indicates two varieties of bridges that can be used. The half wave bridge of Fig. 2A is less sensitive and more non-linear than the full wave bridge of Fig. 2B. In addition, it offers a lower impedance to the driving source. A typical over-all bridge characteristic relating d.c. detector current to applied a.c. voltage is shown in Fig. 3. The bridge is very similar to that used in the complete experimental model (Fig. 4).

THE COMPOSITE VOLTMETER

Figure 4 is a circuit diagram of the complete differential voltmeter. The circuit consists of a high μ-triode driving a twin triode in which the two sections have been paralleled. By paralleling the two sections, a g_m sufficiently large to develop over ten volts across the 2000 ohm bridge load is obtained. The bridge is in a feed-back path to the first cathode, producing high stability and good internal wave form. As shown, the feed-back factor is 0.11 and since the loop gain without feedback is approximately 500, the gain with feedback is approximately 9. A 6000 mfd condenser is placed across the meter to prevent any a.c. from passing through the meter at even the lowest frequencies. The power supply need not be regulated. A line voltage variation from 105 to 125 volts produced an indication of less than 0.3 percent. Barring the input attenuator, which was not frequency compensated, no measurable change in the input voltage necessary for balance was observed between 20 and 200,000 cycles per second. With the indicated feedback, the input voltage necessary for balance was 1.2 volts and by installing a proper attenuator the percentage change about higher voltage levels can readily be obtained. The basic sensitivity of the instrument was ±6 percent full scale but by shunting the meter movement it was preset for a convenient ±10 percent range. A low resistance shunt is provided for coarse zero setting and a reversing switch on the meter allows for positive or negative percentage readings. Figure 5 is the experimental linearity characteristic for the instrument.

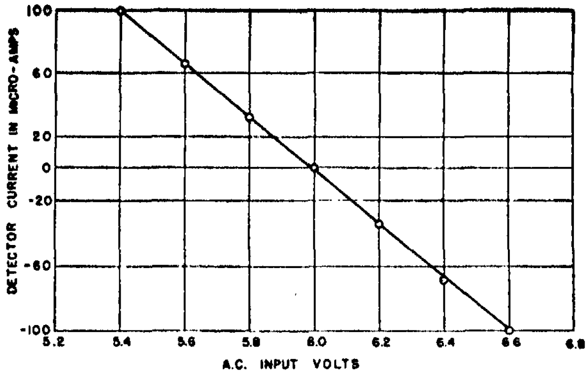

FIG. 5. Experimentally observed linearity characteristic relating meter indication to input amplitude.

ACKNOWLEDGMENT

In conclusion, the authors wish to extend their thanks to the United States Air Force, Watson Laboratories, who made this work possible under Contract No. AF28(099)-33. The assistance of Mr. W. Kurylo and Mr. G. Badoyannis is appreciated.

A Microtome Specimen Holder Advanced by Thermal Expansion

M. Eden, A. W. Pratt, and H. Kahler
National Cancer Institute, Bethesda, Maryland

(Received June 26, 1950)

A microtome specimen holder which advances the specimen by thermal expansion is described. The holder was heated by an electrical current, the value of which could be regulated to give any desired rate of heating and expansion. A quantitative comparison was made between the heating and expansion rates of the Newman, Borysko and Swerdlow CO_2 precooled instrument and the electrically heated instrument. It was found that the electrically heated specimen holder fulfilled the requirements of flexibility, reproducibility, sensitivity and linearity.

INTRODUCTION

Electron microscopy of tissue sections is successful only when the sections are of the order of 0.1-micron thick. It should be possible to study the three-dimensional structure of tissue by preparing a series of sections of a given tissue: each section having a known and uniform thickness. Preparing such a series requires a microtome advancing mechanism that will satisfy rigorous conditions of constancy and reproducibility.

Pease and Baker[1] modified a Spencer microtome by attaching a steel wedge of a smaller angle to the advance plate. They calculated the rate of advance to be one-tenth that of the standard microtome. Gettner and Hillier,[2] later studied this procedure and pointed out the extreme sensitivity to vibration and the need of reducing the friction of the ways.

Newman, Borysko, and Swerdlow[3] suggested a different advancing mechanism. The object holder, a hollow brass block about two inches in length, is pre-cooled about 25° below room temperature with expanding carbon dioxide gas. As the block warms to room temperature tissue slices are cut, the operator guessing at the time interval required to produce a suitable thermal extension of the rod.

It occurred to us that a simpler and more accurately controlled device could be built. A heavy brass rod insulated on its surface by a thin sheet of mica is wound with resistance wire. The outer surface is covered with a thick insulating wrapper. A suitable mount is machined in the end of the block to hold the specimen to be cut (Fig. 1). The power dissipated in the heating coil may be regulated by a variable transformer of suitable range.

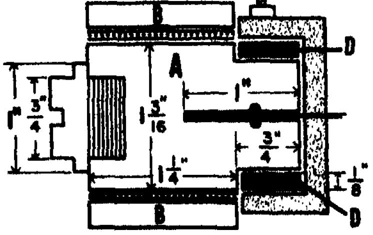

Fig. 1. Expansion assembly. Cross section of the electrically heated microtome specimen holder.

EXPERIMENTAL

A. Procedure

In order to study the performance of the Newman, Swerdlow, and Borysko[3,*] attachment and our modification, we measured two physical properties of the specimen block: temperature and the displacement between the front surface of the specimen holder and the knife holder (Fig. 2).

We determined temperature with a Copper-Constantan thermocouple using a White potentiometer to measure thermocouple voltage. We assumed that voltage varied linearly with temperature over a ten-degree range. The "cold" junction was kept at room temperature and lagged against abrupt room temperature changes by insertion into a Dewar flask. In the case of the N.B.S. attachment the other junction was usually soldered to the front surface of the specimen block. In certain runs the couple was taped to the block. In one experiment one junction of the thermocouple was soldered to the block and the other taped to the block with a gap of about a centimeter between them. No difference between the two couples greater than five microvolts (*ca.* 0.12°) was observed during a warm-up of 10°C. We measured the displacement of the specimen block by means of an unbonded strain gauge[4] mounted rigidly in the knife holder. A small piece of quartz slide was cemented to the front surface of the specimen block and the drive pin of the strain gauge was placed against it.

[3] Newman, Borysko, Swerdlow, J. Research Nat. Bur. of Stand. 43, 183 (1949).

[*] In the following, referred to as the N.B.S. attachment.

[4] The gauge used was a Statham transducer Model No. YE-4-60 manufactured by Statham Laboratories, 9328 Santa Monica Blvd., Beverly Hills, California.

The output of the gauge was measured directly by a galvanometer with a sensitivity of 0.0431 microvolts/mm. The input voltage was usually maintained at 0.750±0.002 volts. The output voltage of the strain gauge was 6.55 microvolts/micron displacement, so that the sensitivity of the complete system was 0.0065 microns/mm.

B. N.B.S. Specimen Holder

We cooled the N.B.S. specimen block to a predetermined temperature as indicated by the thermocouple. The block then warmed up to room temperature. We measured both temperature and expansion during the warm-up. Three typical runs have been plotted in Figs. 3 and 4. The block was pre-cooled about 4.5°C for run *A*, about 7.5° for run *B* and 10.5° for run *C*.

Within a ten-degree rise in temperature (curve *C*) the rate of expansion changes from 1 to 9 microns/minute. In order to cut sections 0.1 micron thick it would be necessary to cut at six second intervals at the beginning of the run and 54 second intervals at the end.

While a cutting program with increasing time intervals is feasible, a more serious difficulty is the lack of reproducibility. The data for curves *A* and *B* in Fig. 3 fit an equation of the form $X = X_0(1-\exp[-kt])$. The rate constant k is 0.93×10^{-3} for *A*, and 1.50×10^{-3} for *B*. No over-all rate constant holds for *C*. It is clear that the same cutting schedule could not be used for these three runs if slices of equal thickness were desired.

This is shown in somewhat different form in Fig. 4. Here the expansion data are plotted against temperature. To a first approximation these curves should be linear. It can be seen that the curves approach linearity as they warm to room temperature but the rate of expansion per unit temperature is different in each run. The effective length of the block has been calculated for the three runs using $L_{\mathrm{eff}} = (dL/dT)1/\lambda$; λ is the coefficient of expansion of brass; dL/dT, the change in length in centimeters per degree centigrade, determined graphically from Fig. 4. The effective lengths were found to be 5.0, 6.7, 10.0 centimeters for curves *A*, *B*, *C*, respectively.[5] It is clear that the previous treatment of the block and microtome has an important influence on the rate of warming.

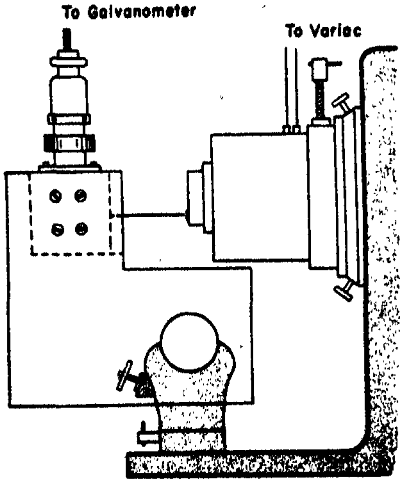

FIG. 2. The specimen holder in position in the Spencer microtome. The Statham gauge is shown mounted on the knife holder.

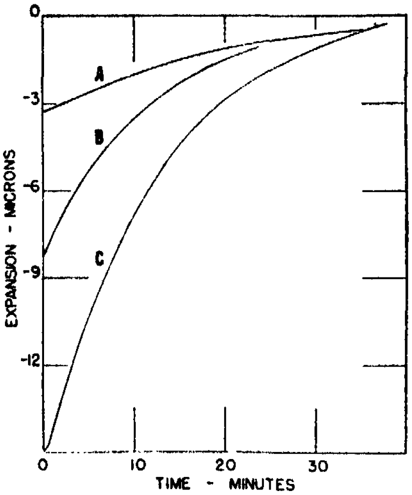

FIG. 3. A plot of three typical runs with the precooled specimen holder. Expansion *vs.* time.

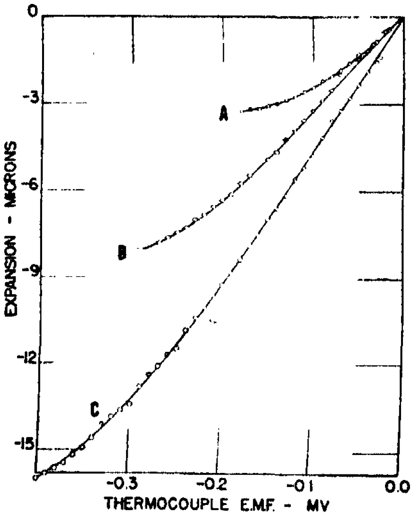

FIG. 4. A plot of three typical runs with the precooled specimen holder. Expansion *vs.* thermocouple voltage.

C. The Electrically Heated Specimen Holder

In view of these difficulties we decided to modify the N.B.S. device to satisfy the following criteria:

1. The rate of expansion should be uniform to within 20 percent for a range of at least three microns.
2. The rate of expansion should be reproducible to within five percent for a range of at least three microns.
3. It should be possible to stop the expansion for one or two minutes if need arises and then to continue with the same cutting schedule.

A plan of our modification is given in Fig. 1. A sketch of the modified specimen block mounted in the Spencer microtome is shown in Fig. 2. A brass block *A*, two inches long and $1\frac{3}{16}$ inches in diameter. was wound with

---

[5] A large measure of the lack of reproducibility could probably be eliminated by exhausting the CO_2 to the side rather than into the body of the microtome.

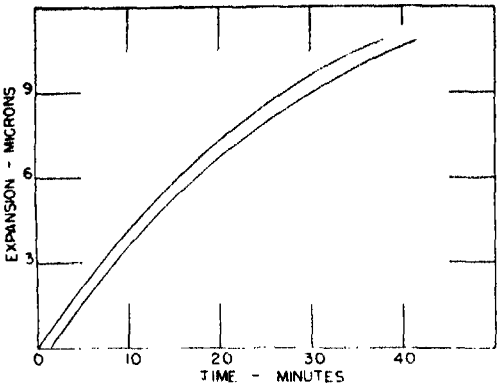

FIG. 5. A plot of two typical runs with the electrically heated specimen holder. Expansion *vs.* time.

twenty feet of B. & S. No. 30 gauge Nichrome wire (resistance 78.1 ohms). The wire was insulated from the block by a sheet of mica. The outer surface of the wire was insulated by a cylinder of Lucite, *B*, 1¼ inches long, 1½ inches i.d. and ¼-inch thick. A 0.032-inch hole, *C*, one inch deep was drilled in the rear of the specimen block. A Copper-Constantan junction was soldered into the bottom of the hole. The block was insulated from the jaws of the microtome by bakelite plates, *D*, ⅛-inch thick.

The 115-volt house line was stepped down to ten volts by a transformer. The voltage was controlled by a small Variac wired across the output of the transformer. All the measurements described below were made using 10.0 volts.

The block was heated to 10° above room temperature (0.400 mv) and measurements of temperature and displacement were made as before. Calculations were made on the basis of eleven runs performed over a period of six weeks. Two typical runs have been plotted in Figs. 5 and 6. The curves were arbitrarily separated.

A determination of the reproducibility of our device was made by comparing the slopes of each run after an expansion of 1.25 and again after 3.25 microns. The averages obtained were $7.57\pm0.16\times10^{-3}$ microns/second at 1.25 microns and $6.50\pm0.08\times10^{-3}$ at 3.25 microns.

The effective length of the block, calculated from the slope of the curve in Fig. 6, was found to be 5.04 cm. This is virtually identical with the actual length of the block, 5.08 cm. It is evident that the runs are reproducible within the error in controlling the input voltage and the instrumental errors of measurement.

The expansion of the block may be described by the equation

$$x=\frac{8.28\times10^{-3}}{5.43\times10^{-4}}[1-\exp(-5.43\times10^{-4}t)].$$

Within an interval of 4.5 microns the slope of the curve changes from 7.7×10^{-3} microns per second at two minutes to 6.0×10^{-3} at twelve minutes elapsed time. If an interval of fifteen seconds is taken between each slice, the advance of the specimen will be 0.115 microns at the beginning of the run and 0.090 microns at the end of the run. It may be possible to decrease the rate constant still further by providing better insulation.

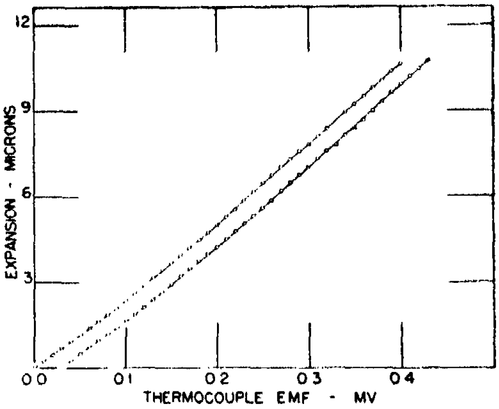

FIG. 6. A plot of two typical runs with the electrically heated specimen holder. Expansion *vs.* thermocouple voltage.

TABLE I.

Expansion-microns	1.00	2.00	3.00	4.00	5.00
Holding resistance-ohms	228	138	98	76	62

It can be seen from Fig. 6 that the specimen holder advances about one micron for each degree rise in temperature. Consequently, forty thin sections might be cut in an interval of four degrees. It is doubtful that such a small change in temperature will effect the physical properties of the specimen or the imbedding plastics.

In order to test the modified specimen block in operation, tissue specimens imbedded according to the technique of Newman, Borysko, and Swerdlow[8] were inserted in the block and cut using a twenty second time interval between slices. No attempt was made to determine the thickness of each slice but a slice was cut from the specimen with each stroke of the wheel. Disturbances such as door slamming will cause the microtome to skip only when the disturbance occurs at the instant of cutting.

Ordinarily an interval of twenty seconds leaves ample time for the operator to remove the slice from the knife and transfer it to the spreading solution. In order to introduce a little more flexibility, a holding circuit was introduced. A variable stepwise resistor was put into the circuit so that it might be inserted in series with the Variac output by means of a double-pole double-throw switch. The holding resistance was defined as the resistance in series with the heater that decreased the rate of expansion to less than 0.01 micron/minute as indicated by the displacement gauge. The holding resistance for various displacement readings is given in Table I.

A Differential Vectorcardiograph*

Stanley A. Briller, Nathan Marchand, and Charles E. Kossmann
*Department of Medicine, New York University College of Medicine, and the Adult Cardiac Clinic,
Third (New York University) Medical Division, Bellevue Hospital, New York*

(Received February 27, 1950)

A vectorcardiograph was designed and constructed for the purpose of separating and recording the temporal components (*P* form, *QRS* form, and *T* form) of the spatial vectorcardiogram in two planes.

The equipment consists of a network to convert the patient voltages into an orthogonal set, a three-channel low frequency amplifier, a synchronized timing unit, a dual-beam oscilloscope, a time marker, an electronically operated camera, and a simultaneous direct-writing recorder.

I. INTRODUCTION

THE usual clinical electrocardiogram is a record of the differences in potential between two points on the surface of the body caused by electromotive forces generated in the heart. These forces vary in size and direction with time, and are subject to a vector-time type of analysis. Assuming, among other things, a point source of the forces in the body, a figure may be constructed for any complete or partial cycle of electrical events occurring either in the atria or in the ventricles by connecting the heads of successive vectors. Such a figure is called a monocardiogram,[1] vectordiagram,[2] vectorcardiogram,[3] or cardiovectorgram.[4] Since two almost inverse electrical processes, excitation and recovery, occur in the normal heart in a relatively fixed sequence, it would be expected that four separate vectoral forms (loops) for each cardiac cycle could be synthesized from a study of surface leads. These have come, by usage, to bear the names of *P* form, T_a form, *QRS* form, and *T* form.

Such vectorcardiograms are three dimensional in the body. Analytical or instrumental synthesis of the spatial forms from surface leads gives rise to what is known as the spatial vectorcardiogram. This is a manifest record; the generator value of the spatial vectorcardiogram cannot be measured because of the unknown attenuating effects of the surrounding volume conductor.

From the points of view of greater simplicity in clinical recording and a newer approach to certain fundamental problems it seemed desirable to devise an instrument which would make it possible to record each of the vectoral forms independently. Vectorcardiographs with different recording principles have been designed,[1–9] but separate recording of the four forms by electrical circuits has not, to our knowledge, been achieved. To report the design and construction of such an instrument, called a differential vectorcardiograph, is the purpose of this paper.

II. GENERAL DESCRIPTION

Voltages are picked up by means of German silver electrodes placed on the arms, on the left leg, and on the back to the left of the seventh dorsal spine. The connection to the right leg is used as a ground return. The voltage expected with each heartbeat from any pair of surface electrodes consists of a group of summits and depressions which are called *P*, T_a, *Q*, *R*, *S*, and *T* (Fig. 3). The time relationships of the 4 vector forms of each heartbeat remain fixed within workable limits for any one subject, but the repetition rate of groups will change since not even the normal heart beats with perfect regularity. It is desirable then for the purpose of separation to activate all timing circuits within the group. The first voltage which is ordinarily available in each group is the beginning of the *P* wave, one of the smallest and slowest rising voltages in the human electrocardiogram.

For presentation purposes, the two planar projections utilized are the frontal (*XY*) and the sagittal (*ZY*). The time dimension is furnished by interrupting the oscilloscopic trace at intervals of 5 milliseconds. The problem of transforming the nonorthogonal voltages obtained from the patient to the classical *X*, *Y*, and *Z* projections

is solved by the methods of Wilson and Johnston,[8] and of Wilson, Johnston, and Kossmann.[10]

Permanent records are obtained by photographing the oscilloscopic images of successive heartbeats. This is done in a semidark room with orthochromatic film (duPont No. 201). The oscilloscope is blanked at all times except during exposure. The time of onset and the duration of exposure is determined by the synchronized exposure timing circuit. Following exposure, the film is automatically advanced in the camera by a solenoid mechanism.

In Fig. 1 is shown a block diagram of the complete instrument. The patient voltages are fed into an input switch (Fig. 2) which has a twofold function: (1) to convert the patient voltages with subsequent amplitude corrections into an orthogonal set; (2) to replace the patient with an equivalent resistive network for balancing and adjusting the circuits.

Three voltages are obtained from the input switch representing the X, Y, and Z projections of the heart voltages. The peak magnitudes of these voltages are of the order of one millivolt. These are amplified separately in a three-channel amplifier.† Each channel is a highly balanced push-pull unit with low hum level. The gain of each is individually controlled and is calibrated by the application of a standard millivolt to the input while a photograph of the oscilloscopic output is taken. The voltage gain is such that about 200 volts is available at the output for every millivolt at the input.

The three outputs of the amplifier are fed into a dual-beam oscilloscope. They are paired off on the deflection plates to create the two desired planar projections (XY and ZY). The outputs from the amplifiers are also fed into a three-channel direct-writing recorder† which furnishes a continuous simultaneous record of the three individual channel outputs.

The outputs of the amplifiers are also fed into the synchronized exposure timing unit where a switch is used to select the channel having the P wave most suited for tripping the trigger circuits. The trigger circuits which form the synchronized exposure timing unit supply two voltages, both in the form of rectangular pulses. The first of these determines the exposure time. The starting time of this exposure voltage is determined by a variable delay which can start the exposure as early as the beginning of the P wave or as late as the end of the T wave. The exposure time is also variable so that either a complete or partial vector form can be photographed. A portion of the exposure timing voltage can be applied, by means of a switch, to one of the three direct-writing units and thus furnish an accurate record of those electrocardiographic deflections actually photographed on the face of the oscilloscopic tube. The second voltage supplied by this unit is a tripping voltage coincident with the end of exposure time. This output is used to advance the film to the next frame.

The time marker voltage consists of a series of rectangular pulses of adjustable width at a constant frequency. These voltages are applied to the grids of the cathode-ray tube.

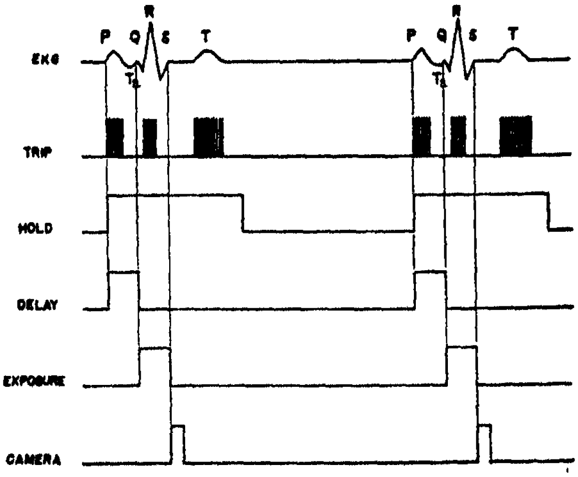

FIG. 3. Diagram illustrating the voltages generated by the synchronized exposure timing unit. The circuits have been adjusted to record the QRS deflections. All positive electrocardiographic voltages are transformed into a series of pulses by the "trip" circuit, but only the first pulse is utilized to energize the "hold" and "delay" circuits.

Simultaneous points are indicated by the vertical lines at P, Q, and S.

---

[10] Wilson, Johnston, and Kossmann, Am. Heart J. 33, 594 (1947).

† The three-channel amplifier and three-channel direct-writing recorder are those contained in the Technicon Cardiograph.

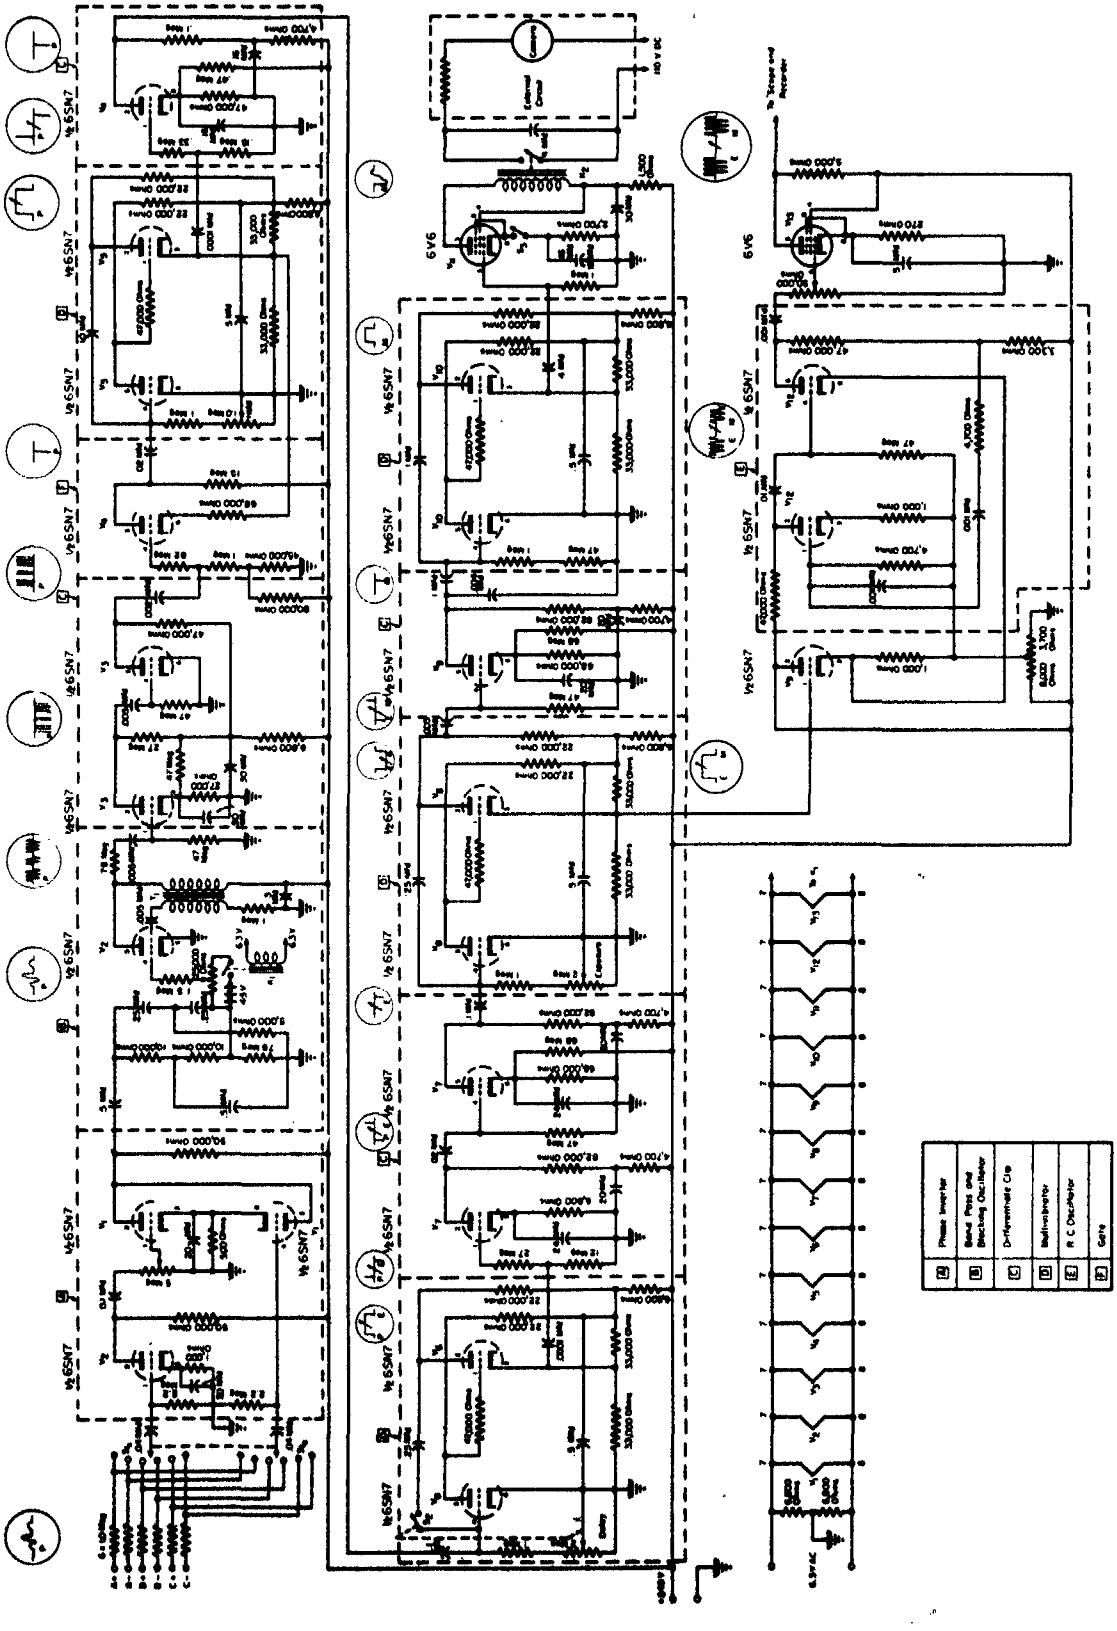

FIG. 4. Schematic circuit diagram of the synchronized exposure timing unit. Functional units of the circuit are enclosed in dashed lines and labeled to correspond to the reference table shown. Oscilloscopic traces are indicated in the circled areas. In these, "*P*" indicates the instant of rise of the *P* wave, "*E*" the beginning of the exposure period, and "*M*" onset of the pulse responsible for movement of the film.

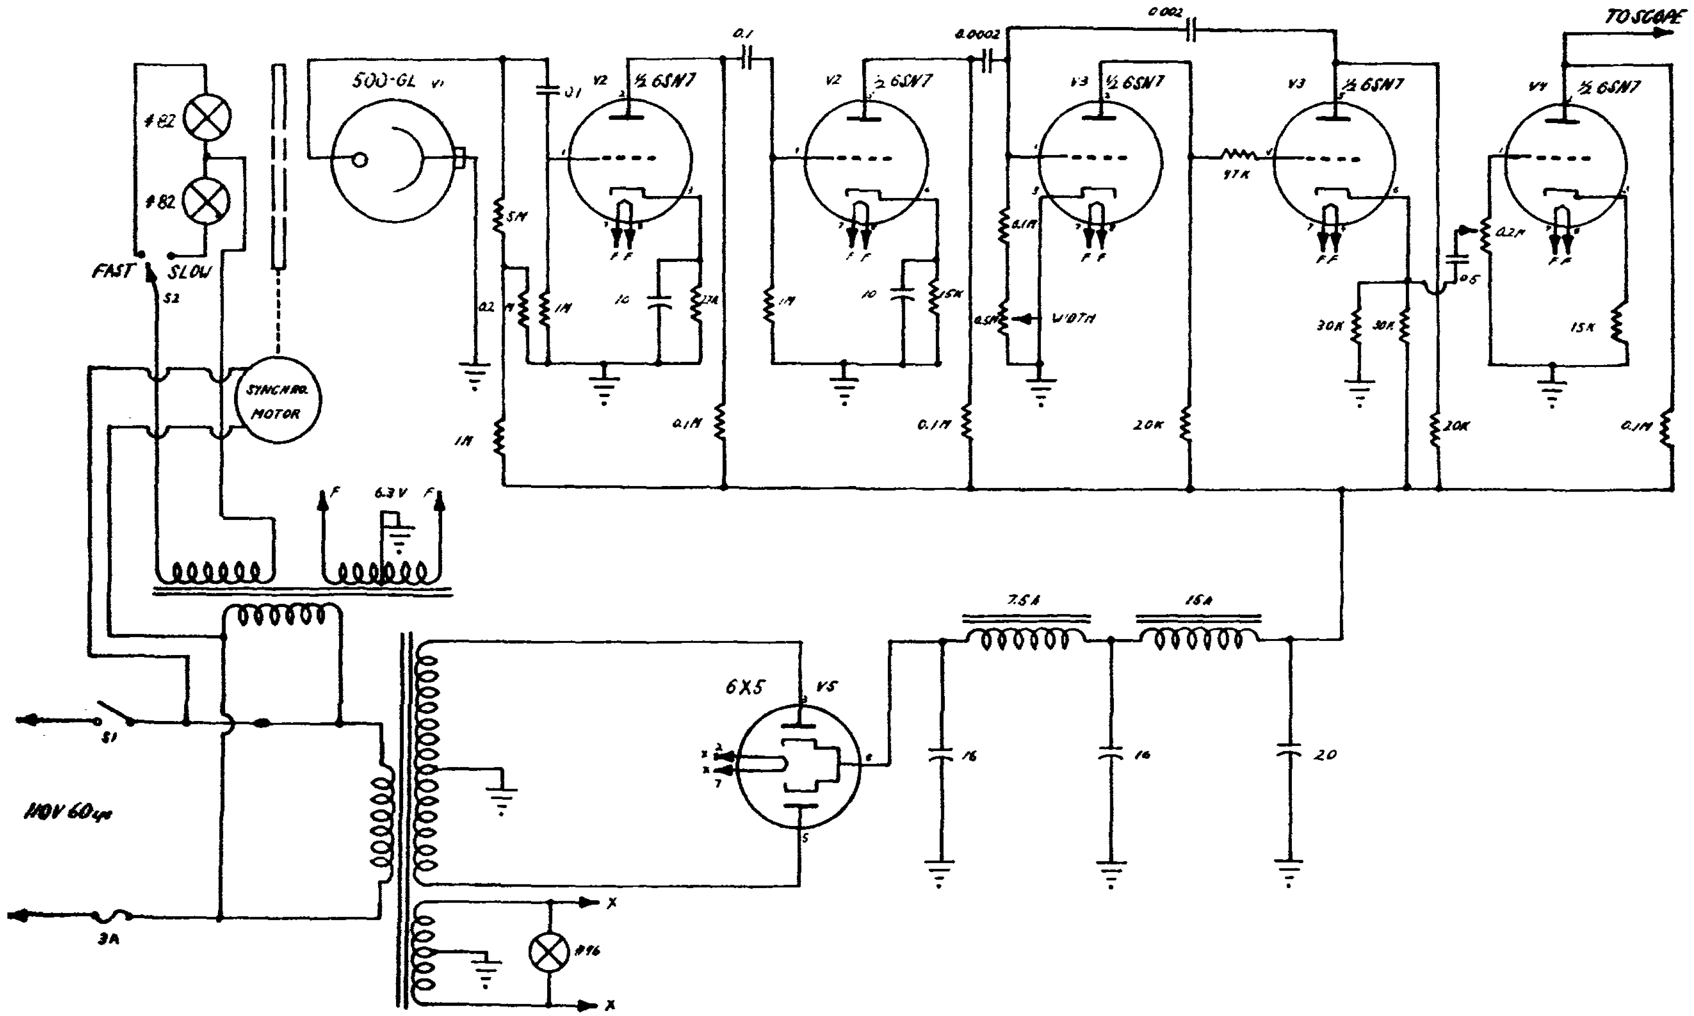

Fig. 5. Schematic circuit diagram of the time-marker unit.

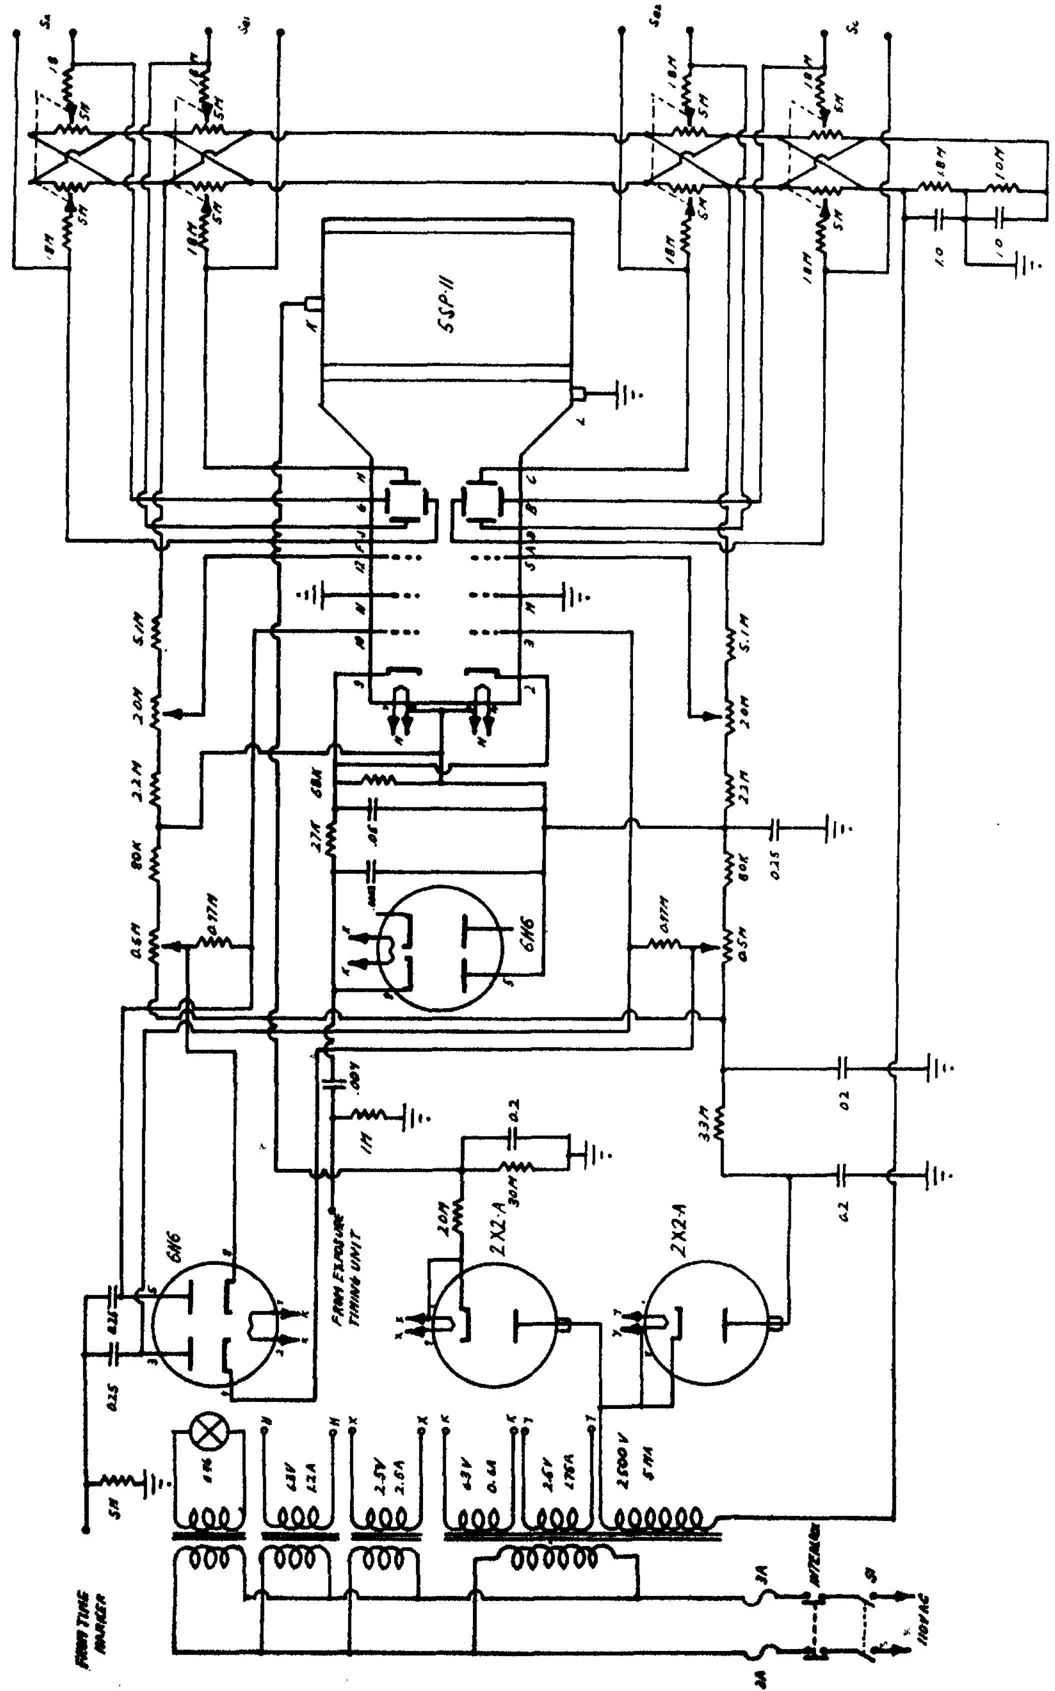

FIG. 6. Schematic circuit diagram of the dual-beam oscilloscopic indicator unit.

Individual regulated power supplies are utilized for each unit to prevent interaction and to reduce to a minimum the effect of power line fluctuations. Special care was given to filtering and decoupling, since even a slight amount of hum or coupling deteriorates the quality of the trace and interferes with the timing circuits.

III. CIRCUIT DESCRIPTIONS

1. The Synchronized Exposure Timing Unit

The time relationships of the important voltages in the synchronized exposure timing unit as compared with two typical, successive electrocardiographic complexes are shown in Fig. 3. In this instance the unit is adjusted to photograph the *QRS* form as a unit. A trip voltage is generated by the leading edge of each *P* wave. Because every other rise in voltage would similarly act as a triggering point, a hold circuit is initiated to inactivate the input until the entire cardiac cycle is completed. The leading edge of the hold voltage initiates a delay circuit and the trailing edge of this latter voltage trips the exposure voltage. The end of the exposure voltage operates the film advance circuit. The hold, delay, and exposure intervals may be varied.

A complete schematic circuit diagram is shown in Fig. 4. The transformation of the *P* wave into a sharp pulse coincident with its instant of rise is accomplished by applying the greatly amplified electrocardiographic voltage to a blocking oscillator which is biased just at cut-off. In a similar fashion, every other rise from the base line such as the *R* and *T* waves are transformed into a series of sharp pulses. To eliminate the effect of drift and pick-up, the input is applied through a band pass filter. The hold circuit allows only the first rise of a particular pulse group, namely that of the *P* wave, to pass to the timing circuits. This operation is accomplished by a gate tube biased by the hold voltage. The basic circuit employed to generate the hold, delay, exposure and camera trip voltages is the "one-shot" multivibrator. Coupling between the various stages is by conventional differentiation and clipping.

The cathode-ray tube is normally maintained at cut-off by the rectified output of a resistance-capacitance oscillator operating at a frequency of about 30 kc. Application of the exposure voltage cuts off the oscillator, gating the beam on. This method was employed to avoid d.c. coupling to a high voltage element.

The film advance circuit consists of a solenoid-operated, pull-down mechanism actuated by a relay. The inertia of the mechanism demands that the relay be held down for a finite amount of time; a separate fixed "one-shot" multivibrator performs this function.

2. The Time Marker

A metal disk driven by a synchronous motor is the basic timing unit. Equally spaced holes around the circumference of the disk interrupts a beam of light falling upon a photo-cell which generates a series of pulses. These pulses are sharpened by differentiation and clipping, and are then used to drive a "one-shot"

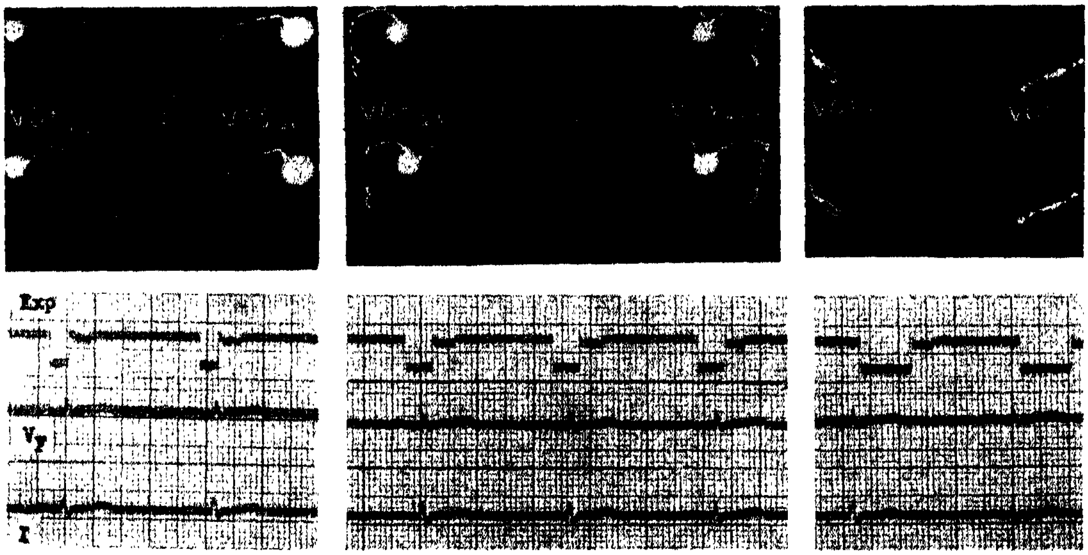

FIG. 7. Partial differential vectorcardiograms of the *QRS* and *T* forms of a normal subject in the frontal (*XY*) and sagittal (*ZY*) planes. In each instance two consecutive vectorcardiograms are shown. In the middle, the frontal (VGF_{QRS}) and sagittal (VGS_{QRS}) forms of the *QRS* complex are recorded. On the right, the frontal (VGF_T) and sagittal (VGS_T) forms of the *T* wave are shown. On the left a portion of the *QRS* is recorded in two planes to demonstrate clockwise rotation in the frontal plane (VGF_{QR}) and counterclockwise rotation in the sagittal plane (VGS_{QR}). The tracings are interrupted every 0.005 second. Below each pair of vectorcardiograms are the simultaneous records made with the direct-writing recorder. The lower record (*I*) is the difference in potential between the two upper extremities or *X* component. The middle record (V_F) is the potential of the left leg or the *Y* component divided by $\sqrt{3}$; the upper record (*Exp*) shows by a downward deflection that part of the *QRST* complex which is recorded in the vectorcardiogram. The small deflections before or after the main downward displacement in this record are artifacts.

multivibrator. For clarity of presentation, the width of the timing pulse is made variable. These pulses are impressed on the grid of the cathode-ray tube. The circuit diagram of the time marker is shown in Fig. 5.

3. The Cathode-Ray Oscilloscope

In Fig. 6 is shown a schematic diagram of the oscilloscopic indicator unit with its power supply. Because of its special requirements, it was necessary to construct rather than purchase this apparatus.

The power supply is standard and employs the 2X2 tubes in a voltage doubling circuit. The usual coupling capacitors employed to isolate the centering circuits on the deflection plates are not shown because these capacitors are incorporated in the amplifier chassis. It was found advisable to incorporate two separate blanking circuits, one for the time marker and the other for the exposure timing pulses. Since the former are short duration pulses, they are impressed upon the two cathode-ray tube grids through a pair of 0.25 microfarad capacitors. The 6H6 double diode is employed as a d.c. reinserter to prevent the grid bias from shifting as the time marker pulses are varied in size or width. Beam brightness thus is maintained constant.

The 30-kc carrier of exposure pulses is coupled into the oscilloscopic indicator unit through a 0.004-microfarad capacitor. It is rectified in one section of a 6H6 double diode and then filtered. The filtered voltage is then impressed directly on the cathodes of the cathode-ray tube.

4. The Camera

A modified Sept camera of French origin is employed to record the oscilloscopic traces. The pull-down mechanism, originally spring operated, was replaced by an electric solenoid. The shutter of the camera was removed. A stand was constructed to hold the camera conveniently in front of the cathode-ray tube. To reduce the force necessary for pull-down, the film is fed directly into a collection bag at the bottom of the camera.

5. The Amplifier Unit

The amplifier employs three push-pull resistance-capacitance stages of voltage amplification in each channel. Low frequency compensation is employed to bring the frequency response to below 0.25 c.p.s. This results in a flat frequency response from 0.25 c.p.s. to 150 c.p.s. The hum level without the patient connected in circuit is kept below an equivalent input level of 10 microvolts.

Since the cathode ray is inertia-less, no damping is necessary and no overshoot is encountered in the vectorcardiographic tracings. The standardization voltage is inserted in the cathodes of the first stages, all standardizations being impressed at once.

IV. RECORDS

Examples of differential vectorcardiograms are presented in Figs. 7 and 8. In the former, a strip of simultaneously recorded standard electrocardiograms (Lead I, x component and Lead V_F, y component/1.7) is shown. Exposure time is recorded above the electrocardiograms. Figure 7 also illustrates the method of obtaining the direction of rotation of a form (loop). By decreasing the exposure time only a portion of the loop is recorded. Comparison of this trace with any other complete loop immediately indicates the origin and hence the direction. Figure 8 shows variations of successively recorded QRS forms with respiration.

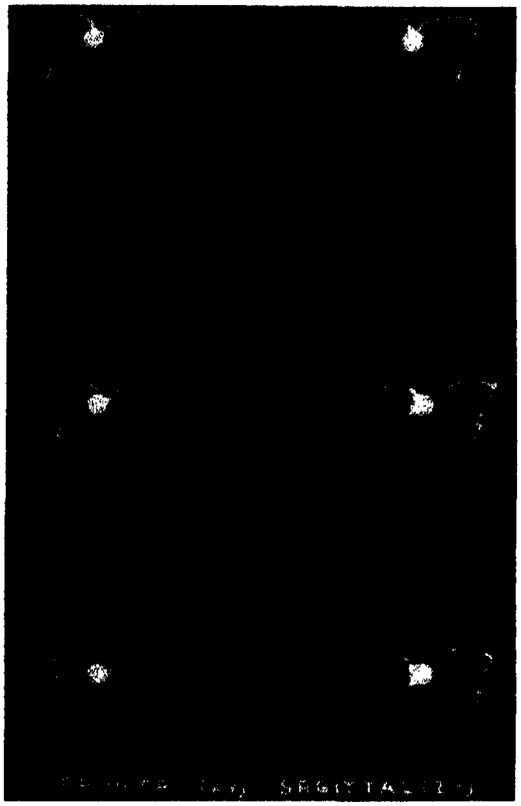

FIG. 8. Frontal and sagittal vectorcardiograms of QRS of three successive heart beats. Variations in the QRS form are due to respiration. Trace interruptions occur every 0.005 second.

V. PROCEDURE

The amplifiers are first balanced for hum and standardized for gain. A short preliminary recording is made of the orthogonal lead on the direct writer. The duration of $PQRST$ ($P-T$ interval) is observed and the calibrated hold-control set accordingly. Also from the recording the lead containing the tallest P wave is selected by means of a selector switch (switch 1 in Fig. 4) and applied to the synchronized timing circuit. Careful adjustment of the blocking oscillator bias control (Fig. 4, B) will result in reliable tripping of the timing circuits at the beginning of each P wave. The hold and exposure controls are then set to obtain the desired portions of the PQRST group under study.

Laboratory and Shop Notes

Expansion Valve for Triggered Cloud Chambers*

Jacob L. Zar
New York University, Washington Square College, New York
April 4, 1950

It has been shown that sharp tracks can only be obtained in a counter-controlled cloud chamber if the time between passage of the triggering particle and the condensation of water droplets is of the order of 0.01 sec.[1] For this type of chamber, an expansion valve and control circuit have been built which are believed to have the advantages of simplicity, ease of construction and rapidity of action.

The valve shown in Fig. 1 is a modification of the one described by Fussel,[2] in which an unsupported rubber ring is sealed against a valve disk mounted on a solenoid armature. The magnetic force on the armature in the closed gap position is sufficient to hold the valve closed; but when the exciting current is removed, air pressure against the disk provides the necessary force for rapidly opening the valve.

A commercially manufactured solenoid is used in place of the laboratory-made units that have been described.[2–4] The one that was found most suitable for a three-inch valve port was the Allen Bradley No. 4 product. Its coil is the standard one supplied for 110 v 60 c although direct current is actually used in this application. The following operating characteristics were determined with the return spring removed: Coil resistance is 25 ohms; normal operating direct current of 0.5 amp. provides 60-lb. force in the closed gap position; a direct current of 0.75 amp. is required to raise the armature against gravity with the gap fully open. In order to increase the speed of operation, the copper shading coils were removed from the face of the gap. The valve disk is three in. in diameter and, together with the solenoid armature, weighs 0.62 lb. If the air pressure acting on the valve is 4 p.s.i., its acceleration is 45 g, and it will open $\frac{1}{16}$ in. in 0.003 sec.

The operating circuit is shown in Fig. 2. The solenoid coil is connected in the "galvanometer position" of a Wheatstone bridge powered by the 110-volt d.c. line. One arm of the bridge is a 2050 thyratron. Its equivalent resistance can be obtained from the fact that its voltage drop is 12 volts when conducting. Normally the thyratron tube is off and the bridge is unbalanced. A coil current of 0.5 amp. holds the valve closed against the force of air pressure. A positive pulse arriving at the grid fires the thyratron, shuts off the coil current, and initiates an expansion. By a judicious choice of bridge resistances the solenoid current can actually be reversed slightly when the tube is conducting. This increases the speed of operation of the valve by counteracting the effect of the inductance and coercive force of the solenoid.

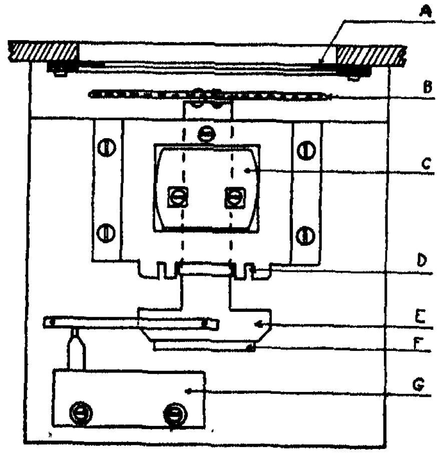

FIG. 1. The expansion valve. *A* is a rubber ring; *B* is the valve disk; *C* is the solenoid coil; *D* is the space where the shading coils have been removed; *E* is the armature; *F* is a stop plate; *G* denotes two microswitches.

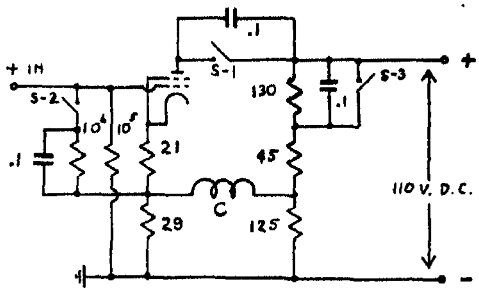

FIG. 2. Wheatstone bridge type circuit for triggering expansion valve. The tube is a 2050 thyratron. *C* denotes the expansion valve coil.

The solenoid armature also operates two microswitches by means of a pivoted link. One of these, S_1, extinguishes the thyratron; the other (not shown in Fig. 2) starts a motor-operated set of switches to prepare the cloud chamber for its next expansion. One of these switches, S_3, momentarily short circuits a section of one of the bridge resistors to increase the solenoid current for reclosing the valve. S_2 is a pushbutton that manually fires the thyratron for testing the operation of the cloud chamber.

The values given in Fig. 2 were chosen for a low resistance coil and are consequently wasteful of power. In many installations this is of little importance. However, in those instances where a d.c. power line is not available, it is advantageous to use higher values of resistance for both the Wheatstone bridge and the solenoid coil. In the Allen Bradley solenoid the coil is very easily removed and replaced with one having more turns of finer wire. The bridge may then be designed with sufficient resistance to operate from a standard *B* supply.

To test the speed of operation of this valve, a contact was mounted directly beneath the valve disk and an oscillograph used to time the delay between the arrival of a pulse and the start of an expansion. It was found that the valve was in actual motion 0.003 sec. after being triggered.

The assistance of a grant by the Research Corporation is gratefully acknowledged. Credits are also due Mr. J. Hershkowitz for valuable help in the construction of this valve, and the late Dr. I. S. Lowen who sponsored the research at the time this work was done.

Waterproof Cable Connectors

K. Feldman
Division of Physics, National Research Council, Ottawa, Canada
March 23, 1950

The need for waterproof cable connectors sometimes arises in situations where, due to space or other limitations, commercially available connectors are unsuitable. The simple solution that was found satisfactory in one such case is described below in the hope that it may be helpful to others faced with similar problems.

It was required that a connection be made between two portions of a cable of $\frac{3}{16}$-in. diameter. The cable contained two conductors to be operated at a potential difference of about 1000 volts. The connection was to be used under a 1000-foot head of water and its diameter was not to exceed one inch.

③ RUBBER COVERED, 2 WIRE CONDUIT ½"O.D.
④ FILLER, INSULATION
⑤ SPAGHETTI TUBING
⑥ SPLICE CONNECTOR

FIG. 1.

The connection was made as follows. (See Fig. 1.) The jacket on each cable was split lengthwise for a few inches to expose the conductors. The corresponding conductors were then connected by the use of disconnect splices of the type indicated in the diagram. These connections were displaced from each other along the cable and were further insulated with spaghetti tubing. The split portions of the cable jacket were then cut back sufficiently to neatly close over the connections.

The connection was rendered waterproof by the use of a length of rubber tubing (⅝ in. i.d. by ⅛ in. wall) slipped over the joint. Suitable cord was then tightly wrapped and tied around the tubing at each of two places near each end.

Such connections have given satisfactory service in the field as well as in laboratory tests. They can be made or broken in a few minutes and practically no tools are required.

Motion within a Vacuum System

FRED A. MCNALLY
Research and Development, Jarrell-Ash Company, 165 Newbury Street, Boston, Massachusetts

July 11, 1950

IN high vacuum evaporation, motion controlled by the operator is frequently desired in order to shield unwanted films from the object. Most systems have a motion introduced by one of several mechanical arrangements. A convenient method used in this laboratory for many months makes use of a set of selsyn motors which were obtained from war surplus instruments.

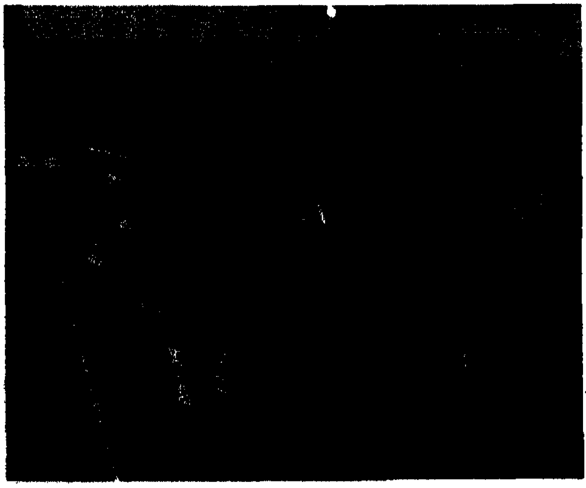

FIG. 1. Base plate arrangement.

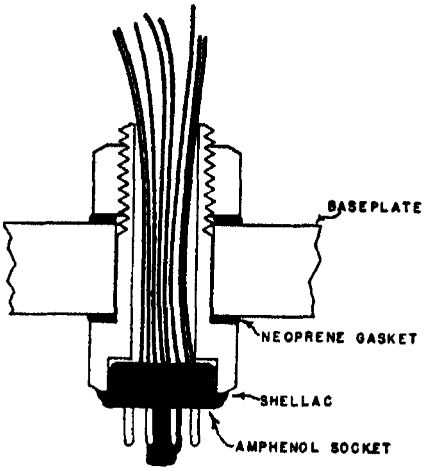

FIG. 2. Lead-in wire seal.

The vacuum system is one using an 18×30 in. belljar with a 6-in. diffusion pump. The repeater motor is centered over the baseplate as shown in Fig. 1. Holding the repeater is a brass disk which is placed high enough to prevent any loss in pumping efficiency.

Five lead-in wires are necessary and several methods of introducing them into the vacuum were tried. Finally a 1-in.-8 bolt, drilled through as suggested by Strong,[1] was fitted outside with an Amphenol PM-8 socket (Fig. 2). In addition the octal socket gives three extra leads for other purposes. Plastic insulated wire was not found to be satisfactory within the vacuum but most silk insulated wire gives no trouble.

The power requirement originally was 115 v 400 cycle and supplied a torque of approximately 54-in. ounces. The system is operated very well however at 20 v 60 cycle giving plenty of torque to rotate the 3-ounce aluminum shield.

By means of a dial on the control panel, the shield may be brought to any angle covering completely the evaporation from any of the eight filaments. The system has been useful in producing multi-layer films and partial-transmission filters.

A Self-Triggering Cloud-Chamber Counter

E. L. FIREMAN* AND G. M. MCHANEY†
Palmer Physical Laboratory, Princeton University, Princeton, New Jersey

June 29, 1950

A SELF-TRIGGERING cloud chamber was made by inserting open counters inside an ordinary cloud chamber. The cloud chamber triggered itself by the coincident counter pulses and the corresponding tracks were observed.[1] This type of chamber permitted the observation of rare events involving coincidences of soft particles, e.g. pairs of electrons from extremely weak sources. It was about 1200 times more sensitive for coincidence electrons than was the corresponding randomly expanding cloud chamber, and therefore was suited to investigate the previously reported possibility of double β-decay in Sn^{124}. The following is a description of this apparatus together with some preliminary results.

The cloud chamber was cylindrical, having an 8½-in. inner diameter and a 4½-in. depth. Ordinary tank argon and helium were used; it was necessary to dessicate the alcohol for good counter operation. Dried ethyl, iso-propyl, and iso-amyl alcohol were used as the condensible cloud and counter quench vapors;

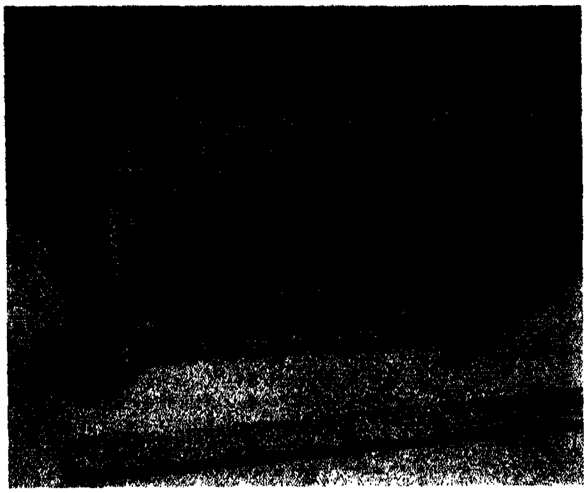

Fig. 1.

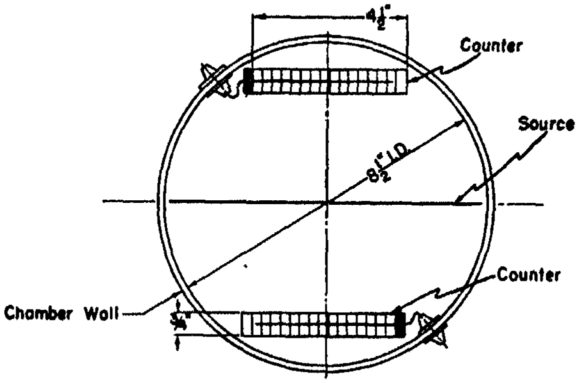

CLOUD CHAMBER COUNTER (Top View)

Fig. 2.

the heavier alcohols seemed to work slightly better. The chamber operated well at pressures between 1 and 2 atmos. No attempt was made to work at other pressures. The counters worked equally well in the proportional and Geiger regions. Since we were interested in events involving soft electrons, we took pictures only from coincident Geiger pulses.

Figure 1 is a photograph of one of the counters. Figure 2 is a diagram of two such counters in the chamber with a source between them. The rectangular copper frame in the center of the counter served to support four turns of 1 mil tungsten wire. The outer wire (No. 22) served as the counter cathode at ground potential. Although various counter sizes were used, a size of 4×4½ in. subtending a solid angle of 0.25 sterad. at the chamber center was most convenient. It was found necessary to bring the counter high voltage leads in through the cylindrical glass wall to avoid surface leakage pulses. Figure 3 shows the plateau curve of two counters having different dimensions. The threshold for Geiger action in argon was about 100 volts higher than in helium; this threshold increased by 200 volts as the pressure increased from 1 to 2 atmos. The threshold also rose slightly with the age of the counter filling (~100 volts/week). The counter pulses were normal, having an amplitude of 0.1 volt at the Geiger threshold. This amplitude increased with the voltage above the threshold. The counter voltage was removed immediately after an expansion because the reduced pressure caused the counter to count very rapidly. This in turn increased the recovery time of the chamber, i.e., the smallest permissible time between successive pictures. As our chamber was usually operated the counter voltage decreased to zero within 2 sec. after the expansion and the recovery time was 90 sec. The chamber could be operated continuously under these conditions for about two weeks before it was necessary to refill. The chamber was in a dark room with the temperature controlled to 1°C. The camera was open all the time and the pictures were taken by flashing the lamps between 3×10^{-3} and 3×10^{-1} seconds after the coincidence. Some of the positive ions from the counters drifted through the counter wires into the center of the chamber. For long lamp delays (>0.1 sec.) it was necessary to place a 1-mil cellophane sheet over the inner side of the counters to retain these ions.

This chamber was used to investigate the previously reported[3] coincidence activity from Sn with the aim of getting more definitive evidence as to whether or not it was a double β-process. Figure 4 is a self-triggered cloud chamber picture showing a pair of electrons from a 1-mil Sn foil of ordinary isotopic constitution. The chamber filling was argon with dried alcohol. Coincidence electrons were observed from various Sn samples, but the measurement of the momenta of the electrons in a field of 300 gauss was not successful because the multiple scattering in argon gave rise to curvatures as great as the magnetic field curvature in

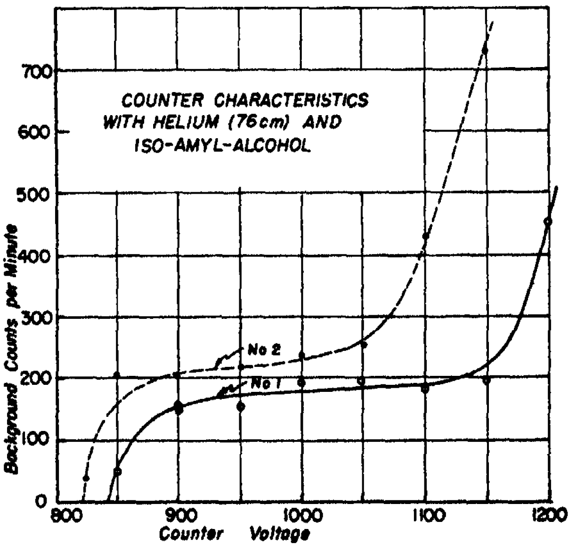

Fig. 3.

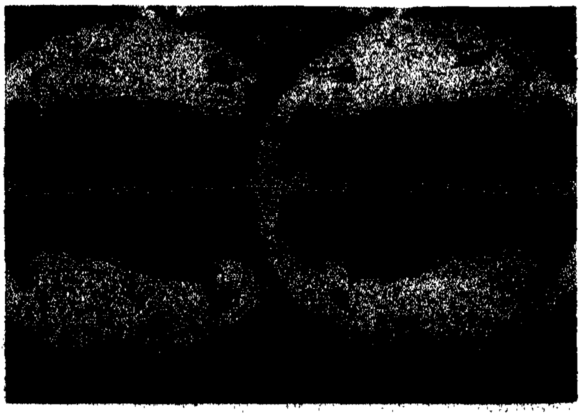

Fig. 4.

more than 50 percent of the cases. Therefore, it was not possible to say whether or not the coincidence electrons were electron-positive pairs, β-internal conversion electron coincidences, or double β-electrons. Self-triggered tracks in helium were not satisfactory even though good electron tracks were observed on random expansions. The reason for this is thought to be the rapid ionic diffusion and mobility in helium.[3] The expansion valve opened about 20×10^{-3} sec. after the coincidence. The clearing field (250 volts) was removed by a 2050 thyratron about 10^{-6} sec. after the coincidence.

In order to obtain momentum measurements of sufficient accuracy to identify with certainty the coincidence process, it would be necessary to use helium with a magnetic field of 1000 gauss or more. Since there did not remain sufficient time to make the required change here, it was decided to report on the apparatus and preliminary results at this time.

We are indebted to Professor R. Sherr for suggesting and supervising the present investigation and to Professor M. G. White whose advice and encouragement are gratefully acknowledged.

A Diamond Bomb for Obtaining Powder Pictures at High Pressures

A. W. Lawson and Ting-Yuan Tang
Institute for the Study of Metals, University of Chicago, Chicago, Illinois

July 7, 1950

RECENTLY a procedure for obtaining x-ray powder diffraction patterns of materials subjected to high hydrostatic pressures has been described in this journal by N. A. Riley and one of the authors.[1] This technique involves the use of a large grain size beryllium bomb for retaining the pressure. Transmission diffraction patterns of samples retained by the bomb are obtained by traversing both the bomb and the sample with an x-ray beam consisting of 50-kv molybdenum K-α-radiation. Because of superposition of the Debye-Scherrer rings diffracted by the bomb, only five or six rings diffracted by the sample are clearly discernible. As a result, the technique is severely restricted in application.

This restriction is considerably reduced by using a single crystal bomb. Indeed, a single crystal Be bomb was constructed and it was possible to recognize fifteen or twenty rings diffracted by the sample (in this case calcite). Unfortunately, however, the Be bomb, although rather brittle at ordinary pressures, is too plastic above 10,000 atmos. to be suitable. For this reason, we have tried using a bomb constructed of diamond and found notable improvements in performance over the older technique at pressures ranging up to 25,000 atmos.

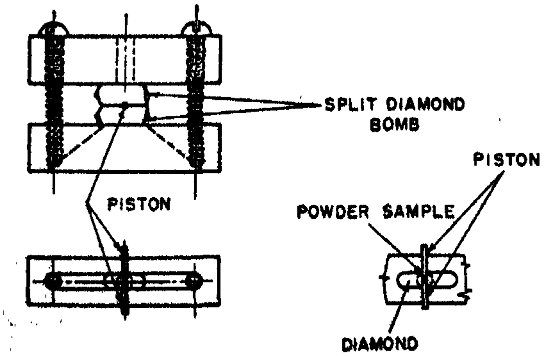

FIG. 1. Diamond bomb assembly.

The exact construction is shown in Fig. 1. The bomb consists of two diamonds, lapped together. A hole 0.015 in. in diameter is drilled through the clamped pair in the manner indicated. The clamp is machined so as to allow the x-ray beam to strike the sample and be diffracted to a cylindrical film holder of the type previously described.[1] The diamond is split to facilitate cleaning of the diamond and removal of the pistons after the application of pressure. No particular precautions were taken to orient the diamonds since, in the selection of the diamonds, size and mechanical properties were given precedence. The cutting and polishing of the diamonds was done by Arthur Crafts and Company, Chicago, Illinois. Although the diamonds were transparent, small optical flaws and even slight cracks were visible under a microscope. These flaws did not appear to grow and otherwise cause trouble even after the application of 30,000 atmospheres pressure for many hours. The upper range of pressure utilizable is limited at the present not by the strength of the bomb but by the failure of the drill rod pistons. It is hoped to extend the range by the use of carboloy pistons.

The two diamond crystals give rise to relatively few Laue spots which cause little confusion in identification of the Debye rings from the sample. As a result we are able to recognize easily at least fifteen rings from a calcite sample. The principal disadvantage of the technique is the appreciably higher friction present in the system as a result of the smaller dimensions involved. Thus, when external loading of the system indicated a peak possible pressure of 30,000 atmos., only 23,000 atmos. were generated in the sample, as determined by lattice constant measurements on AgBr.

In conclusion, because of the insulating nature of the bomb and the conducting nature of the pistons, the possibility of using this technique for exploratory investigations of the change in conductivity and photoelectric properties as a function of pressure should be noted.

A Resistance-Temperature Relation for Low Temperature Thermometry

Harold J. Hoge
National Bureau of Standards, Washington, D. C.

May 31, 1949

THE Callendar-Van Dusen equation, a polynomial in temperature, relates the resistance of a standard platinum thermometer to the temperature in a relatively simple way. Temperatures on the International Temperature Scale (ITS)[1] are defined by this relation from 0°C down to the oxygen point ($-182.970°\text{C}=90.190°\text{K}$), and although these temperatures are not in perfect agreement with the thermodynamic scale, they are sufficiently near it to make the ITS extremely useful for practical purposes. Nothing of equivalent accuracy and simplicity has been found for use at lower temperatures. A table giving R/R_0 as a function of T may be used,[2] but each thermometer must then be calibrated at a rather large number of points in order to establish its deviation from the table.

Recently C. S. Cragoe[3] proposed the use of the linear function $y(R)=(R-R_1)/(R_2-R_1)$, where R_1 and R_2 are the resistances of a thermometer determined at two calibration points, such as the normal boiling points of hydrogen and oxygen. Instead of computing temperature directly from R, the value of y is computed as an intermediate step, after which T is obtained from a master table $T(y)$ that is used for all thermometers. The only calibration of an individual thermometer required is the determination of R_1 and R_2. A proposal to extend the ITS below 90.19°K by this method was made by the National Bureau of Standards. The Advisory Committee on Thermometry to the International Committee on Weights and Measures received this proposal,

TABLE I.

Thermometer	R_0	$R_{20.273}/R_0$	α	δ	β
53	25.56716	0.0047033	0.00392366	1.495	0.1109
48	25.55641	0.0052010	0.00392092	1.496	0.1115
58	25.56384	0.0044661	0.00392596	1.491	0.1103

prior to revision of the ITS in 1948, but did not act upon it. The method gives an adequate temperature scale between 54.363°K (oxygen triple point), and 90.190°K (oxygen boiling point) when calibrations are made at these two temperatures. If calibrations are made at 20.273°K (boiling point of equilibrium hydrogen) and at 90.190°K, results in the interval between the calibration points are not so satisfactory, and the situation is not greatly improved by shortening the range to the interval between calibration points of 20.273° and 54.363°K.

It is the main purpose of this note to propose a somewhat different method of establishing a temperature scale, which on the basis of preliminary tests offers advantages over the methods described above. The advantages are greatest below 20°K, where previously-used methods have either failed or become difficult to apply. Let $P(T)$ and $Q(T)$ be two tables giving the resistances of two platinum resistance thermometers of rather different characteristics. Values of P and Q at 1-degree intervals are adequate for this purpose. Then it is found that the resistance R of a third thermometer can be expressed as a linear combination of the two functions P and Q. That is

$$R=AP+BQ+C, \qquad (1)$$

where A, B, and C are constants to be determined by calibrating the thermometer at three fixed points. This equation has been tested by using the temperature-resistance tables of 7 previously calibrated thermometers. The thermometers selected, and the particular combinations taken to represent P, Q, and R, were chosen to give a reasonable test of the procedure rather than to put the method in the most favorable light.

Two illustrative examples taken from the results will be given, involving the thermometers for which the constants are given in Table I. Using the equation $R_{53}\text{ calc.}=0.26789R_{48}+0.73286R_{58}+0.00097$, having constants determined at 13.813°, 20.273°, and 54.363°K, the maximum value of $\Delta T=(R_{53}\text{ obs.}-R_{53}\text{ calc.})\times(dT/dR_{53})$ between the two lower calibration points was 1 mdeg. and between the two upper points, 2 mdeg. Using only two calibration points, at 20.273° and 90.190°K, the equation $R_{53}=0.32116R_{48}+0.67935R_{58}$ was derived, and for this the corresponding maximum value of ΔT was 4 mdeg. at about 56°K. On the basis of the tests made thus far, the most satisfactory method of applying Eq. (1) appears to be to use a three-constant equation similar to the first example given above for the range below 54.363°K, and to use a two-constant equation ($C=0$) with constants determined at 54.363° and 90.190° for the range between these two calibration points. It may be possible to cover the entire range with a single equation by giving the constants A, B, and C a slight temperature dependence, but this has not been investigated.

The results of the tests of Eq. (1) indicate that above 20°K it should lead to a temperature scale reproducible within ±5 mdeg., with criteria for acceptable thermometers that are no more difficult to satisfy than those now contained in the ITS. Below 20°K, Eq. (1) gives a somewhat more accurate representation of the *resistance* of a thermometer than above. Because dR/dT becomes smaller in this region, however, the reproducibility of a temperature scale defined by Eq. (1) is not as good below 20°K as above. Even so the results are much superior to those obtained when the function $y(R)$ is used.

The electrical resistivity of a pure metal may be expected to be represented by some such function of temperature as that proposed by Gruneisen.[4] This function is defined by an integral similar to that which defines the Debye specific heat function, and in fact the Gruneisen function G and the Debye function D roughly satisfy the relation $G/T\doteq D$. Hence even if the correct analytical expression for the resistivity of a pure metal were known, it would probably be expressed in tabular form as a matter of convenience.

Without knowing the correct analytical expression for the resistivity of a pure metal, it is still possible to make assumptions about how this resistivity will be modified by the introduction of a small amount of impurity. If it is assumed that the modification is roughly proportional to the amount of a given impurity added, Eq. (1) becomes quite plausible. For P and Q then represent the resistance of the pure metal as modified by the presence of two different amounts of this impurity, and by compounding P and Q in different proportions it should be possible to represent the resistance of a sample containing some other amount of the same impurity. If two impurities are present, it might be expected that they would modify the resistance-temperature relation of the pure metal in different ways. It would then be necessary to use three suitably chosen functions to represent the resistance of a sample containing arbitrary amounts of either or both impurities. From the standpoint of resistance thermometry it is rather fortunate that it seems to be possible to lump together the effects of all impurities present, and even to include the effects of any differences in mechanical strain and number of lattice defects.

Note on Reduction of Background Fog in Nuclear Emulsion Plates

P. K. S. WANG
Betatron Section, National Bureau of Standards, Washington, D. C.

June 8, 1950

SOME difficulty has been encountered because of electron background in nuclear emulsion plates exposed directly in the x-ray beam of a betatron.[1,2] This note will describe a refixation technique that helps to reduce the electron background density of emulsions.

Because nuclear photo-disintegration cross sections are small compared with electron pair production cross sections, the number of background electrons is necessarily large when nuclear disintegrations are investigated in plates. The emulsions are usually so blackened that a special technique has to be applied to make the disintegration tracks observable. Recently we found that refixation of the processed plates in Kodak liquid x-ray fixer was very effective in reducing the dense electron background. The reduction of the silver grain density in emulsion plates by refixing is a phenomenon similar to that found in standard negative film and thoroughly investigated by Russel and Crabtree.[3] No adequate description of the basic mechanism has been given.

The refixation technique can be best described by the following experiment: Several Ilford E-1 emulsion plates, 100μ thick, were located in a cadmium box and surrounded with 14 inches of paraffin. The assembly was exposed to the x-ray beam from a betatron running at 35 Mev. The successive exposures measured with a Victoreen r-meter were 200 r, 300 r, and 500 r. The plates were first processed by a standard method and were blackened by the electron background to such an extent that they became opaque. They were then refixed by placing in a Kodak liquid x-ray fixer at room temperature for 2 hours. This comparatively long refixing time was necessitated by the unusually dense back-

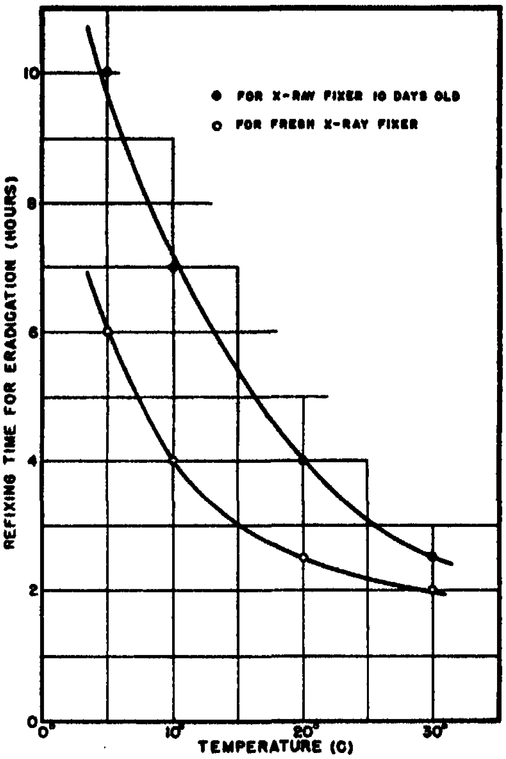

FIG. 1.

ground due to the exposures which were intentionally high. After this treatment, all the plates showed 3 and 4 pronged alpha-stars besides numerous single alpha-tracks as described by Cameron and Millar.[1] The latter used a modified Van der Grinten "grain-gradation" development which permitted them to use an exposure of 200 r. In comparison with the "grain-gradation" development, the present refixation technique has the advantage of being more flexible and convenient. The necessary refixation can be visually monitored and accomplished in small increments.

One objection to the refixing method is the alteration in track lengths which could result from the grain reduction on alpha- or proton tracks of varying grain density. However, this objection can be raised in the case of any similar technique. In order to examine quantitatively the refixing times in Kodak liquid x-ray fixer that would seriously alter heavy particle tracks, a series of tests were made. In all cases the plates used were processed Ilford C_2 emulsions. They were refixed until the proton and the alpha-tracks were made just to disappear. The minimum refixing times required to eradicate all the tracks were determined as a function of the x-ray fixer temperature and age. The results are plotted in Fig. 1 with the time in hours *versus* temperature in °C for fresh fixer and for 10-day-old fixer. With new fixer at 20°C the refixing time for disappearance of proton and alpha-tracks is 2½ hours. Therefore, plates with dense background that require more than one hour of refixing to make proton or alpha-tracks observable should be interpreted with care, because of the possible effects on the track lengths.

According to a report of the Office of Naval Research,[4] a strong ammonium-thiocyanate fixer was recommended by Franzinetti, which reduced the fixing time as compared with hypo fixer. Upon refixing some processed plates, results similar to those found with the x-ray fixer were also found with this ammonium-thiocyanate fixer. Use of the ammonium-thiocyanate fixer, or similar fixers, for work with thick emulsions where long fixing times are necessary should be made with caution in order to avoid alterations in the track lengths. This is true especially for experiments in which energy distributions of particles are involved.

The author appreciates very much Dr. H. W. Koch's constant interest and advice during the progress of this work.

New Instruments

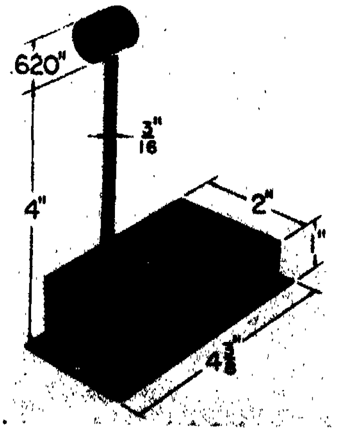
W. A. Wildhack: Associate Editor
in Charge of this Section
National Bureau of Standards, Washington, D. C.

These descriptions are based on information supplied by the manufacturer and in some cases from independent sources. THE REVIEW *assumes no responsibility for their correctness.*

Infra-Red Detector

The thermistor bolometers originally developed by the Bell Telephone Laboratories are now available for infra-red measurements from The Servo Corporation. They are rugged, sealed units suitable for spectrophotometric, industrial, and military applications.

The standard Servotherm bolometer consists of a matched pair of thermistor flakes having similar thermal and electrical characteristics. The thermistor material is a semiconductor with a high negative temperature coefficient of resistance. Positive and negative temperature bias voltages are applied to the active and compensating flakes. Radiation falling on the active flake causes a temporary change in resistance and results in an output voltage which is suitably amplified.



The steady state and dynamic characteristics of thermistor flakes are determined by the properties of the material itself, by their size and shape, and by the rate of thermal transfer from the thermistor flake to its surroundings. In order to have fast response to thermal radiation, the flake is mounted in close proximity to a thermal sink.

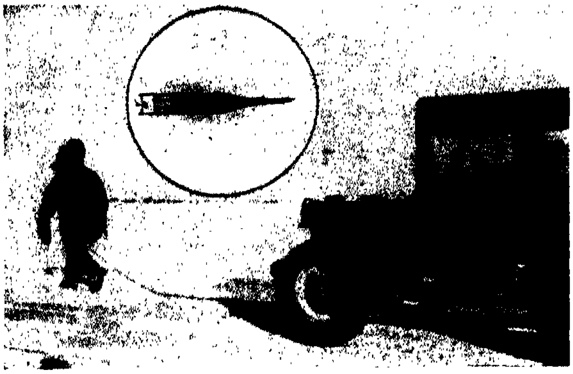
Three types of bolometers are currently available, with sensitive areas of 2.5×0.2 mm, and time constants of 3, 7 and 25 milliseconds, respectively, and noise equivalent power of the order of 10^{-9} watts.

The bolometer shown in the figure is mounted on a pre-amplifier, which provides initial amplification and reduces the impedance to permit use of flexible signal leads.—SERVOTHERM PRODUCTS DEPARTMENT, SERVO CORPORATION OF AMERICA, *New Hyde Park, New York.*

Ventilation Meter

The Air Ventimeter is a new instrument for measuring ventilation air flow. It utilizes a miniature non-directional probe $\frac{3}{8}$ in. long and $\frac{1}{8}$ in. in diameter and has an indicator for reading velocities from as low as 5 feet per minute up to 6000 feet per minute. The indicator and probe operate on the noble metal thermopile principle.

The Air Ventimeter, recently developed for the Army Quartermaster Corps to study ventilation between layers of clothing in a protective research program, has now been adapted for general commercial applications. It is especially suited for micro-climatology studies, controlled ventilation during painting, finishing, and drying processes, cooling and air flow studies in motor and machinery design, air flow measurements within small ducts and grills (probe can be inserted through $\frac{5}{32}$ in. opening) and similar applications. It is of particular value for measurements where the amount of cooling or ventilation must be determined in confined areas and where the direction of air flow is unknown or variable.

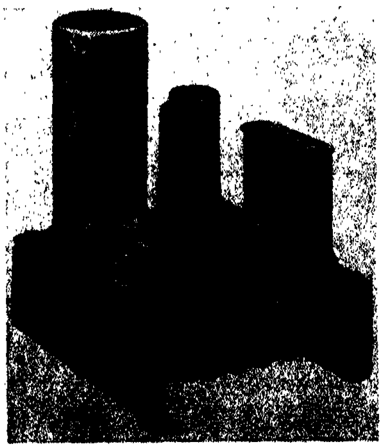


The temperature compensating feature incorporated into the Ventimeter permits accurate measurements even when extreme cases of sudden temperature changes occur.

The indicator movement is calibrated to indicate velocity readings directly in feet per minute. Indicators are available for operation on 115v a.-c. or battery power supplies. An attachment can be provided for use with a suitable recorder.—HASTINGS INSTRUMENT COMPANY, INC., *Hampton, Virginia.*

Frequency Standard

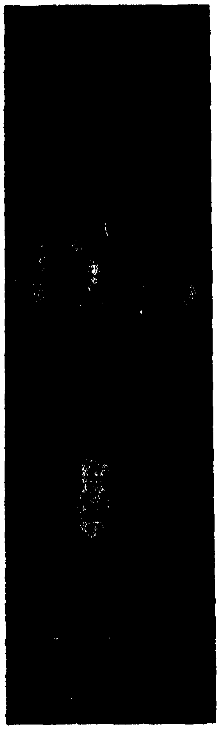
A compact, miniature tuning-fork frequency standard may be used for navigational aids, controlling gyros, firing electronic inverters, time bases, telemetering, and chronometry. It may be readily integrated into basic equipment, and may be operated under conditions of extreme temperature, humidity, and vibration. The manufacturer claims it to be an accurate, stable source for any frequency between 200 and 1500 c.p.s.; dividers and multipliers are available for other frequencies. The accuracy is one part in 100,000 and the temperature coefficient is better than one part per million per °C from 0 to 85°C.—AMERICAN TIME PRODUCTS, INC., *580 Fifth Avenue, New York 19, New York.*



Micro Burette

A platinum-tipped micro burette, designed to deliver drops of approximately 0.01 milliliter, is being made by Kimble Glass, Division of Owens-Illinois Glass Company. It was designed by Kimble research engineers for use in the field of micro chemistry.

The platinum-alloy delivery stem is sealed into a glass tip which can be removed for cleaning. It extends inside the glass tip for a short distance so that dirt and grease cannot clog the opening.



The tip has a standard Luer grinding. Where there is no significant danger of chemical reaction between the titrating liquids and hypodermic syringe needles, the latter can be used with the micro burette instead of the regular tip.

Two types of these micro burettes in each of two sizes are available through laboratory supply houses. One type has a standard-taper straight stopcock and funnel top, and the other a three-way interchangeable ground stopcock and plain top. The smaller size has a 5-ml capacity and 0.01-ml subdivisions, and the larger a 10-ml capacity with 0.02-ml subdivisions. Micro burette or tip may be purchased separately.—OWENS-ILLINOIS GLASS COMPANY, *Toledo 1, Ohio.*

Radiation Monitor

A new laboratory monitor for alpha-beta-gamma-detection has been announced by Nuclear Instrument and Chemical Corporation. Model 1615 is a general purpose count rate instrument with wide utility, which may be used for checking clothing, benches, glassware, and hands or fingertips for contamination, or for continuous monitoring of background air contamination or isotope decay. It may also be used to count samples with activities between 100 and 50,000 counts per minute where accuracy of measurement need not be better than 3 percent standard error. A

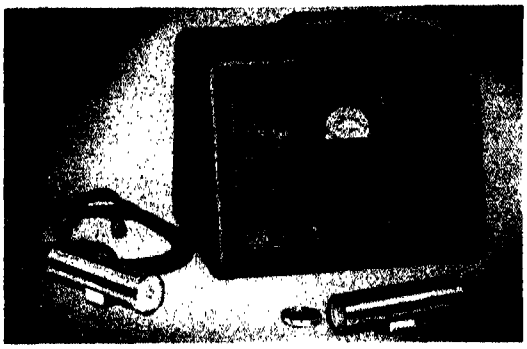


chart type recorder may be attached for maintaining a permanent written record.

A choice of five different ranges, from 500 to 50,000 counts per minute full scale, is provided. Suitable time constants in each range, in conjunction with a switch permitting choice of standard error, allow either 3 percent or 20 percent error to be read on any range if desired. The instrument incorporates a loud speaker with controllable volume and a high voltage supply which is controlled from the front of the panel.

The probe used in this instrument has an unusual mounting arrangement. It incorporates a permanent magnet which allows the probe to be mounted in any position on one side of the cabinet, and also makes possible its use on a ring stand, vacuum line, or any ferro-magnetic material.

If desired, a 10-foot cable and probe can be obtained to permit use of the "Radiation Sentinel" in clinics and hospitals for surveying a patient's body. The recording meter may also be attached in order to provide a permanent record of counts.—Nuclear Instrument and Chemical Corporation, *229 West Erie Street, Chicago 10, Illinois.*

Platinum Thermometer

The conventional precision platinum thermometer is often too bulky to fit the small opening in some types of calorimeters or other apparatus with restricted space. A new type of platinum thermometer of much smaller dimensions has been developed for precision measurements.

The sensitive tip is 5 mm o.d. and 1¼ in. long for a resistance of 25.5 ohms. The stem is 7 mm in diameter and can be several feet long if required.

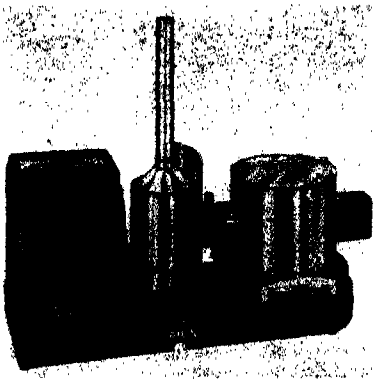
The backbone of the thermometer is a heavy wire of thermometer quality platinum of .050-in. diameter and onto which a glass coating is fused. A resistance winding is placed on this coating, one end being connected to the center wire. An outside coating of Pyrex glass is fused on the winding. In this way the platinum wire is completely sealed off and protected from contamination and mechanical injury, similar to the other types of Weiller resistance thermometers. Four leaves of fine gold wire are provided.

The unit is monofilar. The characteristics of the unit are identical with those of the manufacturer's precision platinum thermometer.—Dr. Paul G. Weiller, *95 Broad Street, New York 4, New York.*

Micro-Photometer

A new Light-Scattering Micro-Photometer which measures 20 micromicrolumens of scattered light, has a sensitivity approximately 100 times greater than similar instruments.

It may be used with any of the accepted techniques for molecular weight, particle size, micro-fluorescence, depolarization, dissymmetry, and micro-turbidity measurements. Its high sensitivity opens new fields in the measurement of optical-glass scattering power and in micro-chemical turbidity analyses.



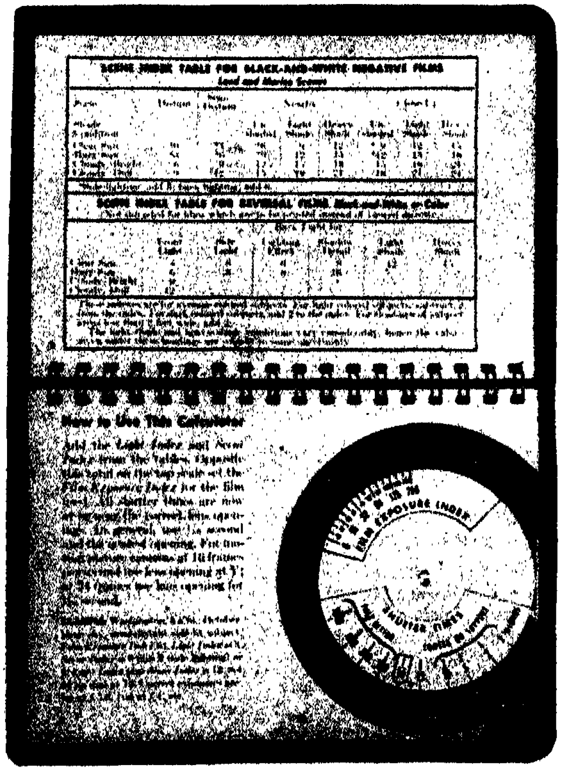
The instrument is portable and completely a.-c. operated. It employs two built-in electronic-regulated power supplies, also a d.-c. amplifier which operates the panel micro-ammeter and which may be connected directly to an external recorder. Full-scale deflections of the panel micro-ammeter are made with photomultiplier tube currents of 10, 1, .1, and .01 micro-amperes.

Details are given in Bulletin 2182, obtainable from the manufacturer.—The American Instrument Company, Inc., *Silver Spring, Maryland.*

Photographic Exposure Computer

Potentially large savings in costs of photographic film used for industrial pictures are among the possibilities of a simple, inexpensive computer with which light conditions can be accurately evaluated, especially when professional photography is not warranted. The device is low enough in cost to be distributed in quantity to field service men, for example.

The new Photographic Exposure Computer is a cooperative development of 45 national technical societies and leading manufacturers of photographic and optical equipment working through American Standards Association. It is a by-product of the war, the first edition having been used all over the world by the Armed Forces.



The value of the computer has now been enhanced by the addition of tables for color film, which requires more accurate exposure settings, and for transparencies or reversal materials in both black-and-white and color for projection or viewing with an illuminator. The computer is an American Standard method for evaluating light conditions. It is based not only on long-existing exposure tables, but also on data on radiant energy reaching the earth's surface. It consists of a pocket-size booklet containing 25 durable, loose-leaf pages, 3¼×4¾ in., with a flexible fabricoid cover. On one page is a circular calculator for determining shutter speed and lens stop or *f*-number with index numbers obtained from included tables and from the film used.

Index numbers allow for all lighting variables, including the altitude of the sun by latitude, date and hour; atmospheric conditions (especially clouds); spacial structure of the scene (especially distance), conditions of illumination (shade and direction of lighting); and film speed. The guide thus evaluates light intensities and luminance of scenes to be photographed. The calculator combines this index with a film exposure index to indicate proper camera adjustment for a picture. Copies of the computer are available at $1.00 each.—AMERICAN STANDARDS ASSOCIATION, *70 East 45 Street, New York 17, New York.*

Ground Resistance

Vibroground Model No. 263 is designed to provide corrosion and electrical engineers with a light, rugged, accurate instrument for measuring soil, anode, and circuit resistances and polarization effects.

It is capable of measuring the true resistance to earth of man-made grounds, irrespective of the earth resistance and conditions. Readings are not affected by the resistance of auxiliary prods or leads, or stray a.c. or d.c. currents in the earth. Accuracy is not dependent upon the meter movement, but upon a carefully calibrated resistance. The instrument circuit is such that it has the ability to discriminate in accepting only currents from its own power supply for measurement.

Ranges are selected by a separate switch at lower left of the panel. Special design features permit direct readings on the single scale of the potentiometer. All resistance values are determined by simple decimal multiplication. The ranges have been incorporated which can give the most accurate readings in soil varying in resistivities from 0 to 1,195,000 ohms per cubic centimeter at 10 feet or greater spacings.

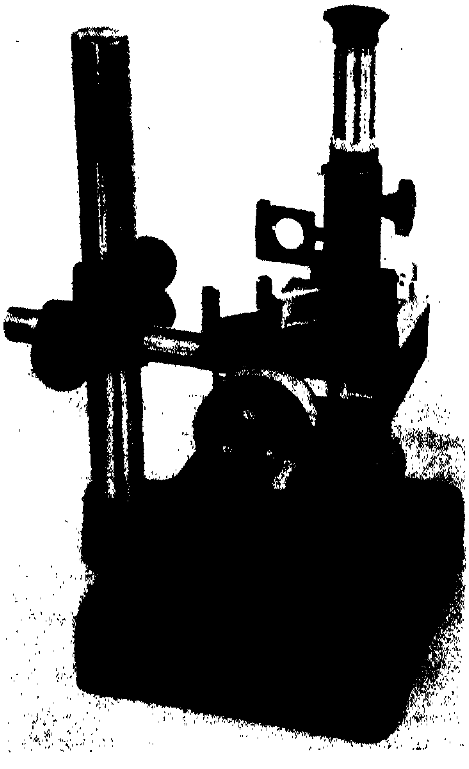
Power is provided by eight standard flashlight batteries, with a circuit incorporating a synchronous self-rectifying vibrator having an output of 125 volts. Resistance measurements can be made by the two-, three-, or four-electrode methods.

Simplicity of operation and ease of use are outstanding features of Vibroground. No previous instruction or training period is required. Vibroground Model No. 263 is mounted in a steel case, with removable cover and quick opening battery drawer. It weighs 10¾ lbs. including cover. Over-all dimensions are 9 in.×6 in.×6¾ in. —ASSOCIATED RESEARCH, INC., *3758 W. Belmont Avenue, Chicago 18, Illinois.*

Michelson Interferometer

This latest design of a well-known laboratory instrument is an economical and accurate device for calibrating finely divided scales, strain gauges, precision dial indicators, and other length measuring equipment using the wavelength of light as the unit of measurement.

The optical system is mounted on a standard Gaertner micrometer slide with a choice of 25-mm or 1-inch range. The micrometer drum is direct reading to 0.01 mm or 0.0001 inch. Settings can be made either by means of a microscope mounted in the carriage or, in the case of dial indicators, by contact with the carriage. Measurements are made either by counting interference fringes directly or by first using them to calibrate the lead screw of the micrometer slide and then employing the divided scale and drum on the slide to obtain the measurements.



The power of the microscope can be varied over a wide range by use of interchangeable objectives. The standard eyepiece and cross-hair reticle can be replaced with a filar eyepiece micrometer which is preferable for some types of microscopic settings. The instrument is designated as M305 Interferometer Attachment.—THE GAERTNER SCIENTIFIC CORPORATION, *1201 Wrightwood Avenue, Chicago 14, Illinois.*

Electrically Controlled Camera

A new 35-mm data-recording camera, Type A-1, has been announced by Cook Research Laboratories. This camera is a completely automatic, electrically tripped instrument built for special applications. It is capable of taking pictures at any rate up to four frames per second.

Provision is made for control of the taking rate by means of an external electrical tripping pulse if desired. This feature widens the scope of usefulness of this camera and makes it adaptable to many additional problems. Large magazine capacity (200 feet) and automatic operation make the unit well suited for applications in remote locations which might be left unattended for long periods of time. The film magazine can easily be replaced with a fresh cartridge when required.

Other features of the Type A-1 Camera are as follows: 1. Film transport is effected by a precision Geneva Type intermittent. 2. All castings are of a high impact strength aluminum alloy. 3. Bearings are of a lifetime porous bronze. 4. Emphasis has been placed on ruggedness and dependability of all components.

Some of the more obvious applications of the camera include photographing of meter readings, oscillographic records, chemical reactions, and general laboratory use.—Cook Research Laboratory, *1457 Diversey Parkway, Chicago 14, Illinois.*

Manufacturers' Literature

Electronic Supplies—Aerovox General Catalog lists capacitors of many different types, many of them new; an entire section is given over to television capacitors for TV servicing. Wire-wound and carbon resistors are listed, and vibrators and test instruments.—Aerovox Corporation, *Bedford, Massachusetts.*

Fractional-Horsepower Motors—Over 200 specifications are listed to fit almost any fractional horsepower requirement—plain motors, and speed reducer motors—in all popular winding classifications. Contained also is such information as connection diagrams, dimensions, how to measure machine torque, how to increase speed reducer motor life, and a listing of typical motor applications. Copies are available upon request.—Bodine Electric Company, *2254 W. Ohio Street, Chicago 12, Illinois.*

Burrell Announcer—No. 50 6 39, describes laboratory centrifuges, "Monochromatic" Colorimeter, and other laboratory apparatus.—Burrell Corporation, *2223 Fifth Avenue, Pittsburgh 19, Pennsylvania.*

High Frequencies—Catalog 20-A, 1950, lists and illustrates a Pulse Generator for radar, nuclear, and TV circuits; Signal Generators for measuring receiver performance, standing wave ratio, gain, antenna and transmission-line characteristics; attenuators for use in measuring gain, frequency response, voltage ratios; and other laboratory instruments.—Hewlett-Packard Company, *395 Page Mill Road, Palo Alto, California.*

Springs—Catalog No. 6, lists and illustrates beryllium copper spring data, including compression, standard brush, flat, strip, etc.—Instrument Specialties Company, Inc., *Little Falls, New Jersey.*

Oxygen Equipment—Aircraft Oxygen Equipment Engineering Manual describes typical installations and recommended practices, and covers masks and accessories, regulators and flow gauges, cylinders, connections, pressure gauges, etc.—Ohio Chemical and Surgical Equipment Company (a division of Air Reduction Company, Inc.), *1177 Marquette Street, Cleveland 14, Ohio.*

Zirconium in Surgery

Various metals and alloys have been utilized at one time or another in surgery, including gold, silver, aluminum, magnesium, tantalum, brass, steel, and vitallium. These uses have been to suture wounds with wire, to unite broken bones with plates and screws, to connect broken channels with tubes and to cover holes in the skull with plates. Materials used in these operations must conform to exacting specifications as to strength, durability, malleability, resistance to fatigue and to corrosion, etc. Materials for cranioplasty should not produce inflammation or foreign body reactions when implanted in tissue. The ideal material should be non-irritating electrically and chemically, equivalent in strength to the skull but easily adaptable to the contour of the defect, light in weight, non-absorbable, non-toxic, unaffected by therapeutic procedures of x-rays and diathermy and by the extremes of heat and cold encountered by humans, unaffected by infection, and inexpensive.

It has been suggested that stress "corrosion" may take place in alloys used as structural replacements, which are initially corrosion-resistant. Thus a bone plate, subjected to multiple stresses over a period of years may become irritating and necessitate a second operation for its removal. For this reason an element is preferable to an alloy.

Tantalum is the only element that has been used so far in surgery with any degree of safety. It is used mainly in cranioplasty (to cover holes in the skull), as small clips to stop bleeding from blood vessels in the brain and as thin sheets to wrap around cut nerves. However, there are several drawbacks to its use. It is rare, extracted with difficulty from its ores, and expensive. Plates are difficult to fashion and usually require careful time-consuming molding in advance. In view of these disadvantages it was decided to study the application of zirconium to surgery. This study was carried out at the Harrison Department of Surgical Research of the University of Pennsylvania Medical School.

Zirconium is relatively abundant, and has been available in a ductile form for a number of years. Although it is extremely active at high temperatures, it is almost completely inert and corrosion-resistant below 200°C. Fully annealed, it is soft and malleable, and can be drawn or shaped easily. Although it work-hardens to a considerable degree, it has a high work capacity and can be fully annealed in 15 minutes at 750–800°C. Chemically one of its most important properties is its corrosion-resistance. Physically, its malleability and low specific gravity are advantages. Its electrolytic action when immersed in a physiological saline solution is, like that of tantalum, minimal.

In animal experiments zirconium wire has been used as sutures in the abdominal wall. In a second experiment zirconium screws and pegs were inserted into the leg bone. Thin strips of the metal have been inserted into the brain along with tantalum and silver. Skull defects have been covered with zirconium plates. Microscopical studies in all experiments proved that zirconium caused little reaction in muscle, fascia, bone, and brain. The third experiment was considered to be a delicate method of evaluating the reaction to brain tissue, and zirconium compared favorably with tantalum. It was much better than silver which was included because it is used in neurosurgical clinics as clips to stop bleeding. Some surgeons feel that tantalum is too hard and cannot be pinched tightly enough to insure adequate compression of the vessel. It is probable that the more malleable zirconium will find use in this application.

These preliminary studies indicate that zirconium has a place in surgical procedures and that further experimental and clinical study is warranted. In addition to hemostatic brain clips, it may be used in the form of plates to cover skull defects and give adequate protection to the brain. It can be machined into screws for fixation of bone plates. It can be drawn into wire of sufficient strength and malleability for use as suture material. Zirconium tubes are being made for the repair of bile ducts. Thin sheets of the foil may be used to seal the ends of cut nerves, and the foil may be used as a burn dressing. It is possible that zirconium rods will prove adaptable for intramedullary bone pinning in which the ends of a broken bone are aligned by a metal rod passed down the central core. Zirconium powder has not been used experimentally or clinically but it will show up on x-ray and might be used to mark the location of certain operations such as intervertebral disks and frontal lobotomies. At present vitallium, 18-8-SMO stainless steel and tantalum are used in surgical operations and can be buried in human tissue for many years without undue irritation. Zirconium appears to be relatively inert and, being an element like tantalum, will also find a place in the operating room.

The above material was abstracted from an article entitled "Zirconium in the Operating Room" by Dr. J. I. Bates. This article appeared in Foote-Notes 22, No. 1, 1950.—Foote Mineral Company, *18 West Chelten Avenue, Philadelphia 44, Pennsylvania.*

Permanent Magnets

Hyflux Alnico V magnets have a guaranteed energy product of at least 5.25×10⁶ BH. This is about 16 percent more than the highest published, guaranteed value for regular Alnico V. These stronger, smaller magnets permit greater compactness in design. They are the result of a special production technique applied to regular Alnico V, not a new alloy.—Indiana Steel Products Company, *Valparaiso, Indiana.*

Static Elimination

Alphatron static eliminators are essentially bars, strips, or foils of brass or nickel on which polonium is electrochemically deposited. The active area is covered by a thin layer of electroplated gold which is finally coated with lacquer. The alpha-particles emitted by the polonium ionize the air and dissipate either positive or negative static charges. Used as a bar, the eliminator is placed about an inch from the surface of moving sheets or films to render surfaces completely neutral. Foils may be placed on the inside of nozzles or blow-guns and the ionized air blown across surfaces to remove dust. Since the surface is neutralized in the process it loses its tendency to attract further dust from the air. Attached as a strip to a brush in such a position that it leads the stroke, it facilitates the cleaning of surfaces by brushing. While it will completely neutralise a charged surface, the action is not of course permanent in that the surface could be recharged by the normal causes for the formation of static. The manufacturer states that the short-range alpha-particles emitted by the polonium do not constitute a radiation hazard.—Recco, *205 East 43rd Street, New York 17, New York.*

Diamond Abrasive Kit

A kit containing the six most widely used NBS grades of diamond compounds is offered by the manufacturer of *Dymo* brand diamond abrasives to facilitate experimental and development work with these materials. The selection is such that almost any desired finish can be produced on carbides, mold, and tool steels and other hard materials. Each grade of diamond abrasive compound is distinctly color-marked and is contained in jars with matching colored tops. The kit is in a sturdy, compact wood case with a hinged top.—Elgin National Watch Company (Industrial Products Division), *Elgin, Illinois.*

Carbide Marking Pencil

A tungsten carbide pencil is now available for permanently marking glassware. Only slightly below the diamond on the hardness scale, tungsten carbide is cheaper than diamond and comes to a definite point rather than an edge as is found on a diamond tip. The point is permanently mounted in a knurled steel pencil shaft and is protected by a cap so that the pencil may be safely carried in the pocket. The pencil is useful for a variety of laboratory tasks: sealed vials can be permanently identified; sheets of glass can be accurately scored for breaking; tubes and rods can be scored more rapidly than with a file.—Fisher Scientific Company, *717 Forbes Street, Pittsburgh 19, Pennsylvania.*

Plastic Products

Lustrex glass mat consists of styrene reinforced with random glass fibers. Molded products have all the advantages of styrene and the additional value of greatly improved strength. It is recommended for molding trays, housings for mechanical devices, paneling, structural laminates, boxes, and other containers where improved strength and chemical resistance are needed. Technical details are available in a bulletin prepared by the manufacturer.

Lauxite UF 77A is a new cold-setting urea resin glue with catalyst incorporated, having greatly improved storage stability. It was developed to meet the hot-weather storage problems of woodwork manufacturers. High standards of strength, water resistance, working life, setting speed, and color have been maintained in developing this product. It has been laboratory- and field-tested successfully both for ordinary cold gluing and for high frequency gluing.—Plastics Division, Monsanto Chemical Company, *Springfield, Massachusetts.*

Flame-Retardant Insulation

Rulan is a plastic electrical insulation that will not support combustion. Whereas flammability has been a characteristic disadvantage of plastics with good electrical properties, tests with this material have shown that it will not burn after a flame has been removed, nor will it drip when molten, a further advantage since plastic drippings can spread fires. Its electrical properties are comparable to, although not the equivalent of, those of polythene, one of the best insulating materials known for high frequency applications. It has a power factor of 0.002, and a dielectric constant of 2.5. It is non-tracking and retains its electrical properties after long immersion in water at elevated temperatures. Its mechanical properties are good and its low temperature properties excellent. It can be injection-molded and extruded on to wire at high speeds. Its use is suggested as insulation for high voltage hook-up, signal-control, lead-in, and flame-retardant line wire, and for high voltage street-lighting cables. Molded electrical parts and extruded tape are also being developed for uses where flammability is a consideration.—E. I. duPont de Nemours and Company (Polychemicals Department), *Wilmington, Delaware.*

Chart Recording of Microsecond Pulse Amplitudes

J. T. DEWAN AND K. W. ALLEN
Atomic Energy Project, National Research Council of Canada, Chalk River, Ontario, Canada

(Received July 7, 1950)

A peak voltmeter circuit is described which will record, on an Esterline-Angus chart, the amplitudes of microsecond pulses generated at random in ionization chambers or similar counters. Slow response of the recording pen prohibits the resolution of pulses less than one second apart. Provision is made for selecting pulses coincident with some triggering event as the low counting rates suitable for the circuit are most often encountered in coincidence experiments. Coincidence resolving times as low as five microseconds may be attained, and the linearity is such that input pulse amplitudes from 2 to 100 volts are reproduced on the chart to within ±1 volt.

INTRODUCTION

IN many instances it is necessary to obtain the distribution in size of microsecond pulses produced in ionization chambers or proportional counters and for this purpose a multi-channel pulse analyzer is normally utilized. However, when the pulses occur very infrequently, at an average rate of a few per minute, as is often the case in coincidence experiments, a high speed pulse analyzer is a much more complex instrument than is required. Its discriminating circuits may tend to drift during the long counting periods necessary to produce good statistics, and usually it has no provision for the selection of pulses coincident with other events. Consequently a circuit has been designed which will indicate, on the chart of an Esterline-Angus 1-ma pen recorder, the magnitudes of random pulses which may, if desired, be selected by coincidence with other events. It was originally used in the study of the energy distribution of long-range α-particles which are emitted occasionally in the fission process,[1] but subsequent experience has confirmed its usefulness in other applications. The rather slow response of the Esterline-Angus pen prohibits the resolution of pulses less than one second apart, although the coincidence resolving time may be as low as several microseconds. The circuit can be readily adjusted to handle input pulses ranging from microseconds to milliseconds in duration and will reproduce on the chart pulse amplitudes from 2 to 100 volts to within ±1 volt. It is, perhaps, somewhat tedious to translate the spectrum of pulses obtained on the chart into a differential or integral bias curve, but on the other hand a permanent record is obtained showing the actual time distribution of the pulses, a feature especially useful when deviations from randomness are suspected.

DESCRIPTION OF THE CIRCUIT

The general operation of the circuit can be readily understood from the block diagram of Fig. 1. Pulses to be recorded, of positive sign and up to 100 volts in amplitude, are normally obtained from a linear amplifier. They are fed into the discriminator D_1, which eliminates amplifier noise and any small undesired pulses, and then into the coincidence gating circuit C. If a given pulse is coincident with one from the gate generator G it passes on with unchanged magnitude to the lengthener L; if not, it is suppressed in the coincidence circuit. The lengthener is a two-stage integrating circuit which, in the absence of the restorer R, would extend the duration of the input pulse from a few microseconds to several minutes thereby allowing the Esterline-Angus pen ample time to record the magnitude of

the pulse before it has appreciably decayed. The rectoring circuit allows the pen about one second to reach its maximum traverse and then returns it in a fraction of a second to its normal position in readiness for another pulse. The use of a restorer decreases the dead time by a large factor since, in its absence, the pen would follow a very slow exponential decay. The calibrating pulse generator provides standard pulses, simulating the transients in speed of rise, to facilitate the adjustment of the recorder and to check the linearity of the system. A complete diagram of the circuit is shown in Fig. 2 and a more detailed description follows.

Pulses with amplitudes sufficiently large to overcome the biased diode T_1 are fed into a coincidence gate circuit consisting of the cathode follower T_2 driving the load R_2 in series with the tube T_3. Normally T_3 has zero grid bias and draws a large screen current so that it has a plate to cathode resistance of about 500 ohms. Consequently only two percent of an input pulse reaches the grid of T_4 when the coincidence gate is closed. On the other hand, when a negative pulse from the gate generator drives the grid of T_3 beyond cut-off, this tube acts as a very large resistance shunted by its plate-cathode capacity, wiring capacity and the input capacity of T_4. Complete charging of these stray capacities through R_2 requires about 1 μsec.; hence if the input transient rises in a fraction of this time it must remain at maximum for a microsecond to ensure that no loss in pulse amplitude will occur in the coincidence gate. This necessitates that exponentially decaying input pulses have a total duration of about 40 μsec.

As it is difficult to predict accurately from the published data the performance of T_3 under such conditions, a number of different miniature tubes were investigated to determine their effective resistances at low plate voltages. The results are shown in Fig. 3. In each case the tube was tested at zero grid bias and sufficiently large screen voltage to produce maximum rated screen dissipation with no plate current flowing. It is evident from Fig. 3 that the 6AN5 is best suited for the application; it has a resistance of 500 ohms at plate voltages up to eight volts. Several other coincidence circuits were investigated but the one described was found to be the most satisfactory. It responds rapidly and has the advantage that small unavoidable delays in the gating pulse cause no loss in the size of coincident pulse reaching the lengthener provided that pulse remains at maximum for at least one microsecond after T_3 has been driven to cut-off.

The pulse lengthening is effected by a straightforward two-stage integrator comprising tubes T_4, T_5, T_6, and T_7.[2] Each stage consists of a cathode follower which charges a reservoir condenser through a sharp cut-off diode. The cathode follower will supply 50 ma without drawing grid current so that the first reservoir condenser

---

[2] W. C. Elmore and M. L. Sands, *Electronics: Experimental Techniques* (McGraw-Hill Book Company, Inc., New York, 1949), p. 196.

C_1 can be charged to 100 volts in a microsecond. It loses its charge in about 25 msec., while the second condenser C_2 is charged in half a millisecond and has a decay time constant of approximately five minutes. As the Esterline-Angus pen requires half a second to sweep fully across the chart, it cannot actually follow this millisecond rise but attains its full traverse before the pulse has perceptibly decayed in magnitude. The use of a "Glassmike"* condenser for C_2 is strongly recommended because of its extremely high leakage resistance. The lengthened pulse appearing across the final reservoir condenser is coupled to the Esterline-Angus recorder through the cathode follower T_8. The d.c. voltage at the cathode is balanced out by a voltage divider so that little current normally passes through the recorder. Accurate balance is not necessary because of the manual pen shift on the instrument. A variable resistor R_4 in series with the recorder is provided for adjusting the size of the pulses on the chart; usually it is arranged that 100 volt input pulses produce full scale deflection. For large pulses the recorder is critically damped by 15,000 ohms shunt resistance but small pulses appear slightly overdamped due to the friction of the pen on the chart. However a small 60-cycle voltage applied to the movement aids the pen in responding more quickly to small pulses. The oscillation caused by this a.c. voltage is barely perceptible, producing only a slight widening of the trace.

As already mentioned the function of the restoring circuit is to discharge rapidly the final reservoir condenser after the recording pen has had ample time to reach its maximum, i.e., after about one second. Otherwise the lengthener would not be ready for another pulse until condenser C_2 had completely discharged, which would require about fifteen minutes. The restoring circuit consists of the cathode-coupled trigger pair T_{12} and T_{13} and a discharge tube T_{14} which normally conducts and acts as a relatively low resistance across C_2. Positive pulses from T_4 fire the trigger pair producing negative pulses of about one second duration and of sufficient size to bias off T_{14} completely. For this interval of one second, condenser C_2 is allowed to retain the charge which it accumulates; at the end of the interval T_{14} conducts and discharges C_2 in a few milliseconds. As the coincidence gate is not 100 percent efficient, small non-coincident pulses of two volts or less can reach the lengthener. The purpose of R_5 is to ensure that these small pulses do not trigger the restorer and hence do not record on the chart. C_2 is actually charged by such pulses but loses its charge through T_{14} before the pen has had sufficient time to respond.

The gate generator was rather arbitrarily chosen to accept negative input pulses, up to 100 volts in magnitude. Pulses large enough to pass the biased diode T_9 fire the direct-coupled trigger pair T_{10} and T_{11} producing fast rising output pulses of 50 μsec. duration. The differentiating combination C_3R_3 transforms these to sharp triangular pulses causing T_3 to be biased off for a well-defined interval of time, which should be somewhat greater than the rise time of the transients under study. The load resistor of T_{11} is tapped to provide a small negative output to feed an external scaling unit. Positive pulses can be obtained equally well by reversing the 1N34 diode.

The internal calibrating pulse generator has been found extremely useful for checking the overall operation, adjusting the recorder to correct full scale deflection and testing the linearity of the transient channel. It consists of a 6D4 thyratron relaxation oscillator T_{15} providing positive pulses at two frequencies, either one every four seconds or two per second, to trigger the thyratron pulse generator T_{16}. The pulse shaping elements in the second stage may be altered at will to provide pulses with rise and decay times simulating those of the actual transients under study.

ADJUSTMENT AND CALIBRATION

The system is adjusted and checked as follows. With the internal pulse generator arranged to give pulses of the desired shape, C_3 and if necessary C_4 are adjusted so that the gate generator biases T_3 to cut-off for roughly twice the rise time of the transients under study, with a minimum of two microseconds. R_3 is then varied by screwdriver adjustment until the cathode of T_2 is at ground potential. With no input pulses to either channel and with the "Operate-Calibrate" switch on "Operate," the recorder pen is balanced to have minimum pressure on the chart consistent with proper tracing and is then brought to the proper baseline by the manual adjustment provided in the instrument. The switch is then turned to "Calibrate," which starts the internal generator operating and connects the standard pulses to the gate generator and transient channels. A discriminator-scaler, whose calibration is known to be accurate, is connected to the monitor output of T_2. With the calibrator frequency switch on "Fast" the magnitude of the pulses entering the discriminator-scaler is adjusted to be 100 volts, the frequency switch is thrown to

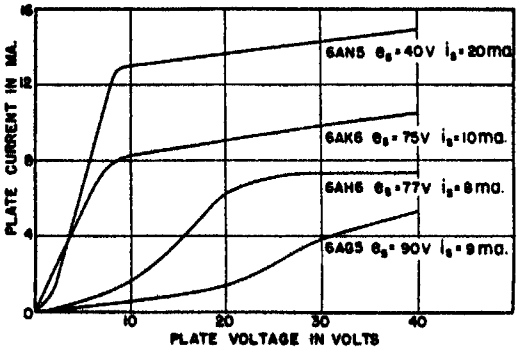

FIG. 3. Low voltage characteristics of several pentodes. Screen voltages are constant and screen currents indicated are those which obtain with zero plate current.

---

* Oil-filled plastic film capacitors supplied by Condenser Products Company, Chicago, Illinois.

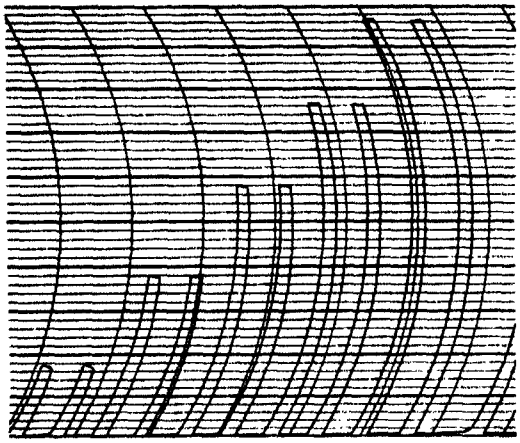

FIG. 4. Response of the recorder to test pulses of one microsecond rise time. The width of each pulse on the chart is approximately two seconds.

"Slow" and the height of the pulses recorded on the Esterline-Angus is adjusted to be full scale by means of the variable resistor R_4. The linearity of the system, as well as the satisfactory operation of the recorder, is then checked by reducing the size of the calibrating pulses in a number of steps, each time noting the pulse amplitude entering the discriminator-scaler at "Fast" frequency and the amplitude on the pen recorder at "Slow" frequency. The "Fast" frequency is provided merely to facilitate finding the cut-off point with the discriminator; this would be a very tedious process at a pulse frequency of one in four seconds. The frequency change is not sufficiently great to cause any change in pulse amplitude. Finally with 100-volt pulses at the monitor output of T_2, but with no gate pulses fed to T_3, R_5 is adjusted until no small pulses are recorded on the chart. The adjustment and checking are then completed and the "Operate-Calibrate" switch is moved to "Operate." Figure 4 shows the response of the Esterline-Angus recorder to test pulses of varying amplitudes, the rise time of the test pulses being approximately one microsecond and the decay 50 μsec.

DISCUSSION

In connection with the use of the pulse recorder one or two points are worthy of note. It is evident from the operation of the coincidence gate that the resolving time of the system for chance coincidences cannot be less than the duration of the input transients and for reasons previously given this is a minimum of 40 μsec. for an exponentially decaying pulse. A resolving time of perhaps 50 to 100 μsec. is not excessive in many experiments. If a spectrum of pulses is recorded in which a fraction of the pulses is due to chance coincidences a correction can be made by triggering the gate generator from an independent source, e.g. an external pulse generator, and subtracting the resulting spectrum of random coincidences from that previously obtained, after normalizing the two to identical counting rates.

When it is desired to achieve the minimum possible resolving time with fast-rising pulses these pulses should be preshaped into flat-topped rectangles of the same amplitudes and of about 3 μsec. duration. As the coincidence gate must remain open for at least 2 μsec. the shortest resolving time attainable is approximately 5 μsec. (If still shorter resolving times are required, coincidences must first be formed with a conventional mixer circuit whose output is then used to trigger the gate generator.) Pretreatment of the pulses may be effected by a simple one-stage integrator with restorer, very similar in nature to the circuits already described. It sometimes happens[1] that gate generating pulses, although nominally coincident with pulses to be recorded, have unavoidable delays of perhaps several microseconds. In such cases preshaping of the transient pulses is necessary because exponentially decaying pulses, unless exceedingly long, would suffer losses in amplitude in the coincidence gate by amounts depending on the delays involved. Preshaping is also necessary when one wishes to record pulses less than a microsecond or so in duration as these pulses are too short to pass through the coincidence gate properly.

If it is desired merely to record the amplitudes of all pulses entering the transient channel, the coincidence feature of the circuit can be eliminated by removing T_3 from its socket. In this case bypassing R_2 and decreasing C_1 will improve the response to pulses rising in less than a microsecond.

Indications are that the pulse recorder described in this paper will find many uses in cosmic-ray research where low counting rates are quite common. In this laboratory it has been used to record the number of counters in a tray of paralleled Geiger tubes which are fired simultaneously by the passage of a cosmic-ray particle, and is currently being used, in conjunction with a proportional counter, to study the specific ionization of mesons of selected ranges. However, it is believed that the circuit is sufficiently versatile to find application in other fields requiring peak voltmeters or pulse recorders.

Technical Apparatus for Determining Thermal Conductivity of Steels up to 500°C

Z. HORÁK AND F. KRUPKA
Department of Technical Physics, Technical University, Prague, Czechoslovakia

(Received November 1, 1949)

An apparatus for determining the thermal conductivity of metals based upon the comparison of flux of heat in a conductor in the usual form of a bar consisting of three parts of different materials has been developed. This method enables one to measure the temperature gradients by only one differential thermocouple sliding in an axial boring of the bar. In this way usually difficult measurements of thermal conductivity can be carried out very easily with sufficient accuracy for industrial purposes.

INTRODUCTION

In practice, methods of comparing the thermal conductivities in a steady state have proved to be very convenient since the difficult measurements of quantity of heat flowing through the whole cross-section area of the specimen are not necessary. Existing methods of comparison, however, require very long rod specimens which are not always at hand and they may be applied at higher temperatures only with difficulty. A new simple method somewhat similar to that developed by Van Dusen and Shelton[1] excludes these disadvantages and may be easily applied to a technical apparatus.

The apparatus described in the mentioned paper requires very difficult fitting-up (bars soldered together, thermocouples attached by peening), very careful and laborious attendance (manual adjusting of currents in the individual heating elements) etc. Under such conditions it does not appear that the comparative method would offer greater simplification and it is more advantageous to make "absolute" determinations directly. The authors intended therefore to develop an apparatus free of all these disadvantages which would enable the measurement to be performed in the simplest and easiest way with an accuracy convenient for industrial purposes.

METHOD OF COMPARING THE THERMAL CONDUCTIVITY

Consider a thermal conductor in the form of a bar consisting of three portions from which the outer ones *I* and *II* are of the same material and the middle portion *III* of another material as shown in Fig. 1. At the upper end of the bar a heater produces (continuously) per second the quantity of heat Q which flows through the bar into a water- or air-cooled receiver mounted on the lower end of the bar. In the steady state and in the case the bar is thoroughly insulated to prevent losses by radiation and convection, the flux of heat through any cross-section area of the bar will be uniform and will be given by $f=Q/A$ where A is the cross-section area of the bar. The quantity of heat Q, transferred across the area A, is given by the well-known equation

$$Q=kA(t_1-t_2)/(x_1-x_2)=f.A, \qquad (1)$$

where k is the thermal conductivity of the material. From this

$$f=k(t_1-t_2)/(x_1-x_2)=k\Delta t/\Delta x, \qquad (2)$$

where $\Delta t/\Delta x$ is the temperature gradient, i.e., the fall in temperature per centimeter. If the cross-section area A is at any point of the bar uniform, the flux of heat f also would be uniform. However, it is impossible to prevent in a perfect way losses of heat by radiation and convection, and for this reason, the average fluxes of heat in the portions *I*, *II*, *III* of the bar will be $f_I>f_{III}>f_{II}$.

When the losses in all three portions of the bar are approximately equal, the flux of heat in the bar will decrease linearly and the average flux of heat f_{III} in the middle portion will be the arithmetical mean of f_I and f_{II}, i.e.,

$$f_{III}=(f_I+f_{II})/2. \qquad (3)$$

From (2) and (3) we obtain

$$f_{III}=k_{III}\Delta t_{III}/\Delta x=(k_I\Delta t_I+k_{II}.\Delta t_{II})/2\Delta x. \qquad (4)$$

The thermal conductivity of the middle bar $k=k_{III}$ may be then computed from

$$k=(k_I\Delta t_I+k_{II}\Delta t_{II})/2\Delta t \qquad (5)$$

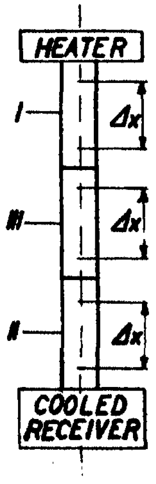

FIG. 1.

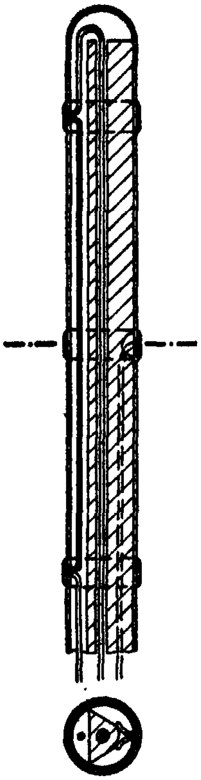

FIG. 2.

by means of observed temperature differences $\Delta t = \Delta t_{III}$, Δt_I and Δt_{II}, if the distances Δx are all equal and the conductivities k_I and k_{II} are known.

The measurement is then performed by inserting a specimen under investigation between two bars with exactly equal diameters made from a metal the conductivity of which is known and by observing the temperature differences which arise in equal distances in the specimen and in the outer bars in positions symetrical to the middle bar.

DESCRIPTION OF THE APPARATUS

In order to obtain the value of the thermal conductivity for the specimen III from Eq. (5), the sectional areas of all bars must be exactly equal. This may be reached with ease by careful machining of the cylindric specimen.

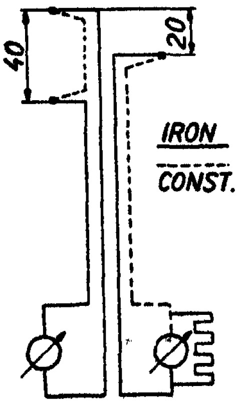

FIG. 3.

Furthermore, the distances Δx over which the temperature differences arise must be equal. It is possible to fulfil this condition perfectly by using a differential thermocouple, as shown in Fig. 2, having its junction placed in fine drill holes separated by a certain distance along the wall of a glass tube which slides in an axial boring of the bars. Besides the temperature differences, the absolute mean temperatures in the bars *I, II, III* are to be measured and for this reason two separate thermoelectric circuits (see Fig. 3) are suitable. By means of one of the circuits made up of iron-constantan wires, the temperature differences Δt in distances of 40 mm are directly read on the scale of the connected galvanometer. It will be noted from Eq. (5) that it is not necessary to graduate the scale of this instrument if the change of e.m.f. with temperature is linear. This is accomplished with the combination iron-constantan to about 500°C with sufficient accuracy. The advantage of such an arrangement is obvious. Then the absolute mean temperatures of the bars are measured by the use of the second circuit and a sensitive millivoltmeter with its scale graduated in degrees centigrade. Figure 2 illustrates the construction of the thermocouple. The fused ends of the wires placed in the wall of a glass tube are covered with 2.5 mm high copper rings fitted with putty; they are in contact with the surface of the axial boring in the bars and receive the temperature belonging to its particular position. Inside the tube the wires are insulated by means of a glass capillary shaped in the form of a three-sided prism.

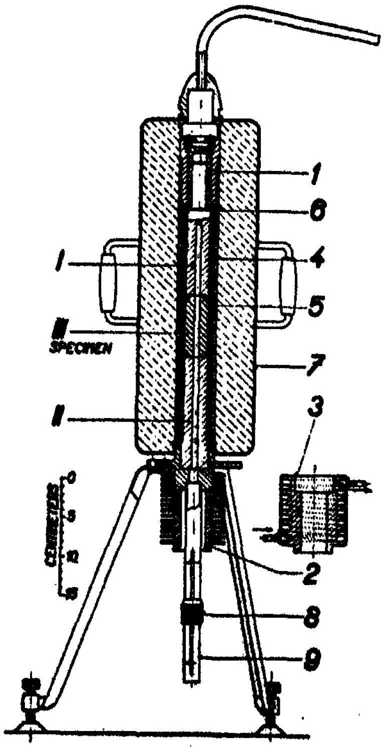

FIG. 4

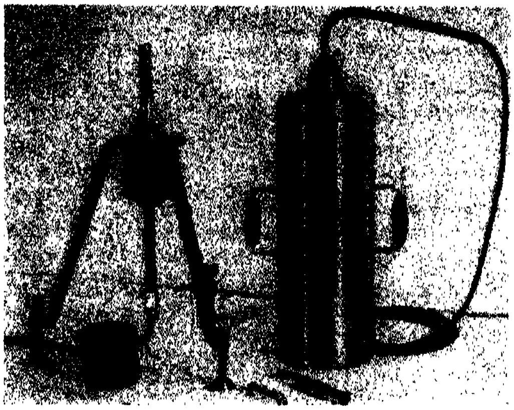

FIG. 5.

The heat transfer by the glass tubes, wires, and air column inside the boring is negligible due to the low thermal conductivity of these materials.

Equation (5) pertains to the case that the flux of heat in the middle bar is the arithmetical mean of the fluxes in both outer cylinders. This condition will be evidently fulfilled with sufficient accuracy if the radial losses are kept to a very low value in comparison to the total quantity of heat transmitted by the bar. In the apparatus the radial losses are reduced to a minimum by means of a porcelain tube 5 and a steel guard tube 4 which surround the bars *I*, *II*, *III* between the electrical heater 1 and the air- or water-cooled receiver 2 or 3, respectively, as shown in Fig. 4. Along this steel guard tube which is heated at its upper end and cooled at its lower end together with the bars *I*, *II* and *III*, a distribution of temperature arises similar to that along the bars. It is possible to adjust the temperature distribution along the steel guard tube by means of the copper tube 6 of a suitable length, joined to the top of guard tube 4. The space between cover 7 and tube 4 is then filled with glass wool and in this way the radial losses are considerably reduced. Cover 7 with guard tube 4 and heater 1 form one compact part which must be removed by drawing upward so that the cylinders will be free. The specimen may then be replaced by another (Fig. 5).

The differential thermocouple is set into position by means of sleeve 8 sliding on tube 9 (Fig. 4) in which the lower end of the thermocouple is suitably fitted. The precise position in which the temperatures are measured are fixed by the notches made in the slit along tube 9 and by a spring-pressed catch mounted in sleeve 8. In this way the required symmetry is secured.

TABLE I.

	Mean temp. deg. C	Temp. diff. div. of galv. scale	Corresp. therm. conductivity cal./cm sec. deg. C
Bar I	212.0	50.2	0.1403
Specimen III	154.5	94.2	
Bar II	99.0	47.7	0.1465

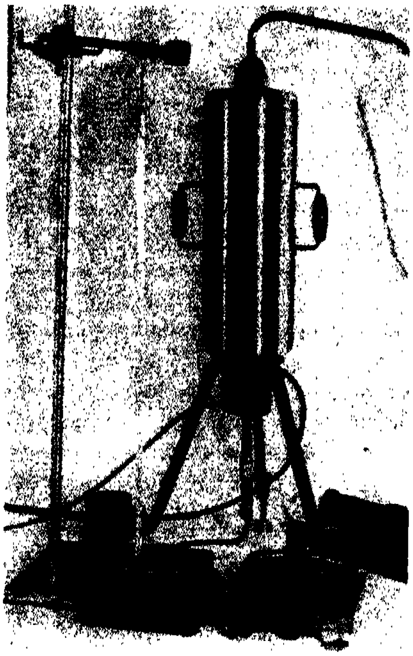

FIG. 6.

In order to exclude temperature drops in the contact areas between the bars, the ends of the specimen are provided with a screw and are screwed into the ends of bars *I* and *II*. The assembled apparatus prepared for measuring is shown in Fig. 6.

PERFORMANCE

In a certain range of thermal conductivities it is possible to adjust the fluxes of heat along the bars and steel guard tube so that an approximately linear temperature gradient is reached. In order to obtain an apparatus suitably for conductivity measurements on steels, bars *I* and *II* have been made from very pure nickel (99.521 percent), its thermal conductivity being similar to that of steels. The relationship of the conductivity to temperature of the pure nickel was given. The apparatus thus has proved to be suitable within the range about 0.18 to 0.05 cal./cm sec. deg. C and for temperatures of 40° to 500°C.

For example, a steel specimen, the chemical analysis of which showed C 0.16 percent, Mn 0.69 percent, Si 0.44 percent, P 0.014 percent, S 0.020 percent, Cu 0.20 percent, Cr 6.65 percent, Mo 0.52 percent, was investigated. The specimen was heat-treated: normalized at 900°C—one hour—cooled in still air and annealed at 750°C—one hour—cooled in still air. Table I shows data obtained in the steady state attained in about five hours.

Using Eq. (5), the thermal conductivity of this specimen at 154.5°C will be found as 0.0746 cal./cm sec. deg. C.

It will be noted that the difference between

$$k_I \cdot \Delta t_I = 0.1403 \times 50.2 = 7.05$$

and

$$k_{II} \Delta t_{II} = 0.1465 \times 47.7 = 6.98$$

amounts to about one percent. At higher temperatures this difference is of course somewhat greater but it proved to be regularly smaller than about 3 to 3.5 percent. The method of temperature measurement employed enables one to detect quite easily drops in temperature across the screwed joints of the bars which may occur. It is found, however, that if the specimen has been carefully manufactured, no remarkable drops in temperature occur which may exert an influence upon the accuracy of measurement.

SUMMARY

The apparatus described was found to be useful for measuring the thermal conductivities in the range of 0.18 to 0.05 cal./cm sec. deg. C, i.e., it is especially suitable for measuring conductivities of steels at temperatures about 40° to 500°C. The accuracy of values obtained is, of course, affected chiefly by accuracy with which the conductivity of bars *I* and *II* has been determined. The method itself is believed to be accurate to about two percent in the above-mentioned ranges assuming the specimen is manufactured carefully enough.

ACKNOWLEDGMENT

The authors wish to thank Mr. J. Junek for his excellent machine work in the construction of the apparatus.

Polarimeter for the Study of Low Frequency Radio Echoes

A. H. Benner and H. J. Nearhoof
Radio Propagation Laboratory, The Pennsylvania State College, State College, Pennsylvania

(Received June 8, 1950)

An instrument is described which allows the determination of the ellipticity, angle of tilt, and sense of rotation of low frequency radio waves returned from the ionosphere.

INTRODUCTION

THREE quantities are important in the observation of the reflected wave in the pulse technique method of radio sounding the ionosphere. These quantities are delay time, intensity, and polarization. The polarization of a radio wave reflected from the ionosphere, in general, is elliptical in shape, and the state of this polarization is defined by three factors. They are the ellipticity, the angle between the major axis of the ellipse and the earth's magnetic field (called the angle of tilt), and the sense of rotation of the ellipse. From a knowledge of the time variation of these factors, conclusions can be made concerning the structure of the ionospheric reflecting layer.

In conjunction with a program of ionospheric research conducted at the Radio Propagation Laboratory, an instrument has been constructed to measure the polarization of radio waves reflected from the ionosphere at low frequencies. It is the purpose of this paper to describe this equipment and its operation.

THE GENERAL SYSTEM

The equipment was designed to receive and record ionospheric echoes from a high power pulse transmitter operating at a carrier frequency of 150 kc/sec., a pulse rate of 1.5625 p.p.s., and with a Gaussian pulse shape whose width is approximately 150 microseconds. The receiving and transmitting site are separated by 4 km and synchronization is accomplished by means of an auxiliary transmitter operating on 2.398 mc/sec. which transmits a pulse 200 microseconds prior to the 150 kc/sec. pulse.

The basic ideas for a polarimeter, for operation on continuous waves, are due to Appleton and Watson Watt[1] and modifications of Martyn and Green.[2] Martyn,

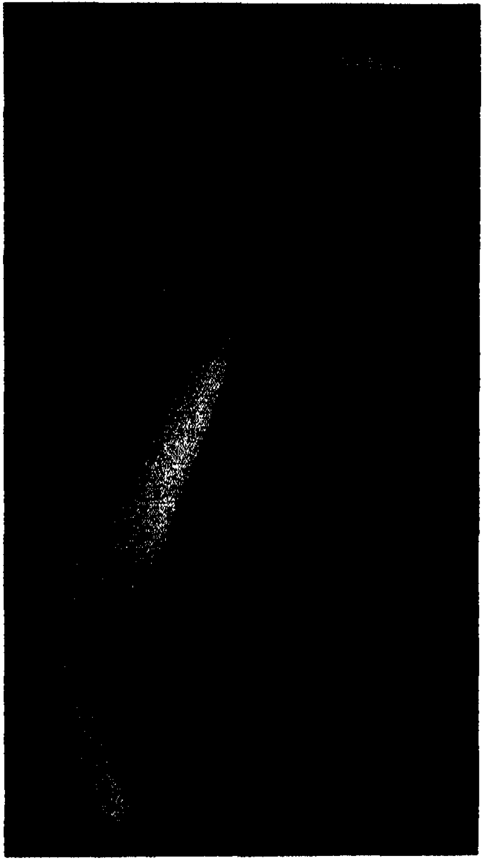

FIG. 2. Photograph of polarization ellipse of 150 kc/s echo with left-handed polarization.

Piddington, and Munro[3] applied these techniques to the pulse system of sounding.

The complete receiving installation is shown in block form in Fig. 1. Referring to the block diagram, two crossed loop antennas are connected separately to two receiver channels. The downcoming elliptical echo is resolved into two quadrature components by these crossed loops, amplified with equal gains and with equal phase, and recombined in the oscilloscope to portray the original ellipse. These receivers are of superheterodyne type with a common local oscillator. The intermediate frequency amplifiers of these channels are coupled by means of a low impedance output to the final deflection amplifiers of a type 208 DuMont Scope. These 'scope amplifiers were tuned to the receiver intermediate frequency of 1050 kc/sec. It was necessary to use such a high frequency in order to realize an adequate number of trace revolutions in the 150-microsecond pulse interval. Also, because of the very small duty cycle (about 10^{-4}), it is necessary to increase the accelerator potential to 4000 volts for greater picture intensity.

Located in the lower left-hand corner of the block diagram is a fixed tuned receiver, modified Wilcox *F*-3, which receives the synchronizing pulse from a separate remote antenna. The band width of this receiver was broadened to that adequate to preserve the synchronizing pulse shape, and noise discriminating threshold and video amplifiers were added. Both positive and negative going synchronizing pulses are available from this receiver.

The positive pulse actuates a delay gate unit whose function is to select a specific portion of the time scale for observation. The output of this unit is a positive pulse which is adjustable in both time location and in width. The negative synchronizing pulse triggers a sweep and range marker. The outputs of this unit are a sweep voltage for a type *A* presentation oscilloscope, an intensity gate for the same 'scope, and time markers.

The output from either channel of the low frequency receiver is detected and coupled to the vertical deflection amplifiers of the *A* 'scope. The pulse from the delay gate unit may be switched to the intensity grid of the *A* 'scope to select the desired portion of the time axis. The output of this unit is also fed to the intensity of the polarimeter 'scope. Thus, this tube is illuminated only during the desired time, and the ground pulse, noise, and interfering signals are not seen except when coincident with this gate pulse.

The sense mixer provides a scheme for ascertaining the direction of rotation of the ellipse. The 1.05 mc/sec. output of one receiver channel is given a 90-degree phase lag, gated by the delay gate pulse, amplified, and fed to the intensity grid of the polarimeter 'scope. It can be shown by a study of the Lissajous figures that, if the ellipse is rotating clockwise (right-hand) and lies in the second and fourth quadrants, only the top portion of the ellipse will be illuminated. If on the other hand, the ellipse lies in the first and third quadrants and is right-handed, only the bottom half of the ellipse is illuminated. In the case where the ellipse lies on either the horizontal or vertical axis, and is right-handed, only the right-half of the ellipse is observed. For left-handed rotation the results are opposite to those for the three cases mentioned above. An example is shown in the photograph of Fig. 2. A somewhat similar system was used by Martyn, Piddington, and Munro.[3]

The signal generator shown in the block diagram, Fig. 1, provides a 150 kc/sec. signal to the calibrate loop, which bisects the angle between the crossed loops. With this signal adjusted to the approximate amplitude of the desired echo, the two receiver channels are adjusted in gain and phase to give a straight line at 45° in the proper quadrants on the polarimeter 'scope. The calibrate loop is then rotated, say counter clockwise as viewed from above, and the line on the 'scope should rotate counter clockwise to assure correct alignment. The amplitude of the calibration oscillator is then varied to assure that the receiver channels do not suffer a phase change within the amplitude limits of the expected echo. After this procedure is completed, the system is ready to operate at this specific frequency and gain setting.

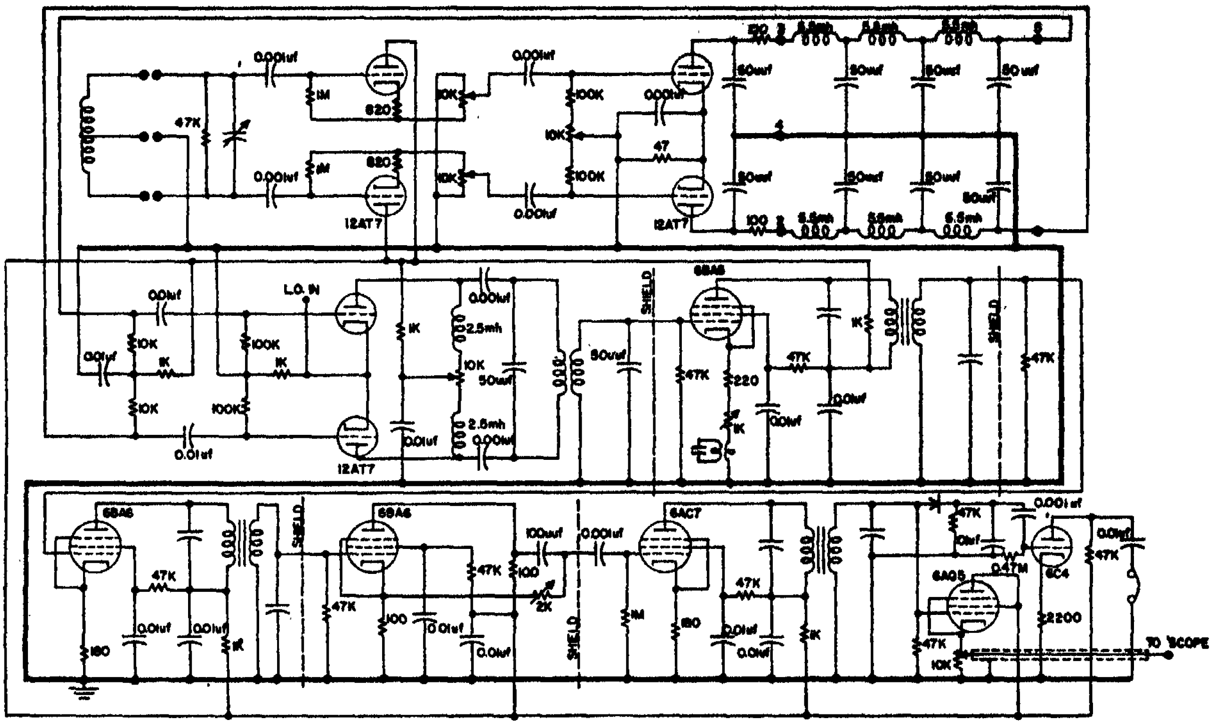

FIG. 3. Schematic diagram of one low frequency receiver channel. Note: Bypass condenser placed in B^+ and filament circuits in both receivers. (Not shown on schematic.) Polarimeter receivers, channels one and two.

In actual operation, the desired pulse as presented on the *A* 'scope, is selected by the delay gate unit. The switches are now positioned to place this gate pulse on the intensity grid of the polarimeter. This allows the observation of the desired pulse, and its ellipticity and angle of tilt may be recorded. By switching the intensity grid of the polarimeter 'scope to the sense mixer, the direction of rotation of the ellipse may be determined. A photographic record of the echoes is made with an Army Air Force Camera type 05 which has an *f* 2–3 lens and a 3 plus portra lens. Because of the very low duty cycle and the resulting low intensity picture, it is necessary to use a time exposure of at least 3 seconds.

CIRCUIT DETAILS

Since the low frequency channels are identical, only one will be discussed in detail. The schematic diagram of one channel is shown in Fig. 3. The input from the loop is coupled into balanced cathode followers. The purpose of this circuit is to facilitate amplitude adjustments without disturbing the phase to any noticeable degree. The outputs of the cathode followers are coupled through balanced, untuned r-f amplifiers to a low pass filter which is designed to attenuate above 300 kc/sec. This system was employed to avoid the difficulty of tracking problems as compared to the slight gain realized by the low *Q* tuned circuits. A push-pull mixer stage was incorporated primarily to balance the local oscillator signal out of the mixer plate circuit and prevent its passing into the I.F. strip.

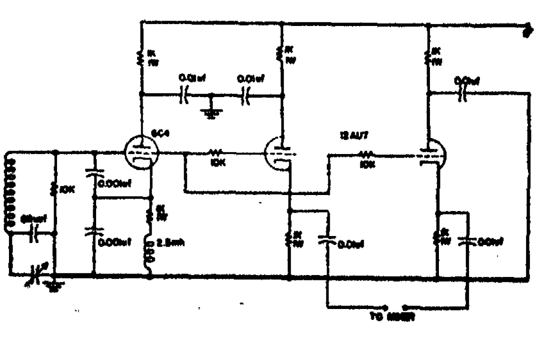

FIG. 4. Schematic diagram of the receiver common local oscillator.

A trap, tuned to the local oscillator frequency of 1200 kc/sec. (150 kc/sec. above the I.F. frequency), is placed in the cathode circuit of the first I.F. stage to eliminate any 1200 kc/sec. signal feeding through from the balanced push-pull mixers. The I.F. stages were designed to have a 40 kc/sec. band width to maintain the pulse shape.

The phase shifting network employes a cathode follower-phase inverter with a resistance-capacitance combination to obtain the desired 90° phase shift. Particular care was taken in the I.F. strip to prevent feedback by shielding each individual stage. The output of the last I.F. stage is connected to a cathode follower which provides a low impedance source to the input of the polarimeter 'scope.

The local oscillator which supplies both receiver channels is shown schematically in Fig. 4. It is a Clapp

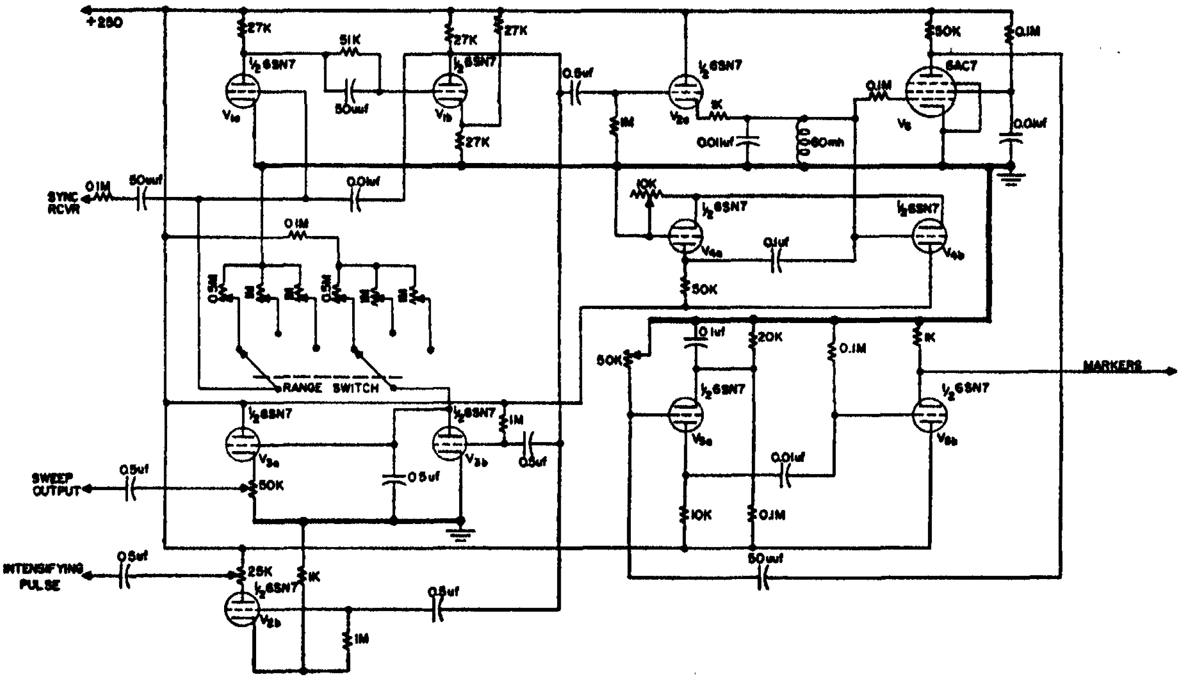

FIG. 5. Schematic diagram of the sweep and range marker.

oscillator[4] designed for good frequency stability. The oscillator is coupled to the two receivers through separate cathode followers to prevent cross-talk.

The sweep and range marker generator is of conventional design. The schematic is shown in Fig. 5. A negative pulse from the synchronizing receiver passes through a differentiating circuit to a monostable multivibrator. A negative square pulse is taken from the plate of V_{1b} and fed to the sweep generator. The saw-tooth output of the generator is coupled to the horizontal amplifier of the *A* 'scope through a cathode follower. The negative square pulse from V_{1b} also goes to V_{2b} which is an amplifier-inverter providing a positive square pulse to trigger the intensity of the *A* 'scope. Tubes V_{4a} and V_{4b} comprise a grounded grid, cathode coupled oscillator[5] whose tank circuit is placed in the cathode circuit of V_{2a}. V_{2a} is normally conducting, thereby placing a low impedance across the tank circuit of the oscillator. This prevents the oscillations until the negative pulse arrives at the grid of V_{2a}, cutting the tube off and allowing the circuit containing V_{4a} and V_{4b} to oscillate. These oscillations are squared and amplified in V_6, and differentiated and peak rectified in V_{5a}. The output of V_{5a} is a series of negative spikes. These markers are coupled to the *A* 'scope through cathode follower V_{5b}.

The positive pulse from the synchronizing receiver is connected to the delay gate unit. The schematic diagram of this unit is shown in Fig. 6. The positive pulse is differentiated and applied to the first half of the 6*SN*7, turning this tube on. The time this tube conducts is determined partially by the *RC* coupling network between plate to grid of the second half of the 6*SN*7. The negative going pulse from the plate of this tube is differentiated and the positive spike from the trailing edge of the pulse, which is adjustable, is used to actuate the second monostable multivibrator. The output of this multivibrator is a positive pulse whose width can be adjusted by the *RC* time constant of the coupling network between the plate and grid of the second 6*SN*7. This pulse is used to gate on the polarimeter 'scope for

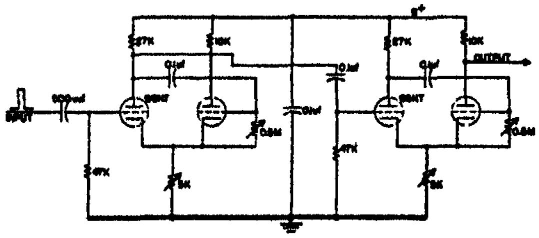

FIG. 6. Schematic diagram of the delay gate unit.

the portion of the sweep that is desired. The same pulse is connected through a switching arrangement to the sense-mixing unit.

The schematic of the sense-mixing unit is shown in Fig. 7. The 1.05 mc/sec. signal from channel one is connected to the sense-mixing unit as well as to the polarimeter 'scope. The signal is shifted 90 degrees lagging, by an identical circuit to the one employed in the 150 kc/sec. receiver. After the signal is shifted by 90 degrees, it is amplified by a tuned amplifier of the proper bandwidth. Tuned amplifiers were used to develop the necessary output voltage in order to illuminate the 'scope. This shifted, amplified signal is coupled to the grid of a *6AS6* switch tube that is biased below cut-off by the suppressor grid. The bias is obtained by the action of the biasing diode.

The positive pulse coming from the delay unit charges the 4 microfarad condenser to approximately 100 volts. When the pulse is removed, the grid is effectively placed −100 volts below ground. The *RC* time constant of the biasing diode is large due to the low duty cycle. The suppressor is held below cut-off until the next positive pulse appears, returning the grid to zero, and allowing the 1050 kc/sec. signal to pass. The 1.05 mc/sec. signal is gated in this manner and then amplified by the *6AG7*. The output is fed to the intensity grid of the polarimeter 'scope through a *6AQ5* cathode follower. The output is 40 volts peak for an input of 0.05 volts r.m.s.

EXPERIMENTAL RESULTS

Measurements have been made with this equipment in August and September, 1949, and March and April, 1950, at vertical incidence at 150 kc/sec. The results of the measurements to date have shown that the night time polarization is steady and conforms with that predicted by the theory. The state of the polarization was reported previously[6] for the early period of observation and has been confirmed by the recent experiments. An example of a typical ellipse seen at night on 150 kc/sec. is shown in Fig. 8. This ellipse, representing the electric vector, has its major axis inclined at an angle of 23° east of magnetic north, and ellipticity (defined as the ratio of the minor to major axis) of 0.563, and its sense of rotation is left handed.

At night, split or double echoes have been studied and found to have the same sense of rotation, but slightly different angle of tilt and elliptical configuration. The leading pulse of such a split is normally of the same character as described above, while the later pulse has been seen to lie at the same angle of tilt but with a tendency to be more linear. A series of measurements have been made comparing the observed ellipses for the first and second hop. All observations thus far, although not great in quantity, give an identity between the two. Other measurements have shown rather unusual and rapid changes near sunrise, while pre-sunset and sunset measurements have shown rather constant conditions; very similar to the nocturnal measurements. More complete experimental results will be presented at a later time.

The authors should like to acknowledge the assistance of Mr. P. G. Sulzer, and Mr. C. H. Grace. This work was done under the direction of Dr. A. H. Waynick and was supported in part by Contract No. *AF*19(122)-44 with the U. S. Air Force, through sponsorship of the Geophysical Research Directorate, Air Materiel Command.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 10 OCTOBER, 1950

The Design of Neutron Counters Using Multiple Detecting Layers

R. D. Lowde
Ministry of Supply, Atomic Energy Research Establishment, Harwell, England

(Received May 25, 1950)

A discussion is given of ion chambers in which a series of electrodes carry layers of solid detecting material. Counters of this type require low operating voltages, and can easily be miniaturized. Formulas are given for the correct layer thicknesses and for the neutron counting efficiency. The equations are applied to boron 10, and it is shown that there is a permissible tolerance of about 50 percent on the thickness of a boron layer, and a very considerable tolerance on the assumed values of the disintegration product ranges. Curves are given relating the optimum boron layer thicknesses and the efficiency to the number of layers. A miniature instrument is described having a sensitive volume of 0.4 cm^3. It operates at a thermal neutron efficiency of 24 percent with a collecting voltage of 70.

1. INTRODUCTION

RECENT experiments in nuclear physics have involved the detection of neutrons at the rate of only one every few seconds. For such work, a counter should be highly efficient, and where possible also small, so as to present a small projected area to the background flux and to require a minimum of the bulky materials used in neutron shielding. If the flux to be measured is in the form of a beam, the counter should in addition have a highly directional sensitivity.

For several purposes a suitable instrument is one which may be called a multiple-layer chamber. The neutrons are detected by a succession of solid coatings of some reacting material such as boron or uranium, on the electrodes of a series of parallel plate ion chambers. This type of counter may be made extremely compact, and may also be operated at a very low collecting voltage. Rossi and Staub[1] have already exploited these advantages of ion chamber methods by using a uranium layer coiled into a region of dimensions about 2 cm. The performance of these counters cannot be equalled by a simple ion chamber filled with detecting gas. For instance, about three atmospheres of $B^{10}F_3$ would be required in the same sensitive volume to give the efficiency of the counter described below; and for operation at this pressure, BF_3 must be purified to a degree that is difficult to achieve.

This paper deals with the theory and design of multiple-layer chambers. After discussing the relation between the layer thicknesses, the counting efficiency, and the number of detecting layers, the arrangement of the electrodes is examined. The performance of a miniature neutron counter designed on these principles is then given, and shown to be in general agreement with the theory.

2. THEORY

For the purposes of this section, a neutron beam is imagined perpendicularly incident on an arrangement of x_0 successive layers of some suitable material. Four assumptions are made: that the detecting substance is deposited with uniform thickness t on smooth thin backing foils impenetrable to the disintegration products, but not absorbing neutrons; that the generation of disintegrations is uniform throughout any one layer; that there are two detectable products of the neutron capture reaction; and that all disintegration products emerging from the surface of a layer are detected by the electronic apparatus.

The Efficiency of an Individual Layer

The counting rate of a solid layer of material depends on both the cross section of the nucleus for neutron capture, and the ranges of the disintegration products in the parent substance. These ranges are referred to throughout as R_L and R_α, with $R_L<R_\alpha$, in view of the later application to boron 10. The weaker long-range group of particles in the boron reaction is ignored.

In any given detecting layer, some of the disintegrations for which the particle tracks lie nearly parallel to the plane of the foil, pass unobserved. The total number of disintegrations taking place may be divided into two halves, according to which particle is projected in the direction of the detection chamber. If the layer is perfectly plane, and t is less than both R_L and R_α, the fraction of the particles emerging from a depth τ is easily shown to be $\frac{1}{2}-\frac{1}{2}\tau/R_L$ in one case, and $\frac{1}{2}-\frac{1}{2}\tau/R_\alpha$ in the other. The efficiency c of one layer therefore increases with t as

$$c=\tfrac{1}{2}\mu t(1-\tfrac{1}{2}t/R_L)+\tfrac{1}{2}\mu t(1-\tfrac{1}{2}t/R_\alpha), \qquad (1)$$

where μ is the linear neutron absorption coefficient. As the thickness of the layer is increased, this efficiency also increases up to $t=R_\alpha$; but at $t=R_L$ and $t=R_\alpha$ the first and second terms in (1) respectively reach a maximum and are replaced in turn by the constant terms

$$\tfrac{1}{4}\mu R_L \quad\text{and}\quad \tfrac{1}{4}\mu R_\alpha. \qquad (2)$$

Writing

$$a_1=(R_L^{-1}+R_\alpha^{-1})/4\mu;\; a_2=\tfrac{1}{2}\mu R_L,\text{ and } a_3=\tfrac{1}{2}/\mu R_\alpha, \qquad (3)$$

this efficiency is conveniently given by

$$c=\mu t[1-a_1\mu t], \qquad 0\leqslant t\leqslant R_L \qquad (4a)$$

$$c=\mu t\cdot\tfrac{1}{2}\cdot[a_2(\mu t)^{-1}+1-a_3\mu t], \quad R_L\leqslant t\leqslant R_\alpha. \qquad (4b)$$

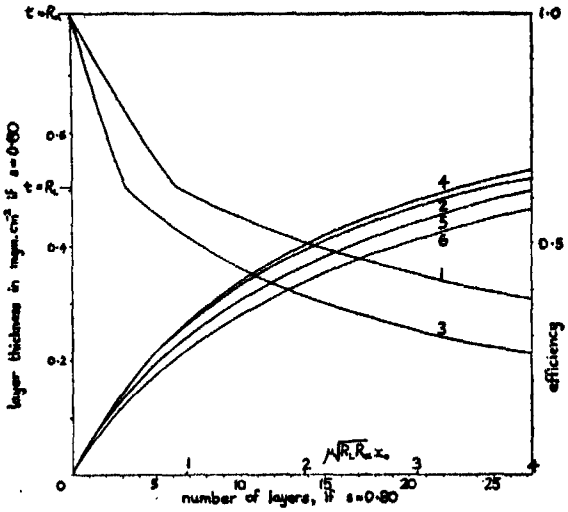

FIG. 1. Boron 10, layer thickness and counting efficiency in multiple-layer chambers. (1). The optimum thickness of boron 10 for x_0 identical layers. (2). The thermal neutron detection efficiency given by (1). (3). Curve showing the best variation of layer thickness along a counter having x_0 layers. Thicknesses are read off above the number of the layer, starting at the back of the counter. (4). The thermal neutron detection efficiency given by (3). (5) and (6). The efficiency given by the thicknesses of curve (3) multiplied by 1.6 and 0.5 respectively. In deriving these curves, the weak long-range group of disintegration products is ignored. s is the atomic stopping power of B^{10} (see Section 4).

The maximum efficiency for a single layer is obtained with $t=R_\alpha$.

Chamber with a Number of Identical Layers

With multiple-layer chambers, on the other hand, the maximum over-all efficiency is *not* obtained by putting every $t=R_\alpha$. For where there is a number of foils in succession, the layers at the front waste neutrons which would otherwise have stood a chance of being detected farther down the counter. It will therefore be profitable to reduce the thickness of the layers to an extent depending on their number, so that the initial waste of neutrons where the beam is at full intensity will be diminished, resulting in a greater total count.

Suppose x_0 identical layers are used. The factor μt in (4), which represented the fraction of the incident neutrons captured in one thin foil, must now be replaced by $(1-e^{-\mu t x_0})$; the bracketed factor in (4), which takes account of the wastage, is unaltered. This leads to an efficiency

$$c=(1-e^{-\mu t x_0})[1-a_1\mu t], \qquad 0\leqslant t\leqslant R_L, \qquad (5a)$$

$$c=(1-e^{-\mu t x_0})\tfrac{1}{2}[a_2(\mu t)^{-1}+1-a_3\mu t], \quad R_L\leqslant t\leqslant R_\alpha. \quad (5b)$$

Equations (5) may be transformed so as to have dimensionless coefficients by the new choice of variables

$$T=t/(R_L R_\alpha)^{\frac{1}{2}}, \quad X_0=\mu(R_L R_\alpha)^{\frac{1}{2}}x_0. \qquad (6)$$

This gives for boron 10 (ignoring the weak long-range group of disintegration products),

$$c=(1-e^{-TX_0})(1-0\cdot514T), \qquad 0\leqslant t\leqslant R_L, \qquad (7a)$$

$$c=(1-e^{-TX_0})0\cdot198(T^{-1}+2\cdot53-T), \quad R_L\leqslant t\leqslant R_\alpha. \quad (7b)$$

The optimum thickness, t_{opt}, giving the greatest efficiency for a given number of layers, is calculated by solving the two equations $dc/dt=0$ in the form $t_{\text{opt}}=f(x_0)$.

A graphical solution for boron 10 is shown in curve 1 of Fig. 1, and the corresponding efficiency in curve 2. The abscissa is $\mu(R_L R_\alpha)^{\frac{1}{2}}x_0$, which has been regarded as a continuous variable to give rise to a smooth curve through the points having x_0 integral. A calibration in x_0, the number of foils, has been made as accurately as measurements of R_L and R_α allow; t has also been calibrated in mg cm^{-2} subject to the same uncertainty. As the number of boron layers is increased, the optimum boron thickness decreases rapidly from the maximum value R_α to less than half that thickness for counters containing more than fourteen foils. The form of the function is different, depending on whether t is greater or less than R_L, since the relation between t and the counting rate is different in these two ranges; it is easily proved that the two branches join continuously at $t=R_L$. The rather sharp drop from R_α for one-layer counters to R_L for six-layer counters is due to this fact: so long as all the layers of a counter are thicker than R_L the waste of neutrons due to the comparative shortness of R_L is severe, and by thinning the boron deposit, advantage is gained on this ground to offset the diminished number of α-particles recorded.

It will be noticed that in this calculation, $t=R_\alpha$ corresponds to $x_0=0$ rather than $x_0=1$. This is caused by the approximation whereby Eq. (1) assumes there is no appreciable diminution of the incident neutron intensity within any one layer. At the extreme left of the graph for boron, this approximation is evidently only just valid.

The Optimum Variation of Layer Thickness

The design in which all foils carry equal deposits is open to further improvement. For when any counter containing several foils is exposed to a neutron beam, those neutrons entering it which escape capture are confronted by a shorter and shorter residual length of counter as they proceed; and it is clear from what has just been said that an improvement will be gained by thickening up the layers successively so that the highest possible detection efficiency for that residual length awaits the neutron at any point of its passage. The best variation of t will now be calculated.

Consider a hypothetical continuous counting medium of length x_0 and detector density t per unit length, instead of, as before, a counter of x_0 layers of thickness t. In a length dx of this counter, the amount tdx of detecting substance has a counting rate per unit incident intensity given by the right-hand sides of Eqs. (4) multiplied by dx. The result of this procedure approximates to a rigorous calculation when x_0 in the solution takes integral values.

The solution for boron 10, again ignoring the long-range group of particles, appears in curve 3 of Fig. 1, with the corresponding efficiency given by curve 4.

Curve 3 has been drawn such that when any number x_0 of layers has been decided on, the shape of the curve from 0 up to the appropriate value of $\mu(R_LR_\alpha)^{\frac{1}{2}}x_0$ gives the best possible distribution of detecting material; with good accuracy, the thickness of individual boron layers in a practical case can be read from the ordinates at the integral values of x_0. The rear foil in the counter should always have the thickness R_α. Again the curve gives the value $t=R_\alpha$ to $x_0=0$ rather than $x_0=1$, due to the continuous model ceasing to represent reality for counters having a small number of foils, up to about three in the boron counter.

The derivation of this function is as follows. Let $x=0$ be the back and $x=x_0$ the front of the counter. For a unit incident intensity of neutrons the intensity of the beam within the counter varies along the length as

$$I(x)=\exp-\int_x^{x_0}\mu t(x)\cdot dx. \tag{8}$$

The number of neutrons detected by the material between x and $x+dx$ is then

$$dc=-I(x)\cdot\mu t(x)[1-a_1\mu t(x)]\cdot dx, \qquad 0\leqslant t\leqslant R_L, \tag{9a}$$

$$dc=-I(x)\cdot\mu t(x)\tfrac{1}{2}[a_2\{\mu t(x)\}^{-1}+1-a_3\mu t(x)]\cdot dx, \qquad R_L\leqslant t\leqslant R_\alpha. \tag{9b}$$

Putting

$$y=\int_x^{x_0}\mu t(x)\cdot dx, \tag{10}$$

Eqs. (9) become

$$dc=e^{-y}\cdot y'[1+a_1y']\cdot dx, \qquad 0\leqslant t\leqslant R_L, \tag{11a}$$

$$dc=\tfrac{1}{2}e^{-y}\cdot[y'(1+a_3y')-a_2]\cdot dx, \quad R_L\leqslant t\leqslant R_\alpha. \tag{11b}$$

The counting rate of the whole instrument is greatest when the integral

$$\int_{x_0}^{0}dc \tag{12}$$

takes its maximum value.

This problem would be elementary, but for the fact that (11) has a discontinuity in the second partial derivative with respect to y' at $t=R_L$. That point is known to be within the range over which a solution for $t(x)$ must be found, and so the integrand (11) does not satisfy the continuity conditions for the application of Euler's equations. However, we can derive by a physical argument a class of functions containing the solution.

Consider first very short counters. The best thickness of deposit for counters of limitingly small length has already been deduced from Eqs. (1) and (2). For very short counters of finite length, the only reason for reducing $t(x)$ below R_α anywhere, is to reduce the waste of neutrons at the front, and it is easy to argue (by discussing the alternatives), that at least for short enough counters, $t(x)$ will be a continuous function, equal to R_α at $x=0$, of everywhere negative slope, and such that $R_L<t\leqslant R_\alpha$.

Thus for x_0 sufficiently small, the correct solution is obtained from (12) simply by Euler's method, using as integrand (11b) alone. This gives at once

$$t(x)/(R_LR_\alpha)^{\frac{1}{2}}=\tan[\tan^{-1}(R_\alpha/R_L)^{\frac{1}{2}}-\tfrac{1}{2}\mu(R_LR_\alpha)^{\frac{1}{2}}x]. \tag{13}$$

Now whatever the length of a counter, there will be a portion at the rear covering a range of x within the region of validity of Eq. (13). If the residual neutron beam which penetrates to this region is to be detected with the greatest efficiency, the function $t(x)$ must therefore follow (13) at the back of a long counter for some distance ξ. But at the point $x=\xi$, whose value may well depend on x_0, the detection efficiency of the rear portion becomes great enough to justify a reduction of $t(x)$ below R_L at greater x, in the interest of reducing the waste of neutrons where the incident beam is most intense.

The argument thus shows the desired solution to consist of two component counters in cascade, each having a different design based on one of the two Eqs. (11). The problem is therefore one of matching these two sections to give the maximum combined counting rate.

If the efficiency of the rear section is written $c_r(\xi)$, the total counting rate is the sum of the contributions of the front and rear sections:

$$c=\int_{x_0}^{\xi}e^{-y}\cdot y'[1+a_1y']\cdot dx+c_r(\xi)\cdot\exp-[y]^{x=\xi}. \tag{14}$$

This may be put in the form

$$c=c_r(\xi)+\int_{x_0}^{\xi}e^{-y}\cdot y'[1-c_r(\xi)+a_1y']dx. \tag{15}$$

Although the maximum value of the expression (15) contains ξ, the function y which maximizes the integral in (15) does not. The desired solution for y' in the region $0\leqslant t\leqslant R_L$ is therefore obtained by applying Euler's equations to the integrand of (15), which gives

$$t(x)=2/\mu(x+\kappa), \tag{16}$$

with κ a constant. Notice that apart from a multiplying factor and dependence on ξ, the integral in (15) is identical with that in (14), so that the solution (16) is the same function that gives the front section the greatest efficiency in itself.

ξ and κ are found by expressing the total counting rate as the sum of two integrals of the form (12) referring respectively to the front and rear sections; thus

$$c(x_0,\xi,\kappa)=\int_{x_0}^{\xi}dc+\int_{\xi}^{0}dc. \tag{17}$$

The integrands in these two integrals are separately, (11a) using (16), and (11b) using (13), in that order. The expression (17) reaches a maximum when

$$\partial c/\partial\xi = 0 = \partial c/\partial\kappa; \tag{18}$$

which yields

$$\mu(R_L R_\alpha)^{\frac{1}{2}}\xi = 4\tan^{-1}(R_\alpha/R_L)^{\frac{1}{2}} - \pi, \tag{19}$$

$$\kappa = a_2^{-1} - \xi. \tag{20}$$

Both ξ and κ are independent of x_0, so that $t(x)$ may be represented by a single function of x whatever x_0. Calculation further shows that the two branches (13) and (16) of the solution meet continuously at $t = R_L$.

Curve 3 of Fig. 1 is this function with x_0 written as the independent variable. Using (6) together with $\Xi = \mu(R_L R_\alpha)^{\frac{1}{2}}\xi$, it may be written:

$$T = \tan[\tan^{-1}(R_\alpha/R_L)^{\frac{1}{2}} - \tfrac{1}{2}X_0], \quad 0 \leqslant X_0 \leqslant \Xi, \tag{21a}$$

$$T = 2/[X_0 - \Xi + 2(R_\alpha/R_L)^{\frac{1}{2}}], \quad \Xi \leqslant X_0. \tag{21b}$$

In these equations, $X_0 = \mu(R_L R_\alpha)^{\frac{1}{2}}x_0$, with x_0 the number of boron layers; $\Xi = 4\tan^{-1}(R_\alpha/R_L)^{\frac{1}{2}} - \pi$, and $T = t/(R_L R_\alpha)^{\frac{1}{2}}$.

The Maximum Efficiency

The result of substituting (11) and (21) into (17) is an efficiency

$$c = \tfrac{1}{2}(1 + R_L/R_\alpha)/(1 + \cot\{\tfrac{1}{2}X_0\}\cdot R_L/R_\alpha), \quad 0 \leqslant X_0 \leqslant \Xi, \tag{22a}$$

$$c = [X_0 - \Xi + (R_\alpha/R_L)^{\frac{1}{2}} - (R_L/R_\alpha)^{\frac{1}{2}}]/[X_0 - \Xi + 2(R_\alpha/R_L)^{\frac{1}{2}}], \quad \Xi \leqslant X_0. \tag{22b}$$

This function is shown for boron 10 in curve 4 of Fig. 1.

The formulas (22) do not reduce to any simple criterion which will decide the most efficient detector for any given number of layers, but they may be illustrated by the following general remarks. A counter will be the more efficient, the greater the product of the neutron absorption coefficient and the geometric mean of the disintegration product ranges. It is also important that the two ranges be nearly equal, for then a thickness of coating which is efficient for the detection of one of the products will also be efficient for the detection of the other. Moreover, when the two ranges are nearly equal, the detecting layer may be deposited onto a thick electrode with little loss, because whichever of the two particles is projected in the direction of the backing plate, the other is thrown in the direction of the ion chamber with much the same probability of detection.

Tolerances on the Design Constants

A striking feature of Fig. 1 is the closeness of curves 2 and 4. Curve 4 exhibits, for any x_0, the highest efficiency obtainable with a multiple boron layer instrument, curve 2 the best efficiency of boron counters having all layers identical. Over the whole range of the figure the latter efficiency is more than 0.97 of the former, which means that any design intermediate between those given by curves 3 and 1 will give rise to a counting efficiency very close to the maximum. This result is fortunate, since thin films cannot be laid down with very great accuracy; and also because the thicker layers at the back of the counter, which are comparatively expensive to make, are shown to be unnecessary.

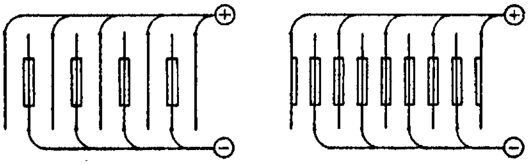
Curves 5 and 6 illustrate the insensitiveness of the over-all efficiency to the fine details of the function t. They allow for the possibility that the boron deposits may unintentionally be laid down too thick or too thin. Curve 5 is the efficiency of a counter whose layers have thicknesses given by curve 3 times 1.6; curve 6 is the efficiency with curve 3 times 0.5. These great errors in the practical values of t, therefore, give rise to remarkably little loss of efficiency. A glance at the form of the ideal curve shows why this is. For fairly long counters, say with $\mu(R_L R_\alpha)^{\frac{1}{2}}x_0 \sim 4$, most of the initial detection of the beam takes place in the front part of the counter, where the foils are too thin for excessive waste of neutrons; while for short counters, having say $\mu(R_L R_\alpha)^{\frac{1}{2}}x_0 < \frac{1}{2}$, thickening the boron gives an increased number of α-particles to offset the increased wastage of lithium recoils. The two factors operating together permit a wide tolerance on t over the full range of $\mu(R_L R_\alpha)^{\frac{1}{2}}x_0$.

Furthermore, some of the generous tolerance on t may be taken up as a tolerance on the assumed values of R_L and R_α. Consider curve 1. When a value of x_0 is chosen, it leads to an abscissa x, say, dependent upon the value R_α used. The graph then reads t as a certain fraction θ of R_α. Suppose the true value of the alpha-range were actually $R_\alpha + \delta R_\alpha$; then the correct thickness is given by the abscissa $x(1 + \delta R_\alpha/R_\alpha)$, for which the corresponding t is $(\theta - d\theta)(R_\alpha + \delta R_\alpha)$. Owing to the difference of sign in the two brackets, and since $t \sim \text{constant}/x_0$, this magnitude differs from the original figure θR_α by second-order quantities only. It therefore follows that the figure used for R_α may be considerably in error before it has a serious effect on the design constants; and in view of the large tolerance on t, an accuracy of 10 percent or so is quite sufficient for R_α. The chief inaccuracy introduced by an error in R_α is in the calibration of the axis of abscissae for the efficiency curves.

3. ARRANGEMENT OF THE ION CHAMBERS

When counting efficiency is important, the thicknesses of detecting material demanded by the theory introduce difficulties in detection. The particles emerging from the layers have all residual energies from the maximum down to zero, and some of the smaller pulses are consequently missed by the detecting equipment, which is set at a finite bias voltage. The need for compactness may also impose restrictions on the design. To find the best possible system taking these considerations into account, it will be necessary to devote the next paragraph to the elements of ion chamber theory.[2,3]

In a non-gridded ion chamber employing electron collection, the height of the pulse received at the amplifier depends not only upon the total amount of ionization produced by the high speed particle, but also upon the position of the original ion track inside the chamber. The peak signal voltage induced across a plane parallel plate chamber is very approximately $(Q/C)f$, where Q is the total charge carried by the electrons, C the capacity of the chamber, and f is the fraction of the interelectrode spacing travelled by the electrical center of the electrons. This is a simple consequence of integrating over the contributions of the original electrons individually. Consider ionizing particles emerging at a fixed energy from the negative electrode of a parallel plate chamber. If the filling gas pressure is so high that the ion tracks are all crowded right over to one side of the chamber, then the pulses observed will all have nearly maximum height, since the electrical centers of the electron tracks cross the chamber almost entirely. On the other hand, if the polarity were the reverse, only a greatly reduced signal would be received. With correct polarity, the curve of counting rate against bias voltage will have a plateau and the bias voltage may be set for operation at a value above noise where the dependence of counting rate upon bias voltage is very small.



(a) (b)

FIG. 2. Electrode assemblies carrying layers of detecting material.

The ideal design therefore requires the chosen number of coated foils to be connected together and interleaved with a set of blank positive electrodes as in Fig. 2(a). This arrangement is to be contrasted with that of Fig. 2(b), which at first sight may seem superior, because the amount of detecting substance present has been doubled, while the physical size and the interelectrode capacity remain the same. The efficiencies of two boron 10 counters, one of which has twice the linear density of layers of the other, are compared in Fig. 3. Curve 4 is repeated from Fig. 1, where it represents the maximum efficiency of a multiple-layer chamber; curve 7 is identical except that the abscissa is $2\mu(R_L R_\alpha)^{\frac{1}{2}}x_0$ instead of the $\mu(R_L R_\alpha)^{\frac{1}{2}}x_0$ shown.

The counting rate with Fig. 2(b) is not simply that of Fig. 2(a) plus the contribution of the extra layers working with reversed polarity; for most of the counting rate and of the waste of neutrons, arises from the first few layers, of which the additional ones in Fig. 2(b) are working inefficiently. With an infinitely high gas pressure in arrangement (b), only those foils on the negative electrode give any count, so that the efficiency is given by curve 7 scaled down by approximately one-half. As Fig. 3 shows, this is always *less* than the efficiency of arrangement (a).

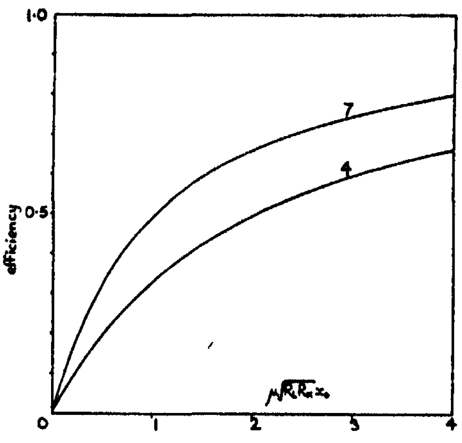


FIG. 3. Curves relating to the efficiency of multiple-layer chambers.

However, with finite gas pressures, the ion tracks extend across the chambers. With reduction of pressure, the count from the negative layers decreases, while that from the positive layers increases to a maximum; the net result is a higher counting rate than that at infinite gas pressure. The question whether a pressure can be found at which arrangement 2(b) is more efficient than arrangement 2(a) is a practical one, since the operating bias voltage is determined by valve capacity and noise. Investigation of the boron counter shows that the maximum efficiency of a counter similar to that of Section 5 below with arrangement 2(b), is only approximately equal to that with 2(a).

The disadvantages of arrangement 2(b) are, on the other hand, that it has twice the amount of boron, three times the bias curve slope, and a greater background count than 2(a).

4. THE DETECTING MATERIAL

The separated isotope B^{10} was chosen as the detecting substance for a slow neutron counter. Being of small atomic weight, this isotope is more easily isolated in a magnetic separator than a heavy substance such as uranium. The constants[4] of the disintegration $B^{10}(n, \alpha)Li^7$ are found in Table I, the reaction being spherically symmetrical. Using the interpolated stopping power 0.80 for boron, the range of the main group α-particle in B^{10} comes to 0.81 mg $cm^{-2} \equiv 3.5$ microns. (Walker[5] has used without reference a stopping power of 0.94, which leads to 0.69 mg $cm^{-2} \equiv 3.0$ microns.) The number

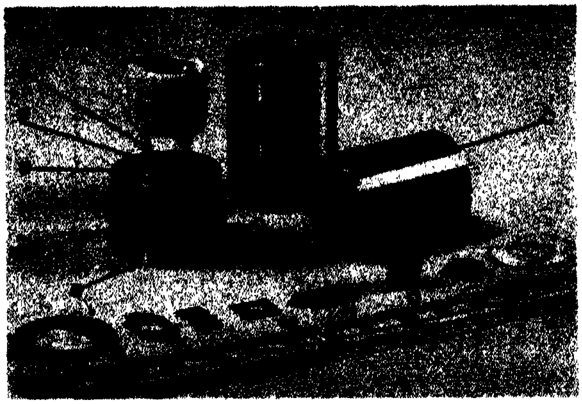

FIG. 4. A miniature neutron counter.

of B^{10} layers of thickness, say, 3 microns needed to capture 95 percent of an incident neutron beam is 19.

A further constant required by the theory of Section 2 is the ratio of the ranges in B^{10} of the recoil nucleus and the α-particle. For practical purposes, the long-range group may be considered weak enough to be ignored. For the main group, the ratio of these ranges in air is, from Table I, 0.62±0.03, and in argon, from measurements on Fig. 8 and similar curves, 0.63±0.03. The value 0.625 has been assumed for the ratio in B^{10}.

5. A MINIATURE NEUTRON COUNTER

Figure 4 shows a fully demountable neutron counter with a sensitive volume of 0.4 cm^3. It operates at a thermal neutron efficiency of 24 percent with a collecting voltage of 70 volts. The whole instrument is contained within a cylinder of length $2\frac{5}{16}$ in. and diameter $1\frac{3}{16}$ in., which is larger than a sealed-off version would need to be.

The outer case *A* screws onto the base *B*, compressing the container *C* into the groove *D* containing a Neoprene gasket *E*. The filling tube *F* passes through a cock *G*, turned by a screwdriver, which is tightened after filling the counter by the threaded ring *H* being upon a Neoprene ring *I*. The electrode assembly *J* comprises twelve ionization chambers of 1-mm spacing. Six negative electrodes *K*, stamped from 0.005-in. nickel foil, each carry two 0.005-in. aluminum squares *L* which fit into a recessed nickel foil *M* spot welded to the electrode. The aluminum squares are coated on one side in an electromagnetic separator with nominally $\frac{1}{2}$ mg cm^{-2} of boron 10, and the boron surfaces face outward through circular windows of diameter 6 mm. The seven alternate positive electrodes *N* are cut from 0.002-in. copper foil. The interelectrode distance is determined by the use of polytetrafluorethylene spacers *O*. All electrodes of the same sign are connected together, the negative ones being connected to the base *B* and the positive ones via the Kovar seal *P* to the signal cable, which enters through the hole *Q*.

The counter is filled with a pressure of 5 atmos. of argon, the counting rate not being improved by any further increase in pressure. (After testing and insertion in the shielding, the actual model of Fig. 4 is operated in a pressurized chamber to prevent eventual leaks through the miniature cock.)

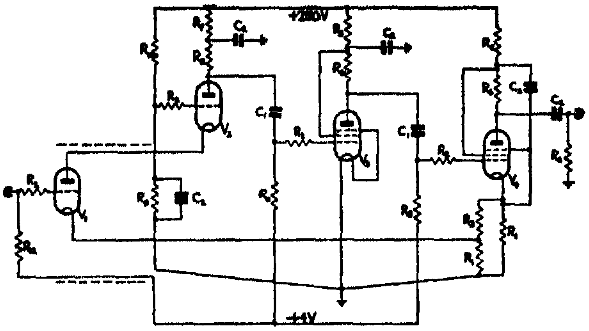

FIG. 5. Head-amplifier suitable for the counter of Fig. 4. R_1, 10Ω; R_2, 47Ω (not high stability); R_3, 100Ω; R_4, 2.7*k*Ω, $\frac{1}{2}W$; R_5, 3.9*k*Ω, 1*W*; R_6, 10*k*Ω, 1*W*; R_7, 22*k*Ω; R_8, 27*k*Ω; R_9, 100*k*Ω; R_{10}, 150*k*Ω; R_{11}, 560*k*Ω (not high stability); R_{12}, 10*M*Ω (not high stability). All resistors $\frac{1}{4}W$, five percent, high stability, except where otherwise stated. C_1, 470*pf*; C_2, 0.5*μf*; both condensers 250 v working. V_1 and V_2, *CV* 139; V_3 and V_4, *CV* 138.

A head amplifier designed by A. B. Gillespie at the Atomic Energy Research Establishment is shown in Fig. 5. It is intended to feed into an impedance of 100 ohms followed by rise and clipping time constants of 3 μsec. Two identical miniature valves in series replace the first valve of a conventional ring of three circuit, giving a stage gain comparable with that of a single pentode while the signal-to-noise ratio remains close to that of a single triode.[6] The first valve V_1, together with only two resistors, may be attached to the counter at the far end of several feet of cabling. The total input capacity of the grid of V_1, adding the capacities of the valve and the counter, is about 25 μμf. The noise voltage adds a half-width equivalent to 29 kv to the α-particle spectrum.

The bias curve obtained with an *HT* of 120 volts is shown in Fig. 6. Since for the sake of efficiency, the thickness of the boron layers has been made comparable with the range of the α-particle, there is no plateau. The counter is operated with twice the amplification of Fig. 6 at a bias voltage of 16, when the slope is 1.4 percent per volt. At this bias voltage, the dependence of counting rate on *HT* is as shown in Fig. 7.

According to Fig. 1, the efficiency of the electrode assembly should ideally be about 46 percent. The

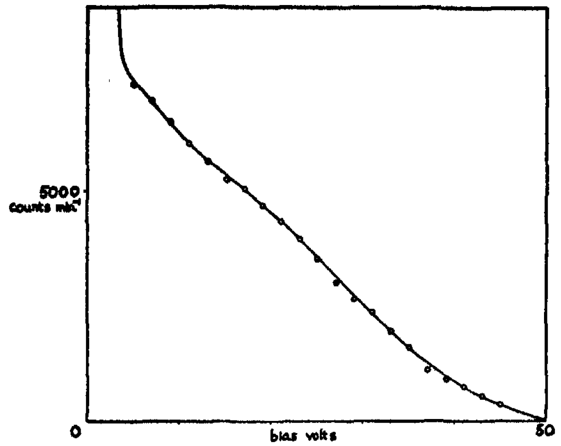

FIG. 6. Bias curve of the miniature neutron counter.

measured efficiency of the counter is reduced below that amount by a factor 0.80 due to the finite bias curve slope, and by a further 0.89 due to the neutron absorption of the counter end wall. There remains a loss of a factor of 0.73. As shown in the next section, this is caused by imperfections in the boron layers, so that an improvement in these should be capable of restoring the over-all efficiency to about 33 percent.

6. QUALITY OF THE BORON LAYERS

In practice, thin boron coatings on foils only roughly approximate to the perfect planes assumed in the theory of the preceding sections. The result of this is a reduced efficiency; for with an uneven boron layer the waste of neutrons is excessive in regions where the deposit is too thick. Indeed, it was found that layers with a visibly rippled surface gave only two-thirds the count of smooth layers of the same nominal thickness of ½ mg cm^{-2}.

A convenient way of checking the adequacy of a given boron layer is by observing the pulse amplitude distribution obtained when the layer is the negative electrode of a parallel plate ion chamber. If the layer were perfectly formed, the function obtained would agree with the theoretical one derived from the range-energy relation of the particles and the constants of the materials. The effect on counter efficiency of deviations from the calculated function is illustrated by the results below.

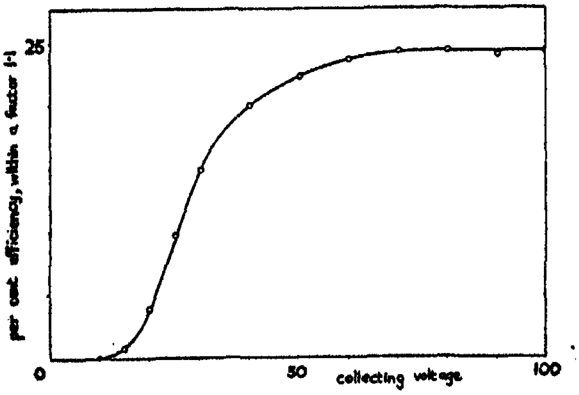

FIG. 7. Dependence of the efficiency of the miniature neutron counter on collecting voltage.

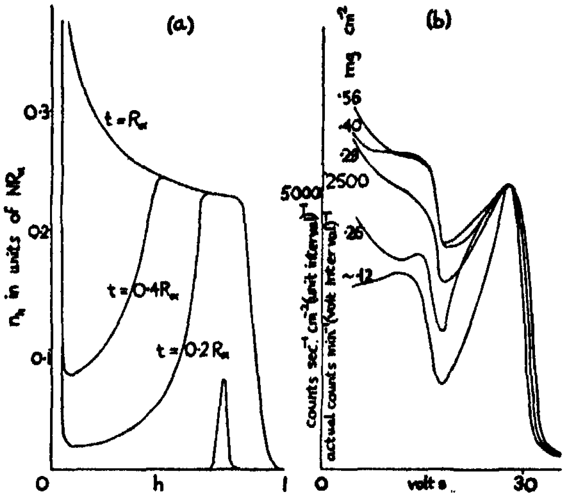

FIG. 8. (a). Theoretical pulse amplitude distribution curves for the main group α-particle component from B^{10} layers of various thicknesses in a given experimental chamber. (b). Observed distribution curves.

A theoretical pulse amplitude distribution curve for the main group α-particle component is shown in Fig. 8(a) for plane boron deposits of different thicknesses. It has been computed for an interelectrode spacing of 5 mm and a filling of 5 atmos. of argon, which were the figures for the experimental chamber, and is accurate to about four percent. Account is taken of the noise level and of the finite resolution of the actual apparatus used in the investigation; the over-all resolution when pulses were sorted into one-volt channels is indicated by the viewing function also shown in the figure.

The ordinate of Fig. 8(a) is the number of pulses having heights between h and $h+dh$; it is given in units of NR_α, where N is the number of disintegrations cm^{-2} sec.^{-1} in the boron. It will be noticed that for deposits thinner than about $\frac{1}{2}R_\alpha$, the pulses are mostly gathered into a sharp peak at the upper end of the scale; under these circumstances the bias curve, which of course is the integral of the distribution curve, has a very good plateau so far as the alpha-component is concerned. Thicker boron layers do not show a higher peak, because this peak is contributed only by the alpha-particles of nearly maximum energy which come from the shallower regions of the metal. Thickening the boron layer may be considered as a process of putting more boron behind it, which can only contribute lower energy particles. The thicker deposits therefore show a progressive filling in of the hollow between the peaks at $h=1$ and $h=0$, until at $t=R_\alpha$ the limiting shape is reached.

A real boron layer having an undulating surface may be considered as thin over some parts of its area and thick over others; the pulse histogram for the alpha-component will therefore be recognizable as a kind of average over all the possibilities shown in Fig. 8(a). Starting from the right-hand end of the diagram, the curve will rise to its peak, which should give the correct amplitude of approximately $0.23NR_\alpha$; but towards the left of this peak it will immediately curve down in a rounded manner which will not lead to any meaningful indication of t/R_α.

Typical distribution curves taken with five apparently smooth boron layers of different thicknesses prepared similarly to those used in the counter of Section 3 are shown in Fig. 8(b). For clarity, the scales of some of the curves have been adjusted by a few percent to bring all five peaks into coincidence. The lithium recoil particle spectrum appears clearly superposed on the α-particle component in each curve.

The agreement of the α-particle spectrum with Fig. 8(a) is, as expected, only qualitative. The factor by which this kind of discrepancy reduces the efficiency, may be estimated from the area underneath the curves, which is always less than the theoretical value. An approximate reading for the twelve-chamber counter of Section 5 is given by the average area under the curves for 0.40 and 0.56 mg cm^{-2}. When this is divided by the theoretical amount, taking account of the operating bias voltage, the ratio comes to about 0.6. This is more than enough to explain the observed loss factor, which from the results of Section 5 is 0.73.

(Received May 20, 1950)

A plant for the collection and purification of radon has been constructed. In order to reduce the gamma-radiation level, the plant was designed to be operated entirely by remote control except for the final sealing of the radon capsule. This plant compares favorably with other collection systems both with regard to the time required for a collection and to the yield of radon obtained.

When investigations in the field of alpha-radiation chemistry were begun at the K-25 Laboratories, it became necessary to design a system for the collection and purification of radon. Due to recent radiation hazard studies, it was decided to incorporate considerable lead shielding and remote control operation in the plant in order to reduce beta- and gamma-ray exposure to the operator. This plant houses 230 milligrams of radium on loan from the Bureau of Mines.

DESIGN AND OPERATION OF PLANT

The collection system, as shown in Figs. 1 and 2, is similar to the one described by Livingston,[1] the essential difference being that all stopcocks are replaced by mercury cut-offs, which are regulated by compressed air and vacuum lines. The latter are valved at a main control panel, Figs. 3 and 4. This panel, located about 12 feet in front of the hood housing the plant, is also equipped with controls to raise and lower two Dewar flasks mounted on sylphon bellows, and to fill the traps with liquid nitrogen.

The radium chloride, in 100 cc of 0.1 N hydrochloric acid, (a), in Fig. 1, is contained in a 200 cc soft glass flask surrounded by six inches of lead shielding. As a precaution against breakage, the flask is contained in a Fluorothene beaker which in turn is placed in a Pyrex beaker. The line from the flask to the Toepler pump, (b), is shielded by one inch of lead to a point well below the mercury level at its lowest position between collections. The free volume above the radium solution is 100 cc and that of the Toepler pump is one liter.

After each collection, the plant is left as shown in Fig. 2, with cut-offs *A* and *C* closed and *B* open. Before starting a collection, a new collection tube is sealed in place at (*d*). The system is then pumped to a pressure of less than 10^{-4} mm of mercury. On obtaining this vacuum, cut-offs *A* and *C* are opened and the entire system up to the mercury in the Toepler is pumped to

remove any water vapor and absorbed gases from the previous collection. Cut-off *B*, to the high vacuum system, is then closed, the mercury being raised to a point just below the junction of *A* and *B*.

Cut-off *A* is closed and the mercury in the Toepler pump is lowered to allow a portion of the accumulated gases to be drawn in. The mercury is then raised in the Toepler pump until the pressure is about 15 cm, as determined by the difference of mercury levels in cut-off *A*, following which the mixture is ignited at (*h*). These operations are repeated until the mercury level can be lowered below the junction of the radon line and the Toepler pump, allowing the gases to distribute themselves freely between the radium flask and the pump.

Before transferring the radon to the purification system, (*c*), which consists of a tube of potassium hydroxide, a tube of phosphorus pentoxide, a side-arm containing copper and copper oxide enclosed in a furnace, and a cold finger, the mercury level in the Toepler pump is lowered to reduce the pressure differential across cut-off *A*. This cut-off is then opened, and the pump and spark gap are filled with mercury, pushing all of the gas toward the clean-up system. When the purification has proceeded sufficiently, as indicated by equality of levels in cut-off *B*, cut-off *A* is closed. The Toepler pump is again used to collect radon from the flask and the whole series of operations is repeated as often as desired.

After the last portion of radon has been transferred to the purification train, the gas is condensed with liquid nitrogen into the built-in Dewar, (*d*), at the final collection point. This procedure facilitates removal of all radon from the section of tubing between the Toepler pump and cut-off *A*. The latter is then closed. The radon is warmed and transferred by condensation with liquid nitrogen into the cold finger on the purification system. After sufficient time for diffusion has elapsed, cut-off *C* is closed, the Dewar around the cold finger is lowered, and a stream of air turned on to warm

the radon and allow it to circulate through the clean-up system. Again it is condensed in the cold finger and with cut-offs *B* and *C* opened, the system is pumped for about 30 seconds to remove nitrogen or other permanent gases. Cut-off *B* is then closed and the radon allowed to warm. It is next condensed at the built-in Dewar and cut-off *C* is closed. The mercury level is then raised to any desired position in the final collection section, depending on the type of collection. The liquid nitrogen is removed from the Dewar and the radon finally condensed into the collection tube. This is sealed off a short distance above the liquid nitrogen level. If traces of mercury or water vapor are undesirable in the reaction system, the built-in Dewar may be filled with a dry ice-acetone slush before the radon is condensed into the collection tube. In this case the mercury must be kept below the Dewar to prevent its freezing.

After the radon has been removed, cut-offs *A* and *B* are opened and the mercury level in the Toepler pump lowered to pump off the residual water, following which the mercury is raised through the spark gap, and up into the capillary tubing. Cut-off *A* is closed and cut-off *C* is opened to pump the clean-up system. The plant is shut down with cut-offs *A* and *C* closed and *B* open by stopping the pumps and admitting atmospheric pressure to the high vacuum system.

RESULTS

This radon plant has been in operation for more than eight months. Measurements of the radon collected indicate an efficiency of 85 to 90 percent. The time required for a collection is 30 minutes, not including either the initial or final pumping operations. This is considerably less time than is required with a comparable system using stopcocks.

SUGGESTED MODIFICATIONS

A number of improvements have suggested themselves during the operation of the plant. The entire line from cut-off *A* over to cut-off *C* should be raised to at least 85 cm, instead of the present 73 to 77 cm, above the mercury. This would allow an atmosphere of mercury on both sides of each of the cut-offs, so that the initial pumping could be started without having to exercise the caution now necessary to keep the mercury above cut-offs *A* and *C*.

FIG. 4. Main control panel. Photograph.

Another change would involve extending the capillary tubing, which now runs from the spark gap to the point (*g*), to include all but a few centimeters on the Toepler pump side of cut-off *A*. This modification would provide a smaller volume so that a higher pressure could be built up in the sparking chamber. Finally, a small bulb, on the clean-up side of cut-off *A*, would prevent excessive turbulence as the gas bubbles through the mercury.

ACKNOWLEDGMENTS

The authors wish to express their appreciation to Dr. S. C. Lind and Dr. H. A. Bernhardt for timely suggestions and help during the construction of the collection system; to Mr. C. Asmanes of the Works Laboratory Department for construction and assembly of the glassware; to Mr. W. R. Smith and Mr. W. A. Pryor of the Radiation Hazards Department of the Safety and Inspection Division for determining the necessary amount of shielding, both for the radium in the plant and the comparison standards; and to the Bureau of Mines for the loan of the radium in solution and the radium standards.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 10 OCTOBER, 1950

Precision Thermostat for High Temperatures

WILLIAM R. EUBANK*
Portland Cement Association Fellowship at National Bureau of Standards, Washington, D. C.

(Received June 5, 1950)

A precision thermostat has been developed, based upon that of Roberts, for the control of high temperatures (1000°–1550°C). With the instrument described, temperatures are readily maintained constant within ±0.1°C for several hours, and within ±1.0°C for several days.

In this method of control a thyratron is used in conjunction with an a.c. bridge and high gain amplifier. The phase angle of the unbalanced bridge regulates the firing of the thyratron. The control is highly sensitive and independent of normal fluctuations in line voltage. The thermostat is convenient to operate, easy to adjust for any temperature, and reliable for periods of continuous operation from a few minutes to several days.

INTRODUCTION

SYSTEMATIC phase-equilibrium studies have been of great value in exploring new systems involving the components of glass, refractories, Portland cement, and other industrial products. In order properly to employ this method of investigation, it is necessary that the specimen under study reach a state of equilibrium at any given temperature. To accomplish this, constant temperature must be maintained until no further change takes place in the sample under study. Even small fluctuations in temperature may be responsible for erroneous data, especially in multi-component systems.

In an attempt to obtain better temperature regulation than had been reached with regulators currently in use, the possibility of employing a thyratron regulator, based on that designed by Roberts[1] was explored.

Many temperature regulators employing thyratrons have been reported. Some of these were designed for use with oil or water baths and others for low temperature furnaces, 1000° maximum.[2] In this form of regulation a transformer is employed partly as a saturable reactor as reported also by others[3, 4] to control load currents of several amp. The output of an a.c. bridge, one arm of which serves both as a resistance thermometer and as a heater element, is amplified and applied to the control grid of a thyratron. Unbalance of the bridge results in a difference in phase between this control voltage and the applied voltage, and determines the firing period of the thyratron. The thyratron action is reflected to the primary circuit through the transformer, thus controlling the amount of energy supplied to the furnace.

Some investigators[5, 6] have employed thyratron-controlled regulators to operate in connection with conventional mercury regulators. Another[7] has employed an optical lever with a photo-tube and galvanometer. In 1938 Sturtevant[8] reported a thyratron regulator adapted from a circuit described by Henney.[3] Modifications on this regulator were later reported.[9, 10] These circuits have the heater load directly in the thyratron anode circuit and are generally designed for low power applications. In describing the performance of the above regulators, Bancroft[11] states, "Circuits in common use are apt to be somewhat erratic and to require rather critical adjustment if uniformly stable operation is to be achieved. In particular, most such devices do not behave properly when the control voltage amplifier is overloaded, as when the resistance bridge is preset for a new temperature." By elaborate tuning and filtering, Bancroft developed a more stable regulator for low temperature operation.

Penther and Pompeo[12] attribute the erratic performance of these earlier circuits to a secondary phase shift. They state, "It was found that this secondary phase shift was caused by the large current amplitudes in the off-balance conditions, overloading the tubes and transformers. . . . The limit of control is a maximum of 1 degree F." These investigators obtained improved operation for bath thermostats by using an amplifier with automatic gain control.

After consultation with Roberts, a controller based upon his original circuit, but with important modifications, was constructed and tested. The wiring diagram is shown in Fig. 1 and a photograph of the assembly in Fig. 2. Several hundred quenching experiments in the temperature range 1000° to 1550° have been successfully performed with this thermostat.

DESCRIPTION

The furnace winding is the temperature-sensitive element of the thermostat. The resistance of this winding, which consists of about 100 g of 0.8-mm platinum-20 percent rhodium wire, changes rapidly with tem-

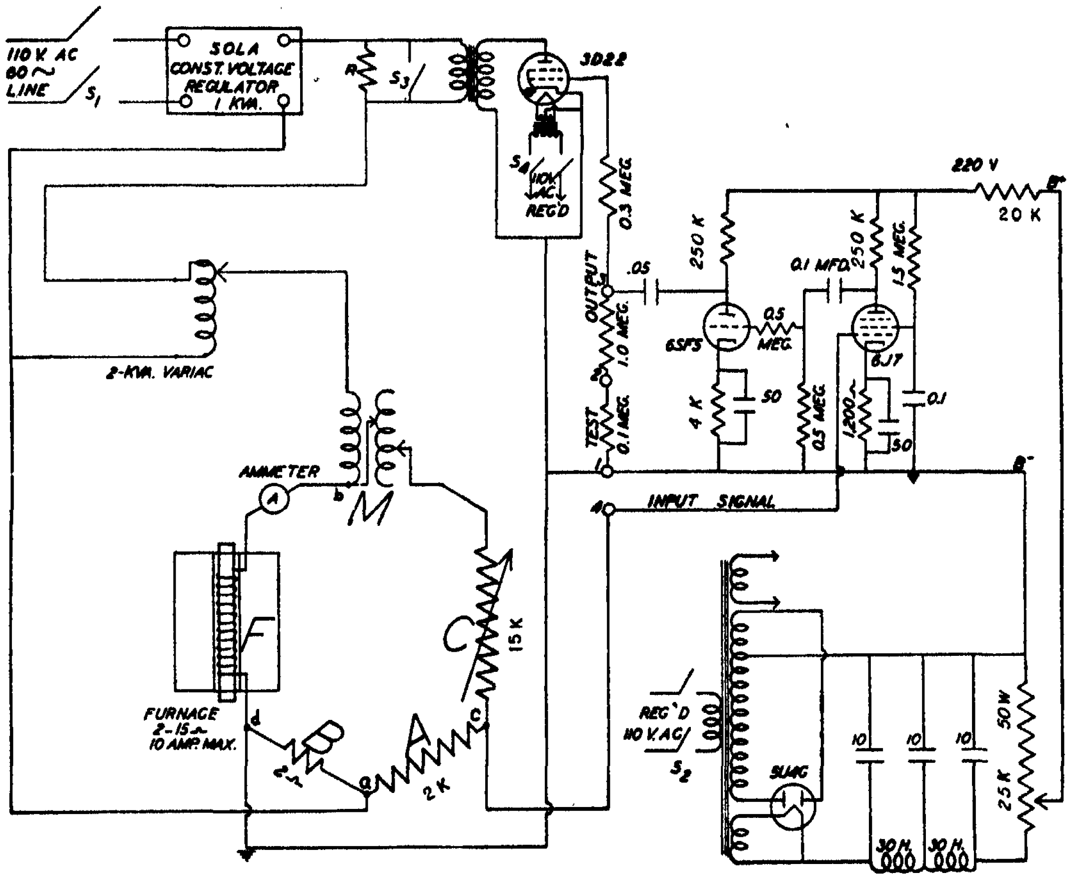

Fig. 1. Thyratron quenching furnace thermostat.

perature (above 1000°) and, except for aging effects, maintains a definite relation to the temperature.

The relation of the furnace winding to the other resistances in the bridge is shown in Fig. 1. The two sides of the bridge have a ratio of about 1000 to 1. This high ratio is possible because the amplifier is voltage-operated. The high resistance arm *C* consists of a 5000-ohm coil and a 10,000-ohm decade box in series. The resistance of the furnace varies from about 2 to 15 ohms. The remaining two arms of the bridge, *A* and *B*, are 2000 and 2 ohms, respectively. Arm *A* is a standard coil used in decade boxes while arm *B* was constructed in the laboratory. The latter carries the entire furnace current and is made of two 1-ohm sections of heavy advance ribbon wound on a core of alundum. Each section is insulated from the other by a thin layer of mica. The second winding is doubled back over the first in order that the inductances will cancel.

The response of the thyratron is determined primarily by the phase angle of the control voltage relative to the anode voltage of the thyratron. The thyratron circuit acts then as a continuously variable rheostat whose setting depends on the phase angle and amplitude of the unbalance voltage across the bridge.

With alternating current it is necessary to balance both the reactive and resistive components of the bridge. For this reason the bridge coils, except that of the furnace, are non-inductively wound. The reactance balance of the bridge is then adjusted by means of the variable secondary of the mutual inductance (*M*, Fig. 1) in arm *C*.

The primary winding of the mutual inductance is a single layer of copper wire (No. 12 *DCC*) having an inductance slightly greater than that calculated from the dimensions of the furnace winding. The primary has 43 turns and occupies 5 inches on a bakelite tube 2.5 inches in outside diameter. In order to use this controller with furnaces of various inductances, the primary winding was tapped at three points. The secondary winding, which is of fine wire (No. 24 *DCC*), occupies the *V*-shaped helical groove between the primary turns. Each of the first 11 turns of the secondary winding is tapped and connected to a point on a rotary selector switch. Turns 12 to 42 are tapped at every fifth turn and connected to a second rotary selector switch. Fine adjustment of the mutual inductance is made by means of one-half turn of $\frac{1}{16}$ inch iron strip cut from a transformer lamination rotated about an axis perpendicular to that of the bakelite tube.

The power to operate the thyratron controller is supplied by a constant-voltage transformer.[13] A variable auto-transformer is utilized to reduce the voltage output of the controller to the value needed for a particular operating range. It should be adjusted with S_3 closed so that, at the control temperature, an appropriate rate of heating results.

The resistance panel *R* consists of five coils of 5, 7.5, 15, 30 and 60-ohms resistance and a 30-volt lamp all connected in parallel. Except for the 5-ohm coil, each unit can be disconnected from the circuit by a switch. These parallel resistances should be adjusted with S_3 open and the thyratron either not firing or removed from its socket so that, at the control temperature, an appropriate rate of cooling results. The maximum drop across *R* should be limited to 25 volts for protection of the thyratron.

The action of the thyratron controls the furnace current by changing the impedance of the primary winding of a transformer connected in parallel with resistance *R*. This transformer is rated at 250 va. and has a 25-volt primary and 1000-volt secondary. If the phase of the control voltage is such that no plate current flows in the thyratron, the transformer is unloaded and the impedance is high. Consequently a negligibly small magnetizing current flows in the primary. When the thyratron fires, however, the impedance of the primary becomes low relative to *R*. The bridge current is thereby increased, nearly the whole of it passing through the primary of the transformer. Thus, this transformer reflects the high-voltage low-current characteristics of the thyratron switch into the power circuit as a low-voltage, heavy-current control. The primary voltage averages about 12.5 volts and the transformer steps up the plate voltage to about 500 volts.

The amplifier has a gain of about 6000 and is of the conventional resistance-capacity coupled type. It is desirable for protection of both thyratron and furnace that a suitable magnetic switch, not shown on Fig. 1, be added to shut down the apparatus in case the a.c. supply is interrupted, and to indicate such interruption to the operator.

The first unit of the thyratron controller was supported together with the furnace in an angle-iron framework, Fig. 2. A second unit was designed to be more compact. It fits into a 12×12×20-inch radio cabinet and is portable. The thyratron tube employed is the sensitive, four-electrode *3D22*. This tube by virtue of its inert gas content has a control characteristic which is essentially independent of ambient temperature variations over a wide range. It also has small preconduction or gas-leakage currents, low control-grid-to-anode capacitance, and low control-grid current. The *3D22* has about 50 percent more current capacity than the *FG*-17 tube used by Roberts, and is more compact and entirely base-connected.

Before the regulator is turned on, switch S_3 must be closed to protect the thyratron unless a time delay relay is placed in the anode circuit. After S_4 has been closed for at least 30 seconds and the cathode has come to operating temperature, S_3 can be opened.

The furnace is brought to approximately the desired temperature by manipulation of the variac. The variable bridge arm *C* is then set at the value found by experiment to correspond with the temperature desired. Adjustment of the control is conveniently checked by means of a 30 v 15 w lamp. The variac is adjusted so that the lamp is neither out nor fully lit, but intermediate between the two.

If an oscilloscope is available it can be connected across S_3 and the inductance *M* adjusted to give patterns like those shown in row *D* of Fig. 4. The adjustment is not critical, however. When the bridge approaches the balanced condition, the glowing lamp, *L*, usually begins to flicker at a low frequency which increases to a maximum rate of 30 per second at balance. This is a useful indication that the regulator is in satisfactory operation.

If the bridge is unbalanced greatly (e.g., in resetting to a new temperature several hundred degrees away) the regulator will lose control until balance is approached. Several manual adjustments of the furnace temperature may therefore be necessary the first time a particular setting is made.

Application of this thyratron control may be made to other furnaces and to baths and heaters operating at other temperatures. At lower temperatures, heater elements of sufficient change in resistance with temperature, such as pure nickel or certain nickel-chromium alloys, will be required.

A certain amount of distortion and constant phase shift is developed in the amplifier. However, this does

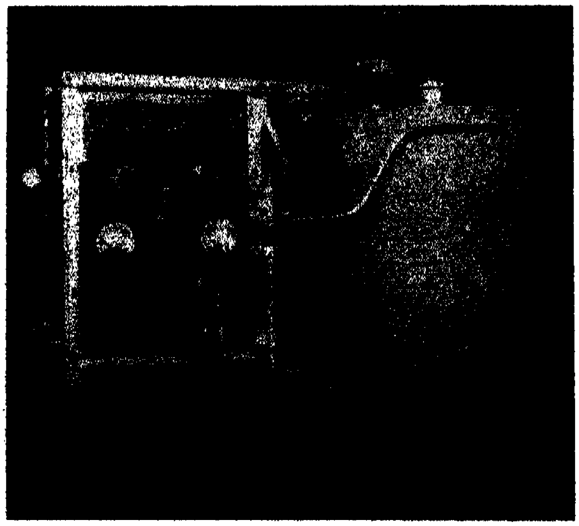

Fig. 2. Thyratron-controlled thermostat and quenching furnace. First model.

---

[13] For this purpose a 1-KVA voltage regulator manufactured by the Sola Electric Company, Chicago, Illinois, was found to be satisfactory.

not appear to interfere with the operation of the regulator. Elaborate tuning and filtering of the control voltage, as advocated by certain investigators,[11] do not appear necessary. No special shielding of the amplifier is required; however, it should be located outside any large external fields such as are produced by the voltage regulator. Proper grounding of both the amplifier and bridge as shown in Fig. 1 is essential, but this local ground is insulated from physical ground because the output winding of the constant-voltage transformer is not isolated from the input.

An advantage derived from the use of the phase-controlled thyratron regulator is gradual or proportional control as contrasted to on-off control. The thyratron circuit acts as a continuously variable valve allowing just enough current to reach the furnace to compensate for a given temperature fluctuation. Thus overshooting, which appears with on-off control, is greatly reduced.

The control characteristics of the thyratron quenching-furnace thermostat will depend on the furnace with which it is used. In the present study, the thermal sensitive element, which is also the heater element, was wound on the outside of a one-eighth-inch-wall alundum tube and the temperature read by means of a Pt-PtRh thermocouple placed inside the tube. Similar windings and tubes are generally used for quenching furnaces.

Thermocouple potentials were read to within 0.5 μv by means of a type *K*-2 potentiometer and a suspension galvanometer.

Several hundred short quenching experiments (one-half to one hour) have been made with the thermostat with average temperature variations corresponding to 1 or 2 μv (1 μv = 0.084° at 1300°). Dependability for long experiments was demonstrated by maintaining the thermostat in constant operation controlling a quenching furnace at 1300° for more than a month. The temperature of this furnace was later maintained at 1350° for three weeks. The average of 20 consecutive fluctuations occurring overnight and weekends was 5.65 μv, or less than 0.5°. These variations were about equally positive and negative. Values of 1 to 20 μv (less than 0.1° to 1.7°) were obtained, although fluctuations of as much as 12 μv (1.0°) were rare. Typical control obtained with the thyratron quenching-furnace thermostat is illustrated by the curves in Fig. 3; *A*, for a period of 60 minutes; *B*, 8 hours: *C*, 7 days at an operating temperature of 1300°. No adjustment was made to compensate for change in resistance of the winding with age.

During long periods of continuous operation the balancing resistance, *C*, in the bridge is usually adjusted at about three-day intervals to compensate for the drift in the resistance of the winding. It is well known that, at high temperature, slight deterioration and accompanying increase in resistance of all wire-wound furnaces occurs, and that this is a function of time and temperature. With no adjustment, after about three days the temperature of the furnace was found to drift downward (see curve *C*, Fig. 3).

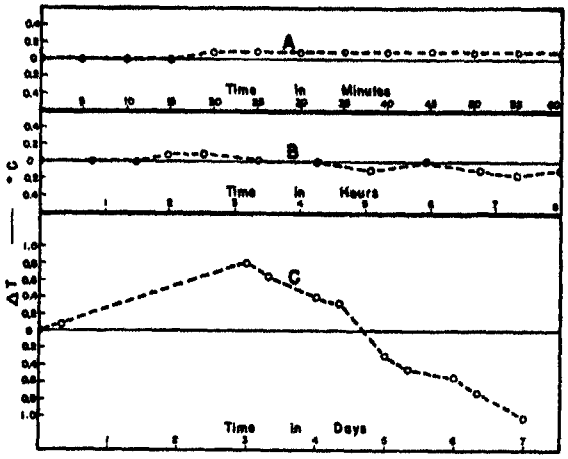

FIG. 3. Typical control obtained with thyratron quenching-furnace thermostat, *A*, for a period of 60 min.; *B*, 8 hr.; *C*, 7 days. Operating temperature was 1300°C.

OPERATION

The operation of thermo-regulators, using phase-shifting a.c. bridges in the temperature-measuring circuit and phase-controlled thyratrons as the power-regulating elements, has been discussed in some detail by Roberts and others as above indicated. The unit described here follows generally the circuit design of Roberts, and the operation is similar for conditions of decided unbalance in the temperature-sensitive bridge (such as immediately follows resetting the control). However, for normal operation in the zone near balance, this system is characterized by stable hunting at 30 c.p.s., one-half the power line frequency. This operation provides the high sensitivity and the flicker indication already mentioned.

The practical advantage of these features has been attested by the performance of the unit. No quantitative analysis of the operation has been made, but the oscillographic records of wave forms at various points in the circuit, under several balance conditions, give a reasonably clear picture of the operating principles. The oscillographs are shown in Figs. 4 through 11.

These may be interpreted in terms of the vector diagrams of Fig. 12, showing the voltage relations in the bridge. The subscripts correspond to those used in designating the circuit components in Fig. 1. The bridge includes two reactances, *F*(*L*) which is due to the self-inductance of the furnace coil, and *M* which is due to the mutual inductance coupling the high resistance bridge arms to the bridge supply current. The reactive components $E_{F(L)}$ and E_M have been purposely magnified in order to provide open diagrams. As the bridge is actually used, the reactive component voltages are on the order of one-thousandth the resistive voltages E_B and $E_{F(R)}$. The lower vectors which are in phase with bridge currents are actually almost in phase with bridge voltage, *E*. Therefore, E_{cd}, the output voltage from the

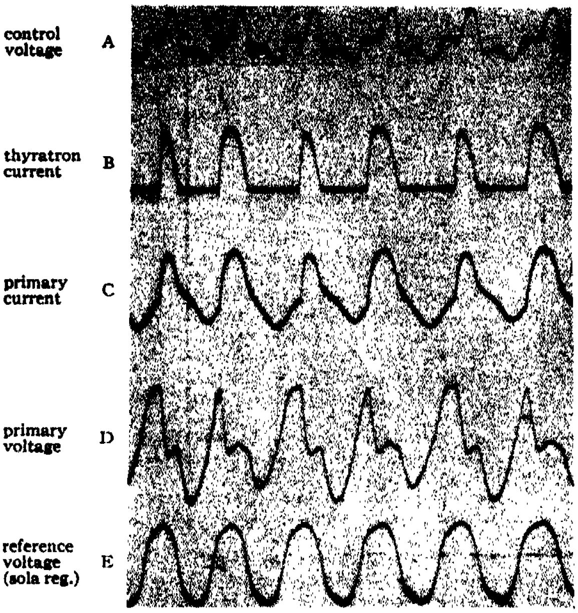

FIG. 4. Flicker indication, bridge in balance.

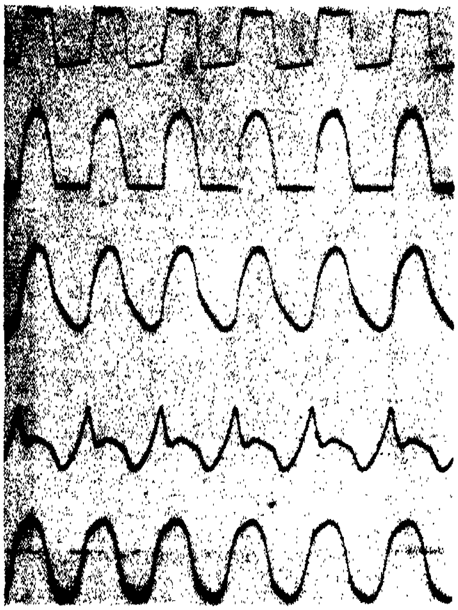

FIG. 5. Thyratron firing for most of positive cycle, bridge unbalanced by +10 ohms.

bridge, has nearly the same phase relative to both bridge voltage and furnace currents, I_F.

With variation of $E_{F(R)}$, it is seen that E_{od} varies monotonically in phase but its amplitude passes through a minimum at the resistive balance of the bridge. At minimum, $E_{cd} = -(B/B+F)\omega(L-M)I_F$. This amplitude is directly proportional to frequency, and to the reactance unbalance, $\omega(L-M)$. Unbalance voltage, E_{cd}, after amplification, and as applied to the thyratron grid, is shown in row *A* of the oscillographic records. For conditions of appreciable bridge unbalance (record *A* of Figs. 5 and 9), the control voltage is so large that its peaks are clipped by saturation of the amplifier, but conventional phase control of the thyratron obtains. The firing voltage is indicated by the notch in the control voltage record, due to grid current effect. Here the operation of the system follows that described by Roberts.

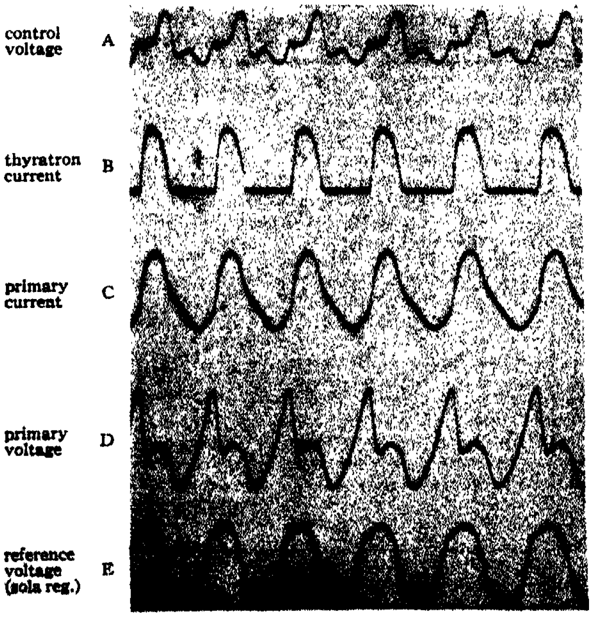

FIG. 6. Thyratron firing for about two-thirds of positive cycle, bridge unbalance less than 10 ohms.

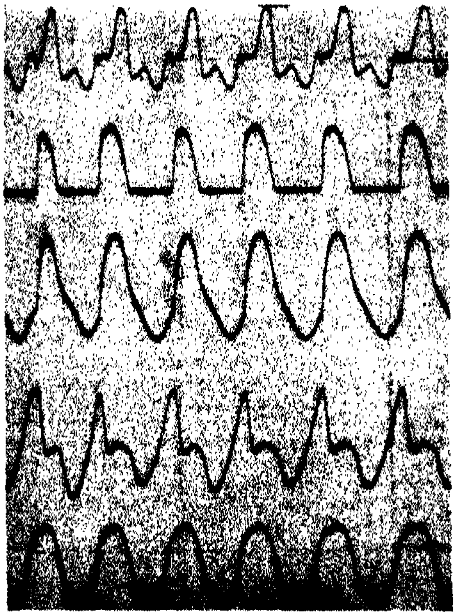

FIG. 7. Beginning of flicker indication, bridge regaining balance.

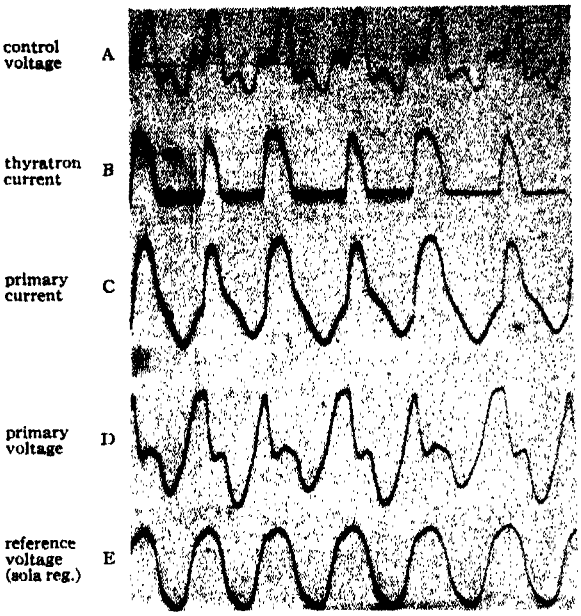

FIG. 8. Flicker indication, bridge in balance.

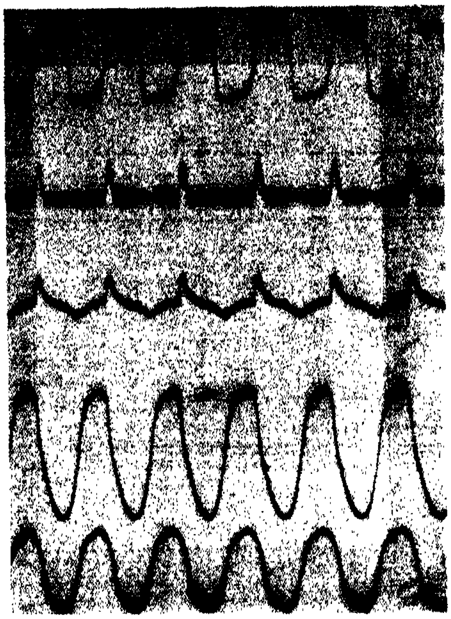

FIG. 9. Thyratron firing for little of positive cycle, bridge unbalanced by −10 ohms.

For conditions very near bridge balance, as shown in record *A* of Figs. 4, 7, 8, and 11, flicker control is obtained. The control voltage is much reduced in amplitude and contains relatively strong harmonics, particularly second and third. Their greater amplitude relative to the 60-cycle fundamental in the bridge output is due to the fact that when resistive balance is approached the output is mainly due to the unbalanced reactive component, which of course is proportional to the frequency of the harmonics.

The effect of harmonics in the bridge is difficult to analyze. The greater dependence of the higher frequencies upon the reactance unbalance of the bridge causes them to show smaller phase variation but greater relative amplitude near resistance balance. Oscillographs *A* of Figs. 4, 7, 8, and 11 indicate that there is some

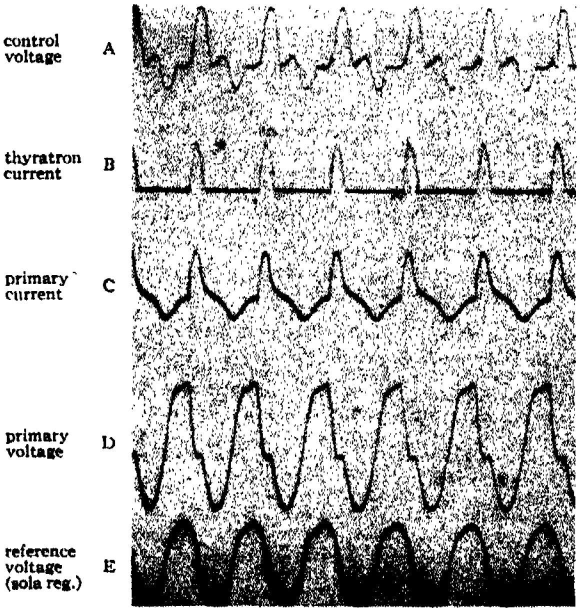

FIG. 10. Thyratron firing for about one-third of positive cycle, bridge unbalance less than 10 ohms.

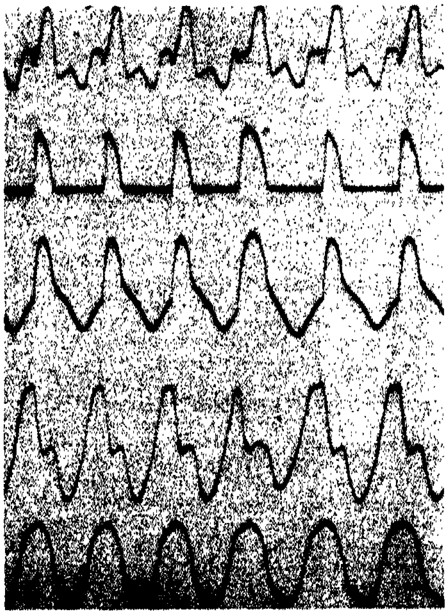

FIG. 11. Beginning of flicker indication bridge regaining balance.

differential phase shift among the harmonic components. Furthermore, the phase variation in this region is extremely sensitive. It is given by the expression

$$\frac{d\phi}{dF}=-\frac{\omega(L-M)}{(\Delta F^2+\omega^2(L-M)^2}.$$

In practice both L and M are small and by adjustment of M their difference is made very small.

In the region of flicker control at balance, as shown in records *B* of Figs. 4 and 8, the thyratron is caused to fire alternately early and late in successive positive half-cycles. This represents a stable operating condition where the average power supplied is that required for maintaining thermal balance in the furnace. In the approach to balance, Figs. 7 and 11, the thyratron fires early or late, but not alternately, in successive positive half-cycles. A flicker appears whenever a change between early and late firing occurs.

The apparent explanation of flicker control hinges upon the extremely high phase-sensitivity of the bridge near resistance balance and the tight thermal coupling between the heater and the temperature-sensitive bridge arm, since they are the same element. The thermal system has sufficiently fast response and the regulation loop has sufficiently high gain to permit an over-all oscillation at 30 c.p.s. This does not require a sharp 30-c.p.s. resonance in the system because the oscillation must be carried around the loop on the 60-c.p.s. carrier frequency.

No simple means of checking this explanation was available because the feed-back loop could not readily be opened for study. However, insertion of a 60-c.p.s. band pass filter into the amplifier circuit eliminated the flicker operation. Removal of the Sola regulator also eliminated the flicker, which suggests that harmonics generated in the regulator are essential to flicker operation.

Inherently the 30-c.p.s. flicker has no merit. It does, however, indicate that the regulation loop is operating with an over-all gain which is the maximum permitted by the phase and attenuation constants of the thermal system. Furthermore, the phase characteristics of the bridge provide a continuous reduction in the loop gain as balance is lost so that the system has excellent transient response with protection against overshoot.

The ultimate perfection of equipment of this character lies of necessity in its use by various investigators. Changes undoubtedly will be introduced involving improvements of one kind or another. Since the apparatus was completed, several minor changes have been proposed and used. They are set forth below for the benefit of those who may wish to build a thermostat.

1. Because the reactances are relatively small, M is not a necessary feature of the circuit. 2. The inability to make a physical ground connection somewhere on the amplifier and power-supply circuit is a disadvantage from a safety standpoint. If the input signal leads from points d and c on the bridge (Fig. 1) were opened, and a capacitance of suitable size inserted in the series with each, the amplifier could then be grounded. 3. If an increase in amplification of the bridge signal and isolation of the amplifier from the bridge network is desired, this could be accomplished by means of a small step-up transformer. Capacitance coupling, however, would be less expensive. 4. The maximum attainable resistance of R may be increased so that the controller can be used with lower furnace currents.

A double-focusing magnetic spectrometer for detecting and analyzing charged particles from nuclear reactions is described. The magnetic field, varying as $r^{-\frac{1}{2}}$ near an average radius of 10.5 in., extends over a semicircle yielding object and anastigmatic image positions some distance outside of the region of strong field. The acceptance solid angle is $\Omega = 0.0061$ sterad. and the momentum resolution with an 8-mm slit at the detector is $R = 128$. The ultimate resolution determined by spherical aberration and some residual astigmatism is about 1000. Applications to the study of the energy and yield of nuclear reaction products are discussed.

I. ENERGY ANALYSIS OF NUCLEAR REACTION PRODUCTS

MUCH of our present knowledge of the structure of nuclei has come from an analysis of the kinetic energies of the particles which initiate nuclear reactions or which are produced in nuclear reactions. For some time improved techniques have made possible the production of ion beams which are monoenergetic to a high degree so that detailed features of nuclear structure such as narrow, closely spaced energy levels have become observable through the study of excitation curves of nuclear processes. The equally precise analysis of the kinetic energies or momenta of the products of the reaction is a technique of equal importance which has remained completely unexploited until recently.

A reaction-product analyzer with high dispersion and energy resolution and with large solid angle has several important functions. (1). Under ideal conditions using highly resolved incident particles and thin targets, it makes possible the investigation of fine structure in the groups of particles produced in a reaction and thus of the corresponding fine structure in the energy levels of the residual nuclei. (2). It makes possible the observation of a single group of particles in the presence of a large flux of other particles of greater range. Although "differential" range techniques have been developed, they have not been successful in isolating "weak" short range groups. (3). It makes possible energy measurements of the hitherto neglected "residual nuclei" whose ranges are so short as to be practically unobservable in the usual type of range measurement. This point is particularly important with respect to neutron reactions, the direct determination of fast neutron energies with high precision (<one percent) being impossible at present. This technique has been used by Tollestrup, *et al.*[1] to infer the neutron energy in the reaction $D^2(d, n)He^3$ by analyzing the energy of the He^3. It can also be used to infer the angular distribution and excitation functions of neutrons produced in nuclear reactions. (4). The analyzer can be used with a thin target to study reaction products produced by monoenergetic incident particles even with high energy accelerators which do not produce monoenergetic beams. (5). With monoenergetic incident particles the analyzer is able to pick out charged particles produced in a thin lamina in a thick target, thus making it possible to obtain thin-target data in cases where the actual production of a thin target without backing is not feasible. This technique has been applied to determine the excitation function for elastic scattering of protons in lithium and beryllium. In addition compounds of the element of interest can be employed, the effects of other components being easily avoided. Similarly the effects of surface contaminants can be avoided.[2] (6). The analyzer can be employed for precise measurements of the differential stopping powers of various materials as a function of the energy of the incident particles. The application of such analysis to the determination of differential stopping powers for natural alpha-particles is well known.[3] (7). By the high resolution analysis of elastically scattered particles the analyzer can be used to determine the nuclear composition of thin layers of unknown materials.

II. GENERAL DESCRIPTION OF THE MAGNETIC SPECTROMETER

We have built a magnetic spectrometer[4] and have used it for analyzing the energy of particles produced in several reactions brought about by bombardment with monoenergetic protons and deuterons from an electrostatic accelerator and analyzer previously described.[5] These particles include protons, deuterons, tritons, He^3 nuclei, alpha-particles, Li^6, Li^7, Be^7 and heavier nuclei. For brevity, we shall refer only to protons in the following. The instrument is a modification of the design of Siegbahn and Svartholm[6] for electrons, employing a ring-shaped inhomogeneous magnetic field having the property of double focusing (i.e., anastigmatism). The choice of this instrument over other possible types of analyzers was dictated by two considerations: (1). the difficulty of obtaining fields sufficient to deflect million-volt protons without using iron in the circuit; it is this point which ruled out the "lens type" spectrometer so popular for electrons, and (2). the increased intensity or aperture obtainable with this design in contrast to other types of ferromagnetic spectrometers,[7] when "point" detectors of limited opening are to be employed. It is true that line detectors of sufficient extent can be employed with astigmatic spectrometers but this is often undesirable for other reasons. The high dispersion (twice that of the "180 degree" spectrometer) is also an advantage.

Several double-focusing spectrometers for electrons have been built and the principle has been extensively discussed in recent literature.[7-10] A magnetic field is required which has cylindrical symmetry about a line (the z-axis) and mirror symmetry about a plane which we shall call the "midplane" and designated by $z=0$ in cylindrical coordinates. For an anastigmatic image, the radial component of the field must vanish in the midplane and the axial component must vary as $r^{-\frac{1}{2}}$ in the vicinity of a particular circle $r=r_0$ which we shall designate as the "midcircle." Conjugate foci lie on the midcircle separated by an angular distance of $(2\pi)^{\frac{1}{2}}$ radians or 254.56 degrees.[8] The required magnetic field shape can be obtained by adjusting the contours of the pole faces.

The proton spectrometer, shown in Figs. 1a and 1b differs from that of Siegbahn and Svartholm principally in having the pole pieces cover an angle about the axis of symmetry of only 180° so that the conjugate foci do not lie in the field. It is easily shown that a first-order focus is still obtained in this case although of course some dispersion and resolution for a given solid angle is sacrificed. In studies of prompt nuclear reactions it is advantageous to have the target or source and the reaction product detector in a field free region; for the target this is required in order not to move the incident beam on the target in a variable manner with changing field and for the detector it is important as certain types of detector components such as photomultiplier tubes, etc., do not operate properly in strong fields. The 180-degree angle was chosen in particular so that both pole faces could be machined simultaneously and it also represents a reasonable compromise between the conflicting requirements just discussed. The pole faces were fastened to a half-inch steel plate end-to-end to form a complete circle and were machined on a gap lathe. Pertinent dimensions in inches are as follows: Core: 11.25 in. diameter×6.25 in. height; yoke: 3.00 in. thick×24.0 in. diameter; pole pieces: 24.0 in. o.d.×18.0 in. i.d.; midcircle radius $r_0=10.5$ in. (26.7 cm); and maximum gap: 1.80 in. at $r=11.2$ in.

The magnetic circuit was made in five parts—two pole pieces, two yokes, and the core. For availability reasons, ordinary hot-rolled steel was used and the dimensions are by no means optimum. For example, it would have been preferable to have a core of larger diameter. The coil was designed to take the full output of a 15-kw 120-volt d.c. generator and still be adequately cooled. The seven "pancake coils" were wound individually, each consisting of two layers of 31 turns of No. 7 rectangular (0.091×0.229 in.) double cotton-covered copper wire, the winding being started at the center of the wire so that both leads are at the outside. Wire somewhat thinner and wider would have been preferable, but was not immediately available. Wrapped with 0.007-inch thick cotton tape, varnished and baked, the coils were smooth, rigid, and quite satisfactory. Two single-layer pancakes were wound to go between the ends of the spool and the end cooling plates, but it was decided to use more insulation and dispense with one of them. The inside lead for the half-pancake comes out through a slot in the adjacent cooling plate.

The cylinder and two end plates of the spool were made of steel, $\frac{1}{4}$-in. thick, and threaded for assembly. The cooling plates between the pancakes were cut from $\frac{3}{16}$-in. copper plate. Copper tubing $\frac{5}{16}$ in. in diameter was fitted into channels machined in the plates, flattened to the same thickness as the plates, and soldered in. The cooling plate design can be seen in the horizontal section in Fig. 1a. In assembly, the pancakes were daubed liberally with insulating varnish and separated from the spool and from adjacent cooling plates by a layer of varnished cambric ("empire cloth") 0.012 in. thick. The resistance between the windings or the cooling plates and the spool is in excess of 20 megohms. Water connections to the cooling plates are made with $\frac{1}{2}$-in. "Aeroquip" rubber hose fittings. Water circulates through the plates in parallel, and at 15-kw input the heating is not excessive except on the spool face adjacent to the half-pancake. Continuous operation at currents over 125 amp. is not possible because of the heating of this plate. Cooling plates adjacent to both spool ends should be incorporated. The coil has a resistance of 0.8 ohm and gives approximately 50,000 amp. turns at 15 kw.

The vacuum chamber was made in two half-shells of brass. Two $\frac{7}{8}$-in. plates were bolted side by side on the face plate of a large lathe and the two halves were carved out simultaneously so that they mated exactly. Grooves $\frac{1}{16}$ in. wide and $\frac{1}{16}$ in. deep were machined in the center of the abutting surfaces of the half shells, and these were filled with a tightly fitting brass strip to position the shells as they were soft soldered together. The ends of the box were closed with brass pieces machined to a close fit in the inside of the box and

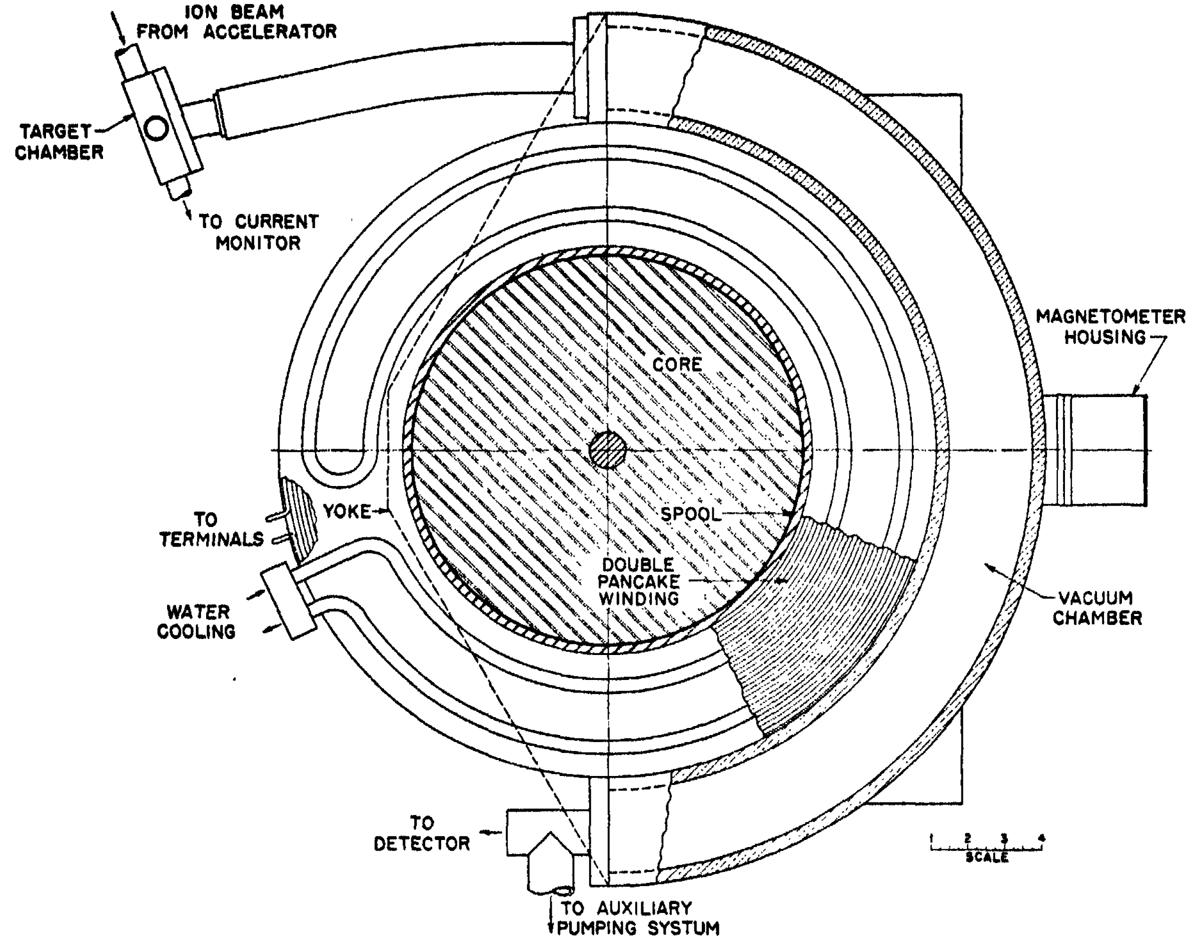

FIG. 1a. Horizontal section of Proton Spectrometer.

soldered in. The box appears to be completely vacuum tight. 0-ring joints are used for connections to the box. The interior cross section is approximately rectangular, $2\frac{1}{4}$ in. wide and $1\frac{1}{2}$ in. high with rounded corners.

The inlet end of the box leading to the target chamber is a length of brass pipe, within which is a short length of brass tubing rotatable about a vertical transverse axis. This aperture stop limits the range of scattering angles accepted by the spectrometer in cases where it is required for precision and is permitted by the intensity. At the exit end of the box, provision is made for attaching a small diffusion pump and liquid air trap. The auxiliary pump and trap are necessitated by the small size of the connections to the main vacuum system.

Shaping of the Magnetic Field

The magnetic field in the midplane can be expressed in the neighborhood of the midcircle in a series of the form[6]

$$H(r)=H_z(r)=H_0\left[1-n\left(\frac{r-r_0}{r_0}\right)+m\left(\frac{r-r_0}{r_0}\right)^2+\cdots\right], \quad (1)$$

where $H_0=H(r_0)$. The double-focusing property requires that $n=\frac{1}{2}$. The values of m and higher order coefficients affect only the aberrations and not the focal length, and they will not be considered here. If n is larger than $\frac{1}{2}$, the r-focal length (i.e., the focal length for trajectories in the midplane with r varying) is longer than the z focal length (i.e., the focal length for trajectories in the cylinder $r=r_0$ with z varying). If n is too small, the reverse is true. In either case the magnetic lens is astigmatic.

The problem of the proper shape of pole face to achieve the field described by $n=\frac{1}{2}$ does not permit of an accurate solution analytically because of the stray field and of non-linearity in the iron. A very simple analysis gives as the first approximation to the slope of the pole pieces at their center the expression

$$\tan u = n z_0/r_0, \quad (2)$$

where u = angle between pole face and midplane; z_0 = coordinate of pole face at $r=r_0$, i.e., half-spacing of pole faces at their center. That this approximation gives the correct answer in the case $n=0$ (parallel faces, uniform field) and the case $n=1$ ($1/r$ field in which equipotentials are coaxial cones with vertices at the origin)

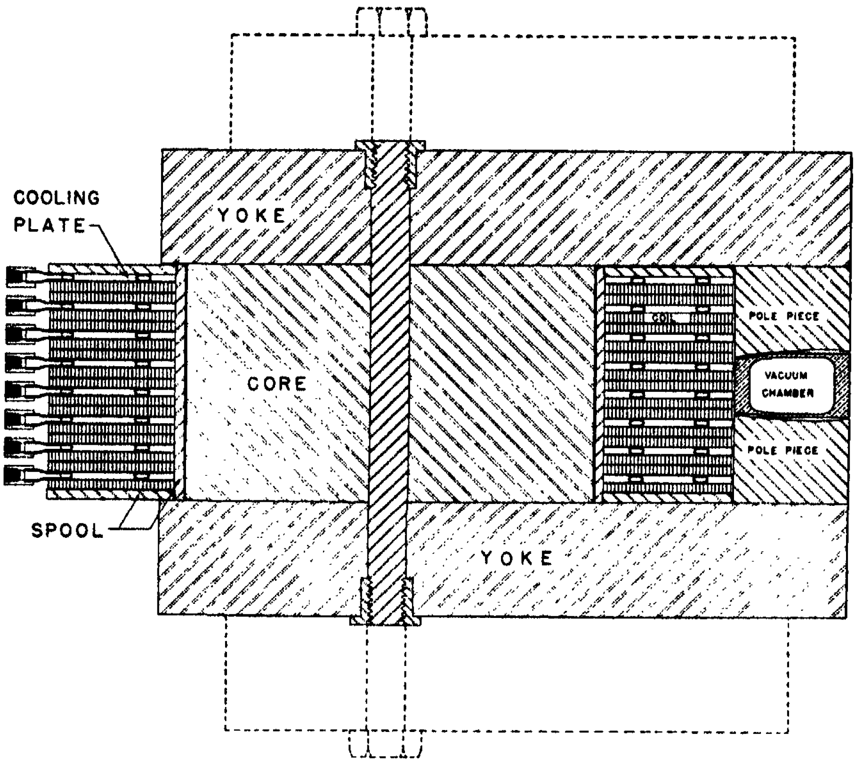

FIG. 1b. Vertical section of Proton Spectrometer.

gives some assurance that it will be valid for the intermediate case $n=\frac{1}{2}$ of interest here. For this spectrometer, it proved to be a good approximation.

Our initial estimate for the proper contour was that shown by the upper curve in Fig. 2. This shape was determined by scaling up the contour published by Siegbahn and Svartholm,[6] but because of slightly altered proportions, the scaling was not exact. The half width of the air gap at its center was 2.20 cm, so that for $n=\frac{1}{2}$ Eq. (2) gives $\tan u=1.10/26.7=0.0412$. Actually $\tan u$ was made equal to 0.0536, and it was expected that this contour might give a field falling off too rapidly with radius and make the z focal length shorter than the r focal length.

Rather than make a detailed investigation of the field shape, the focusing properties were investigated by projecting the proton beam from the electrostatic analyzer directly into the spectrometer and observing the spot produced on a quartz disk at the other end. A small alternating current electromagnet spread the beam in a plane 45 degrees from the vertical so that both radial and vertical focusing effects could be observed. The virtual source in this arrangement is at the center of the magnetic gap. With the source at 36 cm from the end of the pole pieces, the r focus was found to be more than 30 cm beyond the other end and the z focus to be 5 cm inside the gap.

The pole faces were then re-machined to the contour shown in the lower curve of Fig. 2, which was expected to give a slight overcorrection, $\tan u$ being 0.0380, somewhat slightly less than the calculated value 0.0412. Investigation revealed that, for approximately symmetrical cases, the radial focus was now shorter than the vertical focus, but that by moving the source farther away, a very good point image could be obtained. Although a slight improvement in the first-order astigmatism is to be expected from using a larger source than image distance, the improvement observed was considerably greater than that expected and is most certainly to be attributed to second-order effects or to the fringing field. Since the large stray field made it desirable to keep the source well away from the magnet in order to minimize the deflection of the incident beam, this arrangement was adopted, and no further studies of field shape or focusing properties have been made. *Note added in proof:* Field measurements have recently been made by W. D. Warters who finds $n=0.50\pm0.02$ over $r=10.5\pm0.8$ inches.

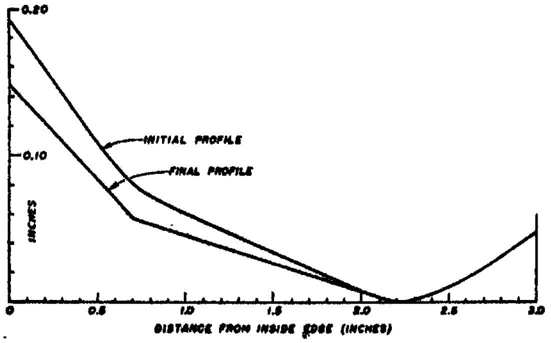

FIG. 2. Profiles of pole faces.

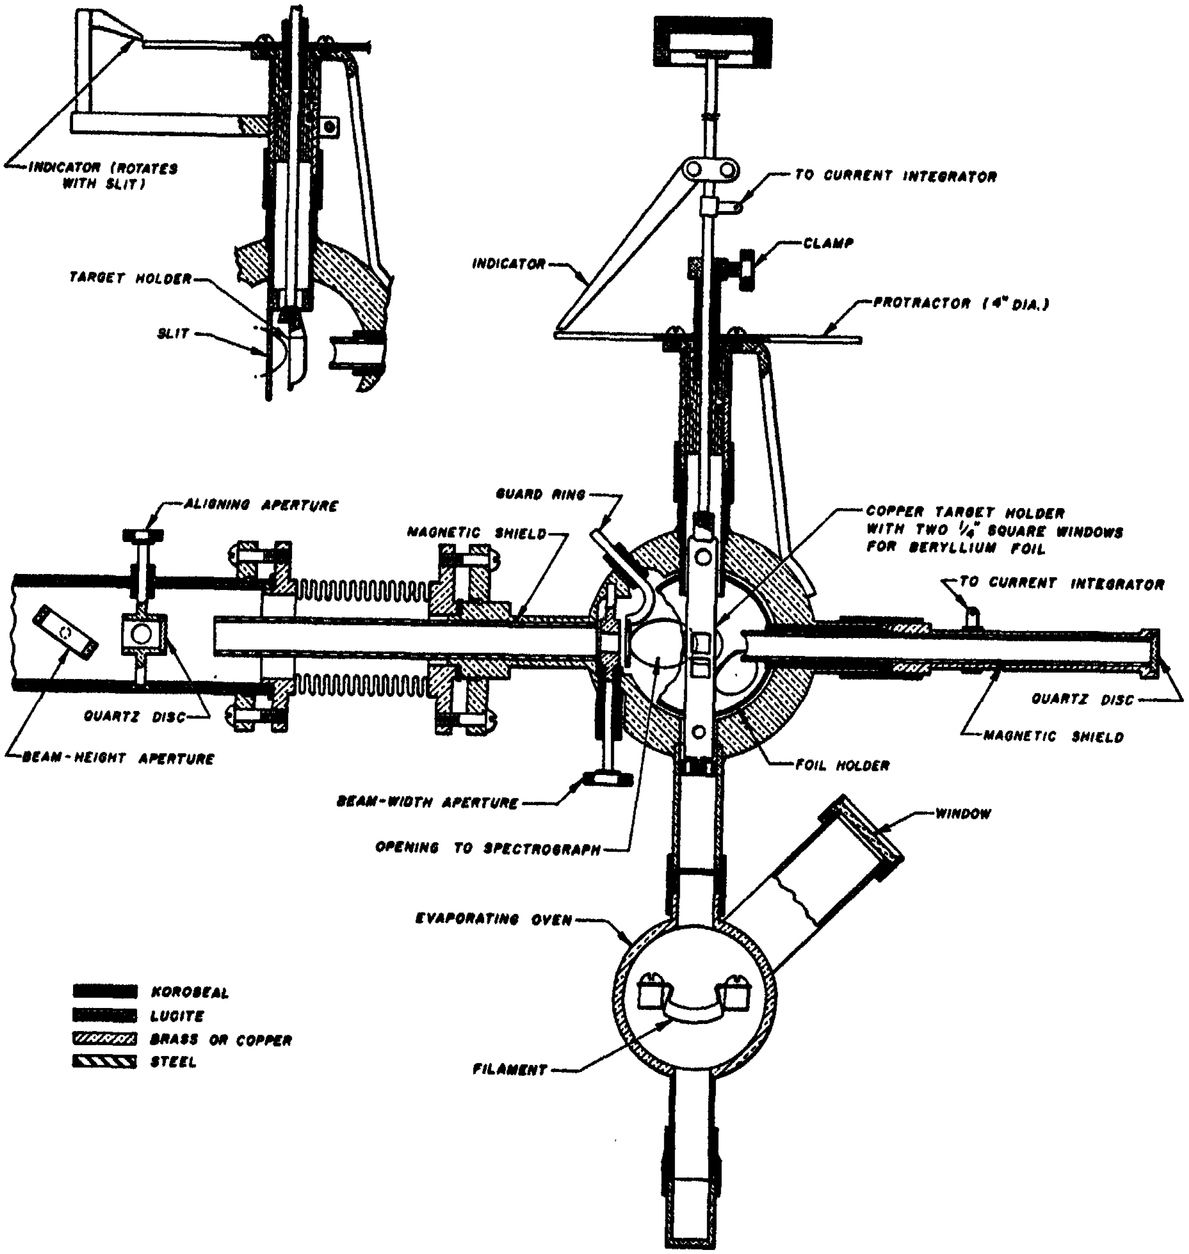

FIG. 3. The target chamber and evaporating oven.

Limitations of Present Design

The maximum field obtainable in the spectrometer with the 15 kw, 120-volt generator proved to be 7000 gauss, corresponding to 2-Mev protons. The most constricted portion of the magnetic circuit was at the intersections of the core with the two yokes. This constriction was eliminated by adding steel pieces as shown by the dashed lines in Fig. 1, but the change increased the peak field in the gap by only about five percent. The difficulty is simply that the leakage flux is very large because of the shape of the magnetic circuit so that the fraction of the total flux which goes through the pole faces is only ⅔ at low fields and less than ½ at high fields. Hence, the core, which carries all the flux, saturates too soon. It seems probable that a magnet with the present dimensions could be made to bend 4-Mev protons by winding the coils around the pole pieces themselves instead of around the core. It must be remembered, however, that the achievement of the proper inhomogenous field by shaping the pole pieces is dependent on having the permeability of the iron very high, so that the pole pieces cannot be magnetized near to saturation without introducing defocusing effects.

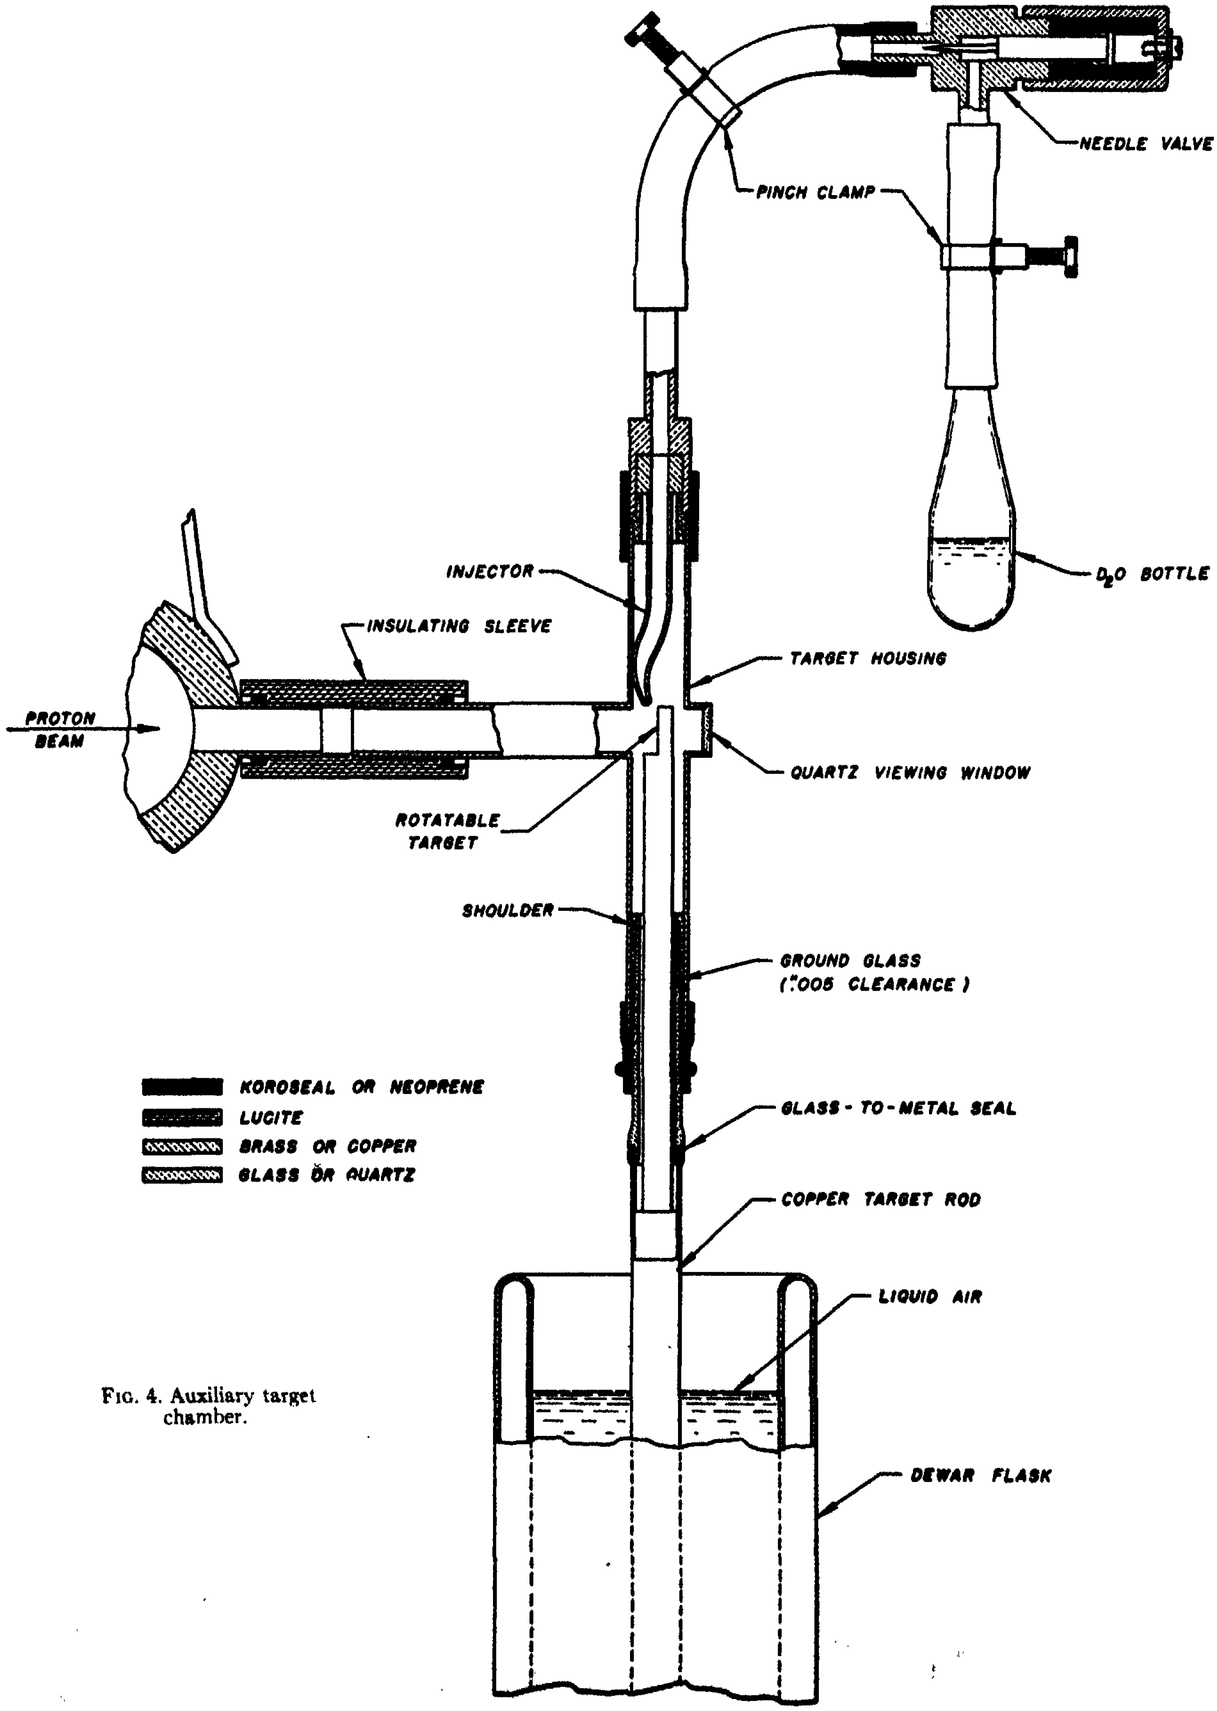

FIG. 4. Auxiliary target chamber.

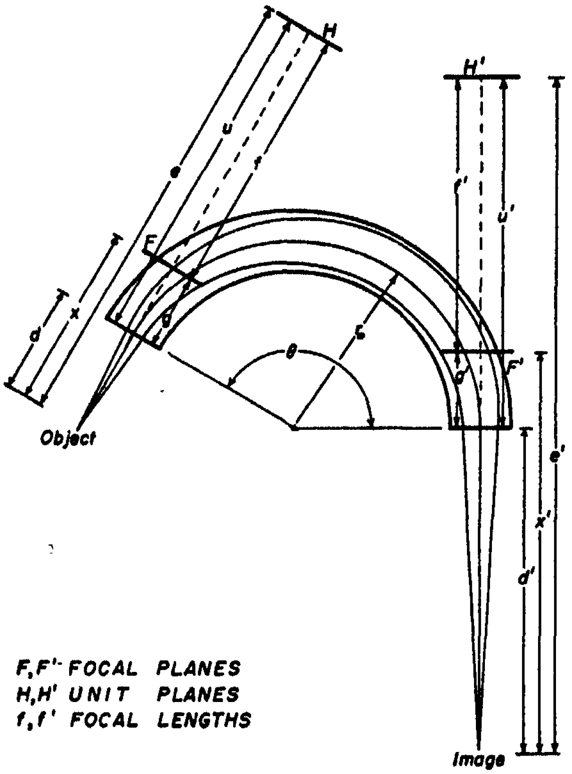

FIG. 5. Constants of the spectrometer as a magnetic lens.

An even more serious difficulty than the inability to focus high energy protons is the presence of the large stray field in the laboratory. It necessitates the magnetic shielding of the incident beam for a distance of several feet and makes the operation of certain instruments (such as photo-multiplier tubes) in the vicinity of the spectrometer very difficult. In spite of the fact that with this spectrometer source and detector are outside of the main field some difficulties remain if the fields outside the gap are not minimized. A 90-degree analyzing magnet[11] and a larger 180-degree double-focusing spectrometer ($r_0=16.0$ in.$=40.6$ cm) have recently been built in this laboratory using "kidney-shaped" coils wound around the pole pieces and having the magnetic circuit completely in iron except for the gap itself. By using flat wire, such a coil can be wound with little difficulty, and the stray field around the magnets is considerably reduced. These instruments will be described in forthcoming publications. The 16-in. double-focusing spectrometer reaches a field of 11,000 gauss (10-Mev alpha-particles and protons) with negligible field outside and has a solid angle of ~0.008 steradian and an observed resolution with a narrow slit ($\frac{1}{32}$ in.) of $p/\delta p=600$.

Fluxmeter

An important auxiliary instrument for use with any magnetic spectrometer having iron in the circuit is, of course, the field measuring device. The fluxmeter designed for this purpose has been previously described.[12] It is mounted so that approximately half the coil is between the pole faces and half in the fringing field. The current necessary to balance the fluxmeter is measured by a Leeds and Northrup Hydrogen Ion Potentiometer Number 7655 and is expressed in millivolts developed across a 1-ohm precision resistor. The readings range from 29 to 100 millivolts and are designated by I in what follows. I is inversely proportional to the magnetic field and thus proportional to the charge/momentum or non-relativistically to the charge/(energy×mass)$^{\frac{1}{2}}$ of the observed particles. The sensitivity is such that the field can be held fixed to 0.05 percent during a run. The pointer is kept on the null mark during a run by manually adjusting the field current in the generator supplying the magnet. The calibration over a period of three years has been reproducible to 0.2 percent.

Target Chamber

The design of the target chamber is shown in Fig. 3. As shown in Fig. 1, it is attached rigidly to the spectrometer through the brass inlet tube and can be moved relative to the proton beam by flexing the sylphon. The alignment of the beam is determined by intercepting it successively at the center of two quartz disks about 13 in. apart. The first disk is mounted in the end of a short length of brass tube pivoted as shown so that the beam can be intercefted by the disk or passed through the ½-in. hole into the target chamber. The other disk is mounted at the outer end of the target tube. For most of its length between these two fixed points, the beam is shielded by steel tubing to minimize curvature of its path in the stray field. The width of beam striking the target is controlled by the defining slit at the left edge of the chamber, which consists of a transverse rectangular opening in a shaft which can be rotated from outside.

The target to be bombarded can be mounted on the end of the second steel magnetic shield, which is beveled so that incident and scattered angles are equal. The tube is perforated so that pressure changes do not damage thin-foil targets and it is insulated from the target chamber by a polystyrene bushing so that it can be used to collect charge for the current integrator. In most experiments the target is mounted on a target holder which can be rotated from outside the vacuum system as shown. A pointer and a fixed protractor indicate the angular position of the target. This target support can also be lowered into a furnace where thin layers of lithium or other materials can be evaporated onto it.

An auxiliary target assembly which can be employed for other types of measurement requiring the proton beam without disturbing the spectrometer is shown in Fig. 4. In this particular assembly a heavy ice target was produced by allowing D_2O vapor to enter the target chamber adjacent to the flat face of a copper rod which was kept at liquid air temperatures. For the study of heavy ice targets with the spectrometer, the copper rod and injector system were made so that they could be inserted into the target chamber of Fig. 3 in place of the target holder and furnace shown there. This arrangement for interchanging targets and bombarding positions was found to be a very flexible and convenient one.

[12] C. C. Lauritsen and T. Lauritsen, Rev. Sci. Inst. 19, 916 (1948).

For determining the scattering angle, the arrangement shown in the inset in Fig. 3 is used. A brass strip containing a vertical 0.003-in. slit is located so that the slit can be moved on a $\frac{1}{4}$-in. radius about the center of the target foil. Particles scattered by a copper target surface are detected. By rotating the slit so that first the incident beam and then the scattered beam pass through it, an accurate measurement of the scattering angle accepted by the spectrometer can be made.

Detection of Reaction Products

Various types of detectors can of course be used at the focus. The double-focusing spectrometer is advantageous essentially because detectors with small openings can be used with it. An ionization chamber,[13] 1 cm in diameter and 5 mm deep has been used for some experiments. The protons pass through a "Newskin" window of approximately 1-mm air equivalent mounted on a grid, and the ionization chamber reliably counts particles having about 1-mm residual range after traversing the window, so that this set-up is usable with protons of at least 150-kev energy and for alpha-particles with at least 300-kev energy.

For low energy protons a scintillation counter has been used, consisting of a small zinc sulfide screen, a hemispherical reflector and a photo-multiplier.[14] Its chief advantage is its ability to go to very low energies since no window is required, but its lack of dead time is also convenient, obviating the necessity for counting rate corrections. Excellent agreement has been found between absolute yields measured by the two types of counters for energetic particles. The pulse size of the scintillation counts relative to background noise was such that with the bias commonly used to eliminate noise, the counting efficiency was about 90 percent even for low energy particles.

Detection has also been accomplished by photographic plates and end-window proportional counters. The photographic plates are useful for searching for unknown particle groups as they allow use of a very wide slit. The proportional counters are useful in distinguishing protons and alpha-particles of the same energy and $B\rho$ by measurements of the ionization produced in short range intervals.

Source of Incident Particles

The incident beam, protons or deuterons, is obtained from the 1.5-Mev pressure-insulated electrostatic accelerator equipped with a precision electrostatic analyzer.[5] The voltage control is such that the incident proton energy relative to some assumed standard can be fixed to better than 0.2 kev at 1.0 Mev but in order to attain this precision, it is necessary to take considerable care in aligning the beam. This is particularly true since the stray field from the spectrometer magnet deflects the beam appreciably even above the electrostatic analyzer, a distance of more than two meters. The effect is compensated by means of three magnets, two with horizontal fields at right angles above the analyzer and one with a vertical field below the analyzer.

III. THEORETICAL CONSIDERATIONS

We have noted previously that in the axially-symmetric double-focusing spectrometer the conjugate foci are separated from one another by an angle $2^{\frac{1}{2}}\pi = 254.56$ degrees. In the present case, the pole pieces are only 180 degrees in extent, and to a first approximation the foci are found by linear extrapolation beyond the pole pieces of the trajectories inside the field. The spectrometer can then be considered as a "thick" spherical lens and the usual optical theory applied.

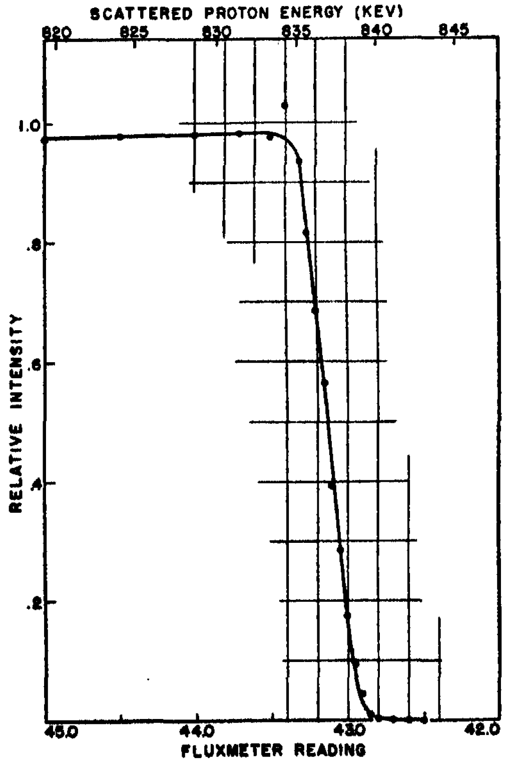

FIG. 6. The elastic scattering of 0.955-Mev protons at 137.8° by a thick copper target.

---

[13] Thomas, Rubin, Fowler, and Lauritsen, Phys. Rev. 75, 1612 (1949).

[14] A. Tollestrup, Phys. Rev. 74, 1561 (1948).

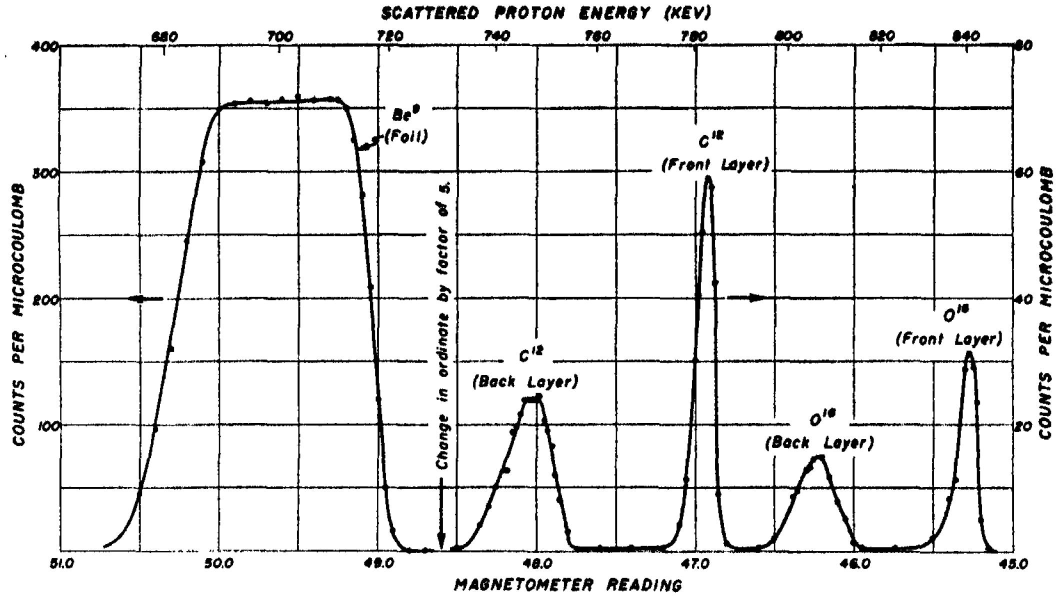

FIG. 7. The distribution in momenta of 1.066-Mev protons elastically scattered at 137.8° by a thin (∼18 kev) beryllium foil. Note the sharp peaks arising from carbon and oxygen layers approximately 50 atoms thick on the front and back surfaces of the foil. The scattering from the front layers and from the front surface of the beryllium indicates an over-all momentum resolution of ∼500. The effect of straggling in energy loss in the foil on the rear layer and rear surface scattering is noticeable.

The results for any n and any angular extent of the field, θ, have been given by Judd.[10] In what follows we first give the formulas for the anastigmatic case, $n=\frac{1}{2}$ and for any θ. The second expressions are for $\theta=\pi$ while the last expression gives the numerical value for $r_0=26.7$ cm as in the spectrometer described in this paper. The results are illustrated in Fig. 5.

Focal length (i.e. distance between focal planes and unit planes)

$$\begin{aligned} f=f'&=\sqrt{2}r_0\csc\theta/\sqrt{2}=1.78r_0 \quad \text{for} \quad \theta=\pi \\ &=47.5\text{ cm} \quad \text{for} \quad r_0=26.7\text{ cm}. \end{aligned} \tag{1}$$

Distance from ends of pole pieces to unit planes (measured inward)

$$\begin{aligned} u=u'&=\sqrt{2}r_0\tan\theta/\sqrt{2}=2.86r_0 \quad \text{for} \quad \theta=\pi \\ &=76.4\text{ cm} \quad \text{for} \quad r_0=26.7\text{ cm}. \end{aligned} \tag{2}$$

Distance from ends of pole pieces to focal planes (measured inward)

$$\begin{aligned} g=g'&=-\sqrt{2}r_0\cot\theta/\sqrt{2}=1.08r_0 \quad \text{for} \quad \theta=\pi \\ &=28.8\text{ cm} \quad \text{for} \quad r_0=26.7\text{ cm}. \end{aligned} \tag{3}$$

The conjugate focal points, object and image, can be determined from either of the standard relations:

$$1/e+1/e'=1/f \quad \text{or} \quad xx'=f^2, \tag{4}$$

where e and e' are measured from the unit planes and x and x' from the focal planes. However Judd has given the image distance, d', measured out from the pole piece directly in terms of the object distance, d, similarly measured as

$$\begin{aligned} d'&=-\sqrt{2}r_0\tan[\theta/\sqrt{2}+\tan^{-1}d/\sqrt{2}r_0] \\ &=-\sqrt{2}r_0\tan[127.28°+\tan^{-1}d/\sqrt{2}r_0] \quad \text{for} \quad \theta=\pi \\ &=-37.8\tan[127.28°+\tan^{-1}d/14.9]\text{ cm} \\ &\qquad \text{for} \quad r_0=26.7\text{ cm}. \end{aligned} \tag{5}$$

We used an object distance, $d=30.5$ cm and found the image distance experimentally to be $d'=8.6$ cm. The calculated image distance is $d'=9.4$ cm in reasonable agreement with the measured value.

The first order anastigmatic image also shows no distortion and the magnification in both the r and z directions is

$$\begin{aligned} M&=\left(\frac{d}{2^{\frac{1}{2}}r_0}\sin\theta/\sqrt{2}-\cos\theta/\sqrt{2}\right)^{-1} \\ &=\frac{d'}{2^{\frac{1}{2}}r_0}\sin\theta/\sqrt{2}-\cos\theta/\sqrt{2} \\ &=\left(0.562\frac{d}{r_0}+0.606\right)^{-1}. \\ &=0.562\frac{d'}{r_0}+0.606 \end{aligned} \tag{6}$$

For $d=30.5$ cm, $r_0=26.7$ cm, this gives $M=0.8$. Judd has also calculated the dispersion of the instrument and finds in the general case

$$D=\frac{\delta r}{r_0}\bigg/\frac{\delta P}{P_0}=\frac{\delta r}{r_0}\bigg/\frac{\delta B}{B_0}=\frac{1+M}{1-n}, \tag{7}$$

where δr is a small increment in the image position measured normal to the optic axis of the spectrometer arising from a change δP in the momentum of the particles injected into the spectrometer or from a change δB in the magnetic induction, B_0, of the spectrometer. We note that $D=2(1+M)$ for the anastigmatic spectrometer as compared with $D=1+M$ for the type with uniform field ($n=0$). For $M=1$ these become $D=4$ and $D=2$ respectively. In the spectrometer described here a magnification of 0.8 was employed for reasons previously given and the dispersion has the value $D=3.6$.

The ultimate resolving power of the instrument can be calculated if the size and shape of the image of a point source formed by the particles emitted in a finite solid angle is known. This in turn depends on higher order calculations and on fringing field effects. Practically we have found no occasion to employ the ultimate resolution as determined by the small image aberrations but have been limited to values of the resolution given by the source and collector sizes dictated by intensity considerations. This resolution in momentum can be computed from the width of the collecting slit, δr_c, by using the expression for D given above

$$R_c=\frac{P_0}{\delta P_c}=\frac{Dr_0}{\delta r_c}=\frac{1+M}{1-n}\left(\frac{r_0}{\delta r_c}\right). \tag{8}$$

In the case described here $R=3.6r_0/\delta r$. For a finite source width, δr_s, a similar expression is obtained by replacing δr_c by $M\delta r_s$ yielding

$$R_s=\frac{P_0}{\delta P_s}=\frac{1+M^{-1}}{1-n}\left(\frac{r_0}{\delta r_s}\right). \tag{9}$$

The apparent spread in momenta, δP_c or δP_s, of particles actually having the same momentum will be indicated in terms of an interval δI_c or δI_s in fluxmeter readings over which counts can be obtained.

For rectangular source and slit the apparent distribution in momentum for monoenergetic particles will be trapezoidal in shape with a width at half-maximum determined by whichever of δP_c or δP_s is the larger and the effective resolution will be determined by the smaller of R_c and R_s. The base of the trapezoid will have a width given by $\delta P_s+\delta P_c$ while the top will have a width given by $|\delta P_s-\delta P_c|$.

For a continuous distribution of particles extending up to a maximum energy as is observed for example when a thick target is used in scattering or reaction experiments, the observed distribution will show the effects of finite resolution near the upper limit. These effects are shown in Fig. 6 which illustrates the distribution in momentum of monoenergetic protons scattered by a thick Cu target. The curve shows a linear portion of finite slope symmetric about the true end point with rounded fillets at each end. If the linear portion be extended from the maximum reading to zero it will be found to cover a momentum range given by δP_c or δP_s, whichever is larger. The corresponding δI_c or δI_s divided into the reading I will give the resolution.

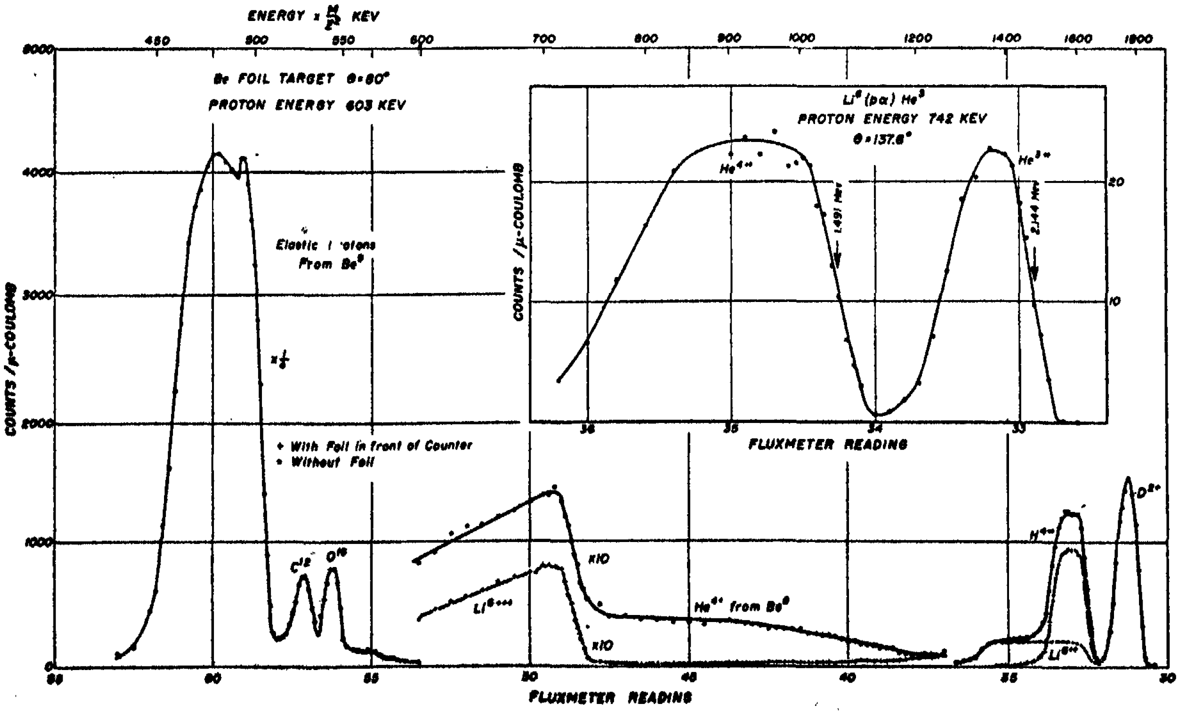

FIG. 8. Momentum analysis of the ions produced in the bombardment of Be^9 and Li^6 by protons.

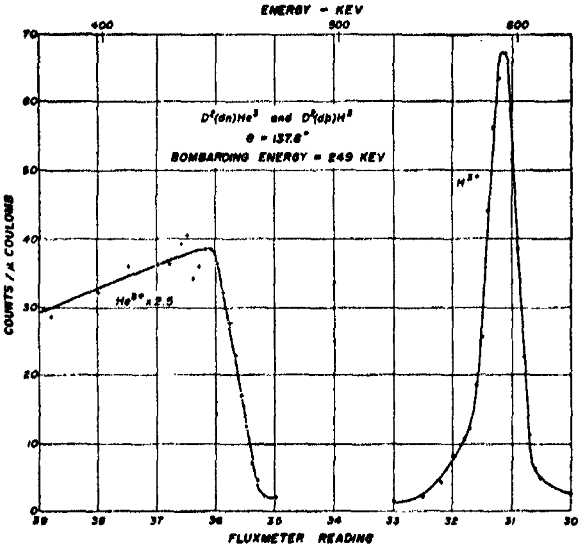

FIG. 9. Momentum analysis of the He^{3+} and H^{3+} produced in the bombardment of deuterons with 249 kev deuterons and with the angle of observation equal to 137.8°.

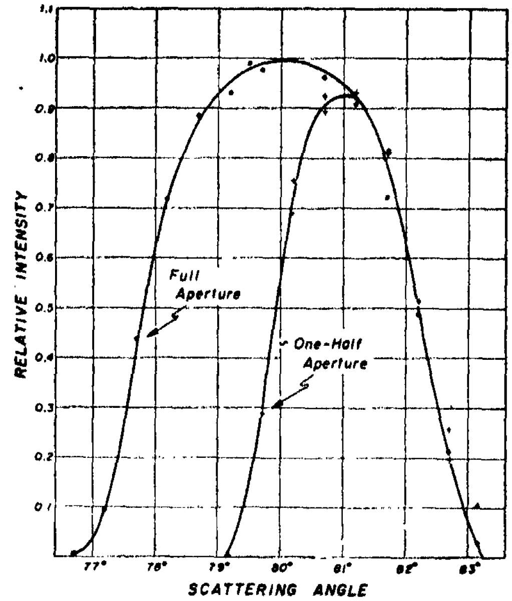

FIG. 10. Distribution in angle of the particles accepted by the spectrometer.

In the use which we have made of the spectrometer δr_c and δr_s have been determined by intensity considerations. The number of counts observed is linear in δr_c as long as the particle spread in energy is greater than that accepted by the spectrometer as is usually the case. The source width is usually determined by the beam width from the electrostatic generator and the useful current depends on the width permitted through the beam slit as long as the focused beam is larger than this slit width. In addition to the apparent spread in energy arising from (1) the source (or bombarding beam) width and (2) the collector width, (3) aberrations and (4) fluctuations in the magnetic field, there are real spreads in energy in the particles entering the spectrometer. These arise from (5) the energy spread in the incident beam (6) the angular extent of the inlet aperture[*] since the energy of a particle emitted in a nuclear reaction or scattering process depends on the angle of emission, (7) the energy loss in the target of both the incident and outgoing particles and (8) the energy straggling in the target of both particles, and (9) the thermal motion of the target nuclei.

TABLE I. The elastic scattering of protons by several materials. Incident energy = 1.2373 Mev. Angle of scattering = 137.8°. (Relativistic corrections included.)

Scatterer	Calculated energy after scattering E (Mev)	Fluxmeter reading I (mv)	Spectrometer constant for protons C_p
Li	0.7475	48.24	1.7390×10^4
Be	0.8367	45.56	1.7366
C	0.9230	43.39	1.7379
O	0.9931	41.83	1.7382
Cu	1.1704	38.52	1.7376
Mean			1.7379×10^4 ± 0.0006

The ultimate line shape can be predicted from a folding of the various contributions listed above into each other. The effect of (7) will depend markedly on whether the outgoing particles emerge into the spectrometer from the same side of the target as the incident particles enter or from the opposite side. The effect will also depend on whether the energy of the particles produced in the nuclear reaction under study decreases as the incident particle energy decreases because of energy loss in the target or whether it increases. For the so-called residual nuclei produced in a nuclear reaction the latter is often the case for angles of observation with the incident beam greater than 90°.

Items (1) to (6) and (9) discussed above make symmetrical contributions to the line shape of a group of particles under observation. Thus for very thin targets for which (7) and (8) can be neglected the observations yield a symmetrical line the midpoint of which corresponds to the momentum (or energy) of the secondary particles produced at the angle corresponding to the mean acceptance angle of the spectrometer by those particles in the incident beam having the mean energy of the beam. Usually for reasons of intensity ideally thin targets cannot be used. In energy determinations if the midpoint of the observed line is employed as a measure of the energy of the secondary particles then a correction must be made for half the energy loss in the target both for the incident and emergent particles. The method of correction will be the same whether the secondary particles emerge from the same side of the target as the primary particles impinge upon or from

---

[*] The finite source size also makes a contribution to the spread in the angle of observation. Its effect must be combined algebraically with (1).

TABLE II. The elastic scattering of protons by copper at several energies. Angle of scattering = 137.8°. (Relativistic corrections not included.)

Inc. energy $\bar{E}$ (Mev)	Scat. energy	Fluxmeter Reading H^+	HH^+	HHH^+	Spectrometer constant for protons calculated from H^+	HH^+	HHH^+
1.3314	1.2603	37.08	52.51	64.34	1.733×10^4	1.737×10^4	1.739×10^4
0.8876	0.8402	45.35	64.30		1.728	1.737	
0.4438	0.4201	64.26			1.735		
Mean						1.735×10^4 ±0.002	

the opposite side if the inclination of the target to the incident and emergent beams is properly taken into account. The contribution to the observed width of the line will of course be markedly different in the two cases. It is clear that other characteristics of the observed thin-target curves such as extrapolated end points can be employed if properly interpreted but we have found it most convenient to use midpoints representing mean energies with appropriate corrections for target energy losses.

Actually in our most accurate energy determinations with the spectrometer we have preferred to employ thick targets. It is then necessary to observe the particles emerging from the surface of the target upon which the incident particles impinge. The measurements yield a step curve (see Fig. 6 for example) which is essentially just the integral of the curve arising from contributions (1) to (6) and (9). The midpoint of the sloping front of the step is taken as the momentum of the secondary particles produced at the mean acceptance angle of the spectrometer by the particles of mean energy in the incident beam. In some cases we have employed semithick targets which do not completely stop the incident particles but which give a spread in energy large compared to that arising from (1) to (6) and (9). In this case we have also used the midpoint of the initial rise just as with thick targets but the accuracy is not as great primarily because of the effect of straggling on the peak reading obtained.

The error in the determination of the energy of a group of particles arises from the following causes with which we also list an estimate of the contribution to the probable error: (1) uncertainty in the fundamental constants, 0.01 percent, (2) uncertainty in the energy of calibration particles, 0.1 percent, (3) uncertainty in fluxmeter setting and line location, 0.2 percent, and (4) uncertainty in the particle path arising mainly from variations in the target or beam position and from saturation effects in the magnetic field, 0.05 percent. The over-all error is slightly over 0.2 percent. In the determination of the Q of a nuclear reaction in addition to (1) the error in the energy of the observed particles, errors arise from (2) uncertainty in the energy of the incident particles, (3) uncertainty in the angle of observation, (4) uncertainty in the masses of the particles involved, (5) uncertainty in the thickness of surface contamination layers on the target, and in some cases, (6) uncertainty in the interpretation of the line structure.

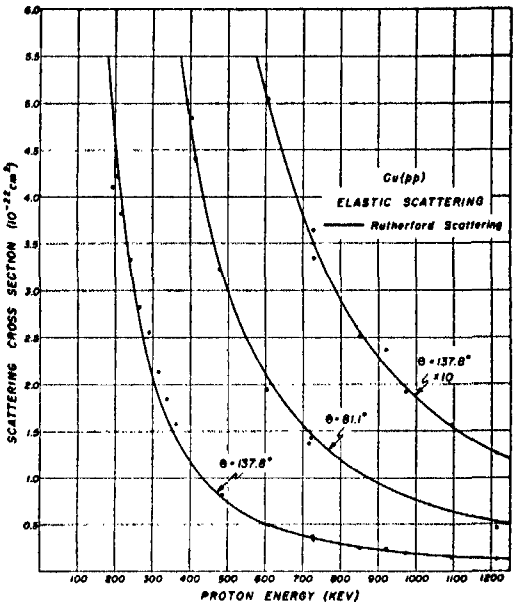

FIG. 11. The cross section for the elastic scattering of protons by copper as a function of energy. The experimental point at $E_p=610$ kev, $\theta=137.8°$ has been fitted to the Rutherford cross section (solid curves) yielding a value for the spectrometer solid angle of 0.0061 steradian.

IV. TESTS AND CALIBRATION

Energy Measurements

The characteristics of the spectrometer have been investigated by scattering protons and deuterons elastically from various targets, particularly gold, copper, oxygen, carbon, beryllium and lithium. A thin beryllium foil* gives a particularly interesting trace as shown in Fig. 7. The foil was thin enough and the bombarding energy high enough so that the scattered protons from beryllium, from carbon and oxygen contamination on the front of the foil, and from similar contamination on the back of the foil are all distinctly separated in energy. The separation occurs because of the differing amounts of recoil energy imparted to nuclei of different mass and because of the energy loss of incident and scattered protons in the beryllium. The high resolution in momentum (~500) arises from the fact that $\delta r_c=\delta r_s=0.1$ cm in these measurements. Figure 8 shows an example of what happens with a lower bombarding voltage and a wider exit slit (0.8 cm). Here the peak from the front oxygen layer is clearly apparent while the peaks from the rear oxygen layer and the front carbon layer occur at the same reading. The peak from the rear carbon layer lies atop the beryllium peak, which therefore appears to have an unusual shape. Such effects must be taken into consideration in making accurate energy measurements.

---

* This foil and others were very kindly supplied to us by Dr. Bradner of the University of California. The technique of preparing them is discussed in Rev. Sci. Inst. 19, 662 (1948).

Figure 8 also shows the nuclear reaction products obtained in the bombardment of Be^9 and Li^6 by protons. The reactions are $Be^9(p, \alpha)Li^6$, $Be^9(p, d)Be^8$, and $Li^6(p, \alpha)He^3$. The singly ionized deuterons, doubly ionized alpha-particles, doubly ionized He^3 and both the doubly ionized and the triply ionized Li^6 give definite peaks. The Be^8 produced in the second reaction breaks into two alpha-particles with random directions in the moving center of mass system yielding the continuous distribution of alpha-particles in the laboratory system which is also clearly indicated. These results have been analyzed in a previous publication.[15] Another set of measurements which have also been previously described[1] are shown in Fig. 9. Here the residual nuclei from $D(d, p)H^3$ and $D(d, n)He^3$ have been measured by bombarding heavy ice targets with deuterons. In these measurements considerable analysis was necessary to properly interpret the "thin" target curve for H^3 and the "thick" target curve for He^3 obtained using the same target and the analysis carried out along the lines discussed above is given in detail in the reference.

The results obtained by elastically scattering protons or deuterons of known energy at a known angle from various targets has been used to calibrate the momentum (or energy) scale of the fluxmeter. The energy of the incident particles is determined by means of the electrostatic analyzer calibrated at the strong gamma-resonance in $F^{19}(p, \alpha'\gamma)$ at 873.5±0.9 kev.[16] The angle of scattering was determined by means of observations with the rotating slit described previously. A record of the data taken with the slit and two settings of the entrance aperture is shown in Fig. 10. With the aperture stop completely open the mean scattering angle seen by the spectrometer as set up in this particular experiment is 80° with some particles being accepted up to 3° on either side of this. To improve the resolution some data has been taken with the aperture stop partially closed. It will be noted in Fig. 10 that for this setting the mean angle is 81° with a spread of slightly less than 2° on either side.

In Table I we present the results of the elastic scattering of 1.2373-Mev protons at 137.8° by Li, Be, C, O, and Cu. Column 2 lists the energies after scattering (E) calculated using the conservation laws of energy and momentum. Small relativistic corrections have been made. These arise in the energy determination in the analyzer and in the calculation of the energy after scattering. Column 3 lists the fluxmeter readings in millivolts (I). In column 4 are listed values of the spectrometer constant for protons as calculated from:

$$C_p = I^2E[1+(E/2M_pc^2)],$$

where M_p is the mass of the proton appearing in the second terms in brackets which is a small relativistic correction. The results for the various determinations of C_p indicate the high precision possible with the spectrometer. The average value from these determinations is $C_p = 1.738\times10^4$ for E in Mev and I in millivolts. This value for C_p holds only for protons. The constant for any other ion of charge Z and mass M can be obtained by multiplying C_p by M_pZ^2/MZ_p^2 or by Z^2/M for M in proton mass units.

In passing it is worth noting that the observation of elastic scattering peaks with spectrometers of high resolution is an excellent method for determining the nuclear composition of thin layers of unknown materials. Since the Rutherford scattering increases as the square of the nuclear charge the method is especially sensitive in detecting minute quantities of heavy nuclei. Very high resolution (10^4) and very thin targets (<100 ev) are necessary to separate the heavy nuclei even at large angles of scattering.

By using the hydrogen ion beams of masses one, two, and three with a constant setting on the electrostatic analyzer for the incident protons, one can check the linearity of the magnetic fluxmeter and establish the precision with which measurements can be made with the spectrometer. Similarly with fixed fluxmeter settings one can check the linearity of the analyzer. In Table II we give readings for three energies in the ratio 3,2,1 taken with copper as the scattering material. The calculated values for C_p are also given.

Small relativistic corrections and corrections for the electrons carried by ions of mass two and three have not been included. Even without these corrections the results show that the over-all combination of electrostatic analyzer for incident particles and of magnetic analyzer for outgoing particles gives consistent results within a probable error of 0.1 percent.

Resolution and Line Width

Very thin targets or infinitely thick ones can be used in elastic scattering experiments to yield a measure of the line width arising from source and exit slit size. In the former case the energy losses can of course be neglected while in the latter case the slope of the rise to the maximum reading can be employed to calculate the line width neglecting target losses. Using an exit slit $\delta r_e = 0.8$ cm and an entrance slit $\delta r_s = 0.2$ cm so that δr_e determines the resolution we have made careful measurements using thick Cu targets of the rise in the scattering curve. We find $\delta I/I = 0.0081$, 0.0075, and 0.0078 in measurements at 1240, 992, and 744 kev yielding an average value 0.0078 and a resolution $R = 128$. Our expression for R is the resolution in particle momenta. Since energy is proportional to momentum squared, we have $E/\delta E = \frac{1}{2}P/\delta P = \frac{1}{2}R = 64$. If we substitute $M = 0.8$, $n = 0.5$, $\delta r_e = 0.8$ cm, $r_0 = 26.7$ cm into expression 8, we obtain $R = 122$ in good agreement with the observed value. Simple calculations indicate that the spread in energy in the incident beam and in the scattered particles over the entrance aperture contribute values of $\delta I/I \sim 0.001$ and merely increase the fillets on the observed curves. The widths of the carbon and oxygen peaks shown in Fig. 7 which were obtained using 0.1-cm entrance and exit slits indicate $R \approx 500$ while the calculated value is $R \approx 1000$. In this case the contribution to line width from the angular extent of the aperture is not negligible.

---

[15] Tollestrup, Fowler, and Lauritsen, Phys. Rev. **76**, 428 (1949).

[16] Herb, Snowdon, and Sala, Phys. Rev. **75**, 246 (1949).

We have made no attempt to measure the ultimate inherent resolution of the spectrometer. However the image size due to aberrations of a point source of protons as described above was visually estimated to be of the order of 0.1 cm in size. Substitution in 8 above yields $R \sim 1000$. There is reason to believe that the recognition of detail even to better than one part in a thousand in momentum is possible with sufficiently intense sources.

Solid Angle

The solid angle of acceptance of the spectrometer can be determined by measuring the yield of elastic scattering from a substance such as copper. The measurements we have made are illustrated in Fig. 11 and show a $1/E^2$ dependence over the entire energy range showing that there are no anomalies in the Rutherford scattering. With a thick target the yield is of course proportional to the Rutherford cross section and to the target thickness in which the over-all losses are just enough to fill the exit slit of the spectrometer. This involves the instrument resolution and the stopping cross section for protons in Cu. The data shown in Fig. 11, using Mano's stopping power for Cu, are consistent with a value for $\Omega = 0.0061$ steradian or $\sim 1/2000$ of the sphere. Using the formula for Ω given by Judd we calculate $\Omega = 0.008$ steradian from the *maximum* available cross section of the spectrometer vacuum tank. That the experimental result is slightly smaller than the value so calculated is not surprising in view of the fact that other stops in the system probably determine the solid angle.

Yield Measurements

In a future paper we intend to discuss the use of the spectrometer in the measurement of the intensity of particles produced in a nuclear reaction. We note at this point that the number of counts observed in the detector, N, for a given yield, y, of particles produced at the target per unit momentum interval per 4π steradians of solid angle, is

$$N = y(\Omega \delta P_c / 4\pi),$$

where δP_c is the momentum interval corresponding to the collector slit width and Ω is the solid angle through which particles leaving the source can traverse the spectrometer and enter the detector. In terms of $R_c = P/\delta P_c$ we have

$$N = y(\Omega P / 4\pi R_c).$$

We emphasize that it is the resolution, R_c, appropriate to the collector size which appears explicitly in this expression and not the resolution, R_s, appropriate to the source, nor the resolution, R_a, arising from aberrations such as spherical aberration. It is true that in certain cases y may depend on the area of the source, as for radioactive deposits with a limiting surface activity or for targets which can be bombarded only by beams of limited concentration. Also, of course, Ω and R_a are intimately related and numerous papers have been written proposing methods for obtaining small aberrations and thus high resolution R_a for a given solid angle. In the last analysis it must be noted that it is R_c which appears in N and there are many practical cases in which to obtain sufficient counts for the maximum solid angle in the available magnetic field volume, one must reduce R_c to a value considerably below the ultimate value R_a so that the observed resolution is of the order of R_c and not of R_a. In these cases many other considerations may dictate a choice of design parameters which do not yield a high value of R_a but other desirable features such as low power consumption, ease and simplicity of construction, and so forth. Only in those cases where R_c can be matched to R_a will the practical resolution and the ultimate be approximately equal.

For the spectrometer discussed in this paper we have found

$$\frac{N}{yP} = \frac{\Omega}{4\pi R_c} = 3.80 \times 10^{-6}$$

or

$$R_c/\Omega = 21{,}000,$$

where $R_c = 128$ for the 0.8-cm collector slit which was employed in most measurements and $\Omega = 0.0061$ steradian for the full aperture. If R_c had been matched to the ultimate resolution $R_a \sim 1000$, a result eight times smaller would have been obtained which would have been impractical for applications involving nuclear processes of low probability.

In determining yields and cross sections in nuclear reactions from observed counting rates, we have

$$y(I) = \frac{4\pi R_c}{q\Omega_c} \frac{N(I)}{I} \times 1.6 \times 10^{-13}$$

$$= \frac{2R_c}{q\Omega_c} \frac{N(I)}{I} \times 10^{-12}$$

where $y(I)$ is the yield per incident singly charged particle per 4π steradians in the center-of-mass system per unit interval on the fluxmeter scale and $N(I)$ is the number of counts observed at the fluxmeter reading I when q microcoulombs strike the target. The equivalent solid angle Ω_c, in the center-of-mass system, can be calculated in a straightforward manner from Ω. *For thin targets* one can integrate over the total area under the peak corresponding to a given group of particles and obtains

$$Y=\int y(I)dI=\frac{2R_c}{q\Omega_c}\int\frac{N(I)}{I}dI\times 10^{-12}$$

which is the yield in disintegrations per incident particle per 4π steradians appropriate to the target thickness and angle of observation employed. The cross section is then given by thin target measurements as

$$\sigma=Y/nt=Y\epsilon_1/\xi_1$$
$$=\frac{2R_c\epsilon_1}{q\Omega_c\xi_1}\int\frac{N(I)}{I}dI\text{ millibarns,}$$

where n = disintegrable nuclei per cc in the target, t = target thickness parallel to the incident beam in cm, ξ_1 = energy loss of incident particles in target in ev, and ϵ_1 = stopping cross section[15] in 10^{-15} ev-cm^2 for the incident particles per disintegrable nucleus in the target molecules. *For targets thick* enough that the energy spread of the outgoing particles exceeds the total energy spread from all other causes including in particular the energy interval accepted by the spectrometer collecting slit, it is often convenient to use the maximum reading over the flat portion of the observed curve of counts *versus* spectrometer setting. Similarly for very thick targets it is convenient to use the maximum reading obtained after the initial rise. In both cases if $N_{\max}$ is this maximum reading for q microcoulombs

$$Y=2N_{\max}/q\Omega_c\times 10^{-12},$$

where Y is now the yield in disintegrations per incident particle per 4π steradians appropriate to the target thickness which just gives a spread in energy of the outgoing particles equal to that accepted by the spectrometer collecting slit. A simple calculation gives this thickness in energy units as

$$\xi_1=\frac{\epsilon_1\delta E_2}{|\epsilon_1(\partial E_2/\partial E_1)+\epsilon_2(\cos\theta_1/\cos\theta_2)|}$$
$$=\frac{2\epsilon_1 E_2}{R_c|\epsilon_1(\partial E_2/\partial E_1)+\epsilon_2(\cos\theta_1/\cos\theta_2)|},$$

where ϵ_2 = stopping cross section in 10^{-15} ev-cm^2 for the outgoing particles per disintegrable nucleus in the target molecules. E_2 = energy of outgoing particles in electron-volts. θ_1 = angle of incident beam measured from the normal to the target on the side of the incident beam. θ_2 = angle of outgoing particles measured from the normal to the target on the side of the incident beam. $\partial E_2/\partial E_1$ = variation in energy of outgoing particles with that of the incident particles calculated from the expression $E_2=E_2(E_1,\theta,Q)$ given by the application of the usual conservation laws. The cross section is thus given by thick target measurements as

$$\sigma=\frac{N_{\max}R_c}{q\Omega_c E_2}\left|\epsilon_1\frac{\partial E_2}{\partial E_1}+\epsilon_2\frac{\cos\theta_1}{\cos\theta_2}\right|\text{ millibarns.}$$

Great care must be observed in using this expression if $\partial E_2/\partial E_1<0$ as is often the case for residual nuclei or if $\cos\theta_1/\cos\theta_2<0$ as in transmission experiments. In either case straggling in energy loss of the outgoing particles may make a large contribution to their observed spread in energy and a calculation taking this into account must be made. In most of our experiments observations have been made on the light particles emitted in a nuclear reaction for which $\partial E_2/\partial E_1>0$. The one exception has been discussed in detail previously.[1] In addition, in most of our experiments we have observed on the side of the target on which the bombarding particles were incident so that $\cos\theta_1/\cos\theta_2>0$. The reason for this is that this choice is convenient for large angles of detection with the incident beam. At these angles Rutherford scattering of the incident particles is small and not considerably greater than nuclear processes as it is at forward angles. This reduces the interference from the scattered incident particles. Observations in this manner are of course the only method for targets so thick that the particles cannot emerge from the side opposite to the incident beam.

In conclusion we wish to thank Professor R. F. Christy and Dr. D. L. Judd for many illuminating discussions of this paper.

This work was assisted by the joint program of the ONR and AEC.

University of Pennsylvania, Philadelphia, Pennsylvania

Vibrating Probe Electrometer for the Measurement of Bioelectric Potentials

O. Blüh and B. I. H. Scott*
Physics Department, University of British Columbia, Vancouver, Canada

(Received May 22, 1950)

The instrument described in this paper is intended for the measurement of bioelectric, membrane, and diffusion potentials. The principle of the method has been suggested previously and applied to the study of contact potentials and electrical properties of adsorptive films.[1] Apparently it has not been used for the purposes mentioned above.

The construction of the instrument is shown diagrammatically in Fig. 1. An insulated metallic probe is set into vibration by means of a telephone *T*, and brought close to the surfaces of the object to be investigated, in this case a plant. As long as a potential difference obtains between probe and surface, the induced charge on the former undergoes alterations with the change of capacity due to the vibration of the probe. Corresponding potential changes are produced on the grid of the electrometer tube *E*, the output of which is fed to an amplifier *A* and displayed on a C.R.O. screen as a sinusoidal curve. The amplitude of this curve depends on the potential difference between *S* and *P*. The action of the instrument can also be compared to that of a generating voltmeter.

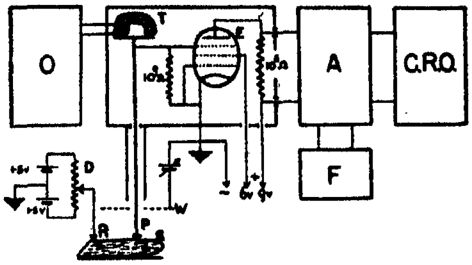

Fig. 1.

With the help of a potential divider *D* an opposing potential is introduced between surface and ground, which is varied until the trace on the C.R.O. screen is reduced to zero amplitude, when the probe and the opposite region of the surface are at equal potentials. Alternatively the compensation voltage could be introduced into the circuit between cathode and earth.

A photograph of the apparatus is shown in Fig. 2. Telephone and electrometer tube, carefully shielded from each other, are enclosed in a tinplate box which is mounted on a microscope rack allowing vertical movement of the probe with the help of the coarse and fine controls. The object is placed on the mechanical stage of a microscope, and can be moved in the horizontal plane. A reference electrode *R* is in contact with the object, and connects it to the compensating circuit *D*. Both platinum and silver-silver chloride electrodes have been used and found sufficiently stable.

The probe vibrates at a frequency of 280 sec.^{-1}. A 959-acorn tube operated at reduced potentials with *G*3 as its control grid to reduce grid currents[2] was chosen as

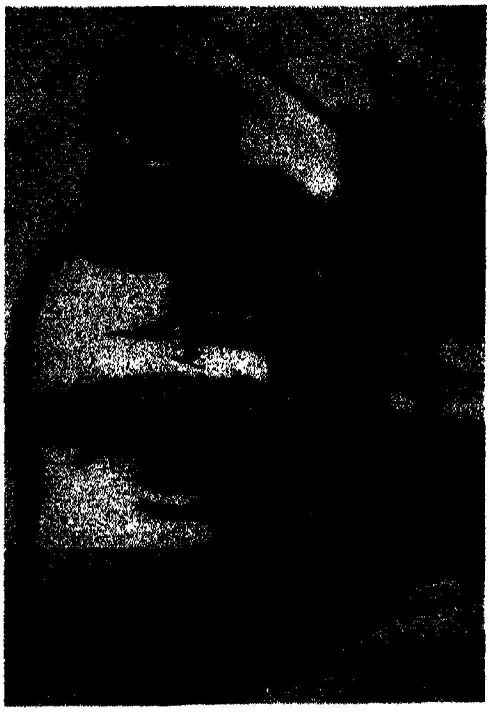

Fig. 2.

[2] C. E. Nielson, Rev. Sci. Inst. 18, 18 (1947).

electrometer tube. The amplifier *A* is a three-stage battery operated General Radio Company Model 1231-A.[3] A parallel antiresonant filter *F* tuned to 280 $\mathrm{sec.}^{-1}$ is used to reduce the noise level and 60 $\mathrm{sec.}^{-1}$ alternating current interference. The object is shielded with wire gauze *W* to reduce a.c. pick-up.

One of the main advantages of the instrument is the possibility of using a.c. amplification. Further, since the probe does not make contact with the surface, no galvanic current is drawn from the source of potential and no diffusion potentials are introduced, as by the use of conventional electrodes. The possibility of producing injury potentials through the mechanical contact between electrode and object also does not arise. The use of the instrument is, of course, limited to surface measurements. The vibrating probe electrometer can be used for the investigation of resting potentials and their slow changes in time (growth, external influences), or for the study of the electric potential distribution across an extended surface; it could also be adapted for the measurement of action potentials. With the present arrangement and a probe area 2-mm^2 readings could be obtained only within 2–3 mv. It is hoped that the noise level can be still further reduced with more adequate shielding, and by using an electrometer tube of lower input capacity. This would permit the use of smaller probes, and even microprobes for the mapping of microscopic electrical structures. The instrument has been used in preliminary experiments for the mapping of surface potentials of various plant materials, and the observation of diffusion processes in ionic solutions.

[3] The amplifier has been placed at the disposal of one of us (O.B.) by the National Research Council of Canada in connection with another research problem.

Book Reviews

Molecular Spectra and Molecular Structure. I. Spectra of Diatomic Molecules

By Gerhard Herzberg. Second edition. Pp. 658+xv, Figs. 207. D. Van Nostrand Company, Inc., New York, 1950. Price $9.75.

The first edition of this book, published in 1939, was the leading book in its field. In fact, there was no other book to compare with it for the excellent presentation of the material, for comprehensiveness, and for the large number of references to the original literature. Although the subject of molecular structure and molecular spectra is complicated, the reader was introduced to these complexities gradually, so that he did not become aware of the complexity too soon. The book was illustrated with a wealth of spectrograms, energy level diagrams, potential energy curves, and other figures, and provided with tables, which helped to bring abstract theory down to earth and make the presentation vivid. Although this subject can be understood only with the aid of considerable theory, based on quantum mechanics, the theory was kept as simple and non-mathematical as is practical in a book of its caliber. Furthermore, it was written both for the beginner and the research worker. The sections that were not necessary for the understanding of fundamentals were put into small type, so that the reader could omit them if he wished. A great deal of the less important mathematical theory was put into small type.

The second edition is a revision of the first edition, but a rather complete and thorough revision to bring it up to date by adding new material and to improve the presentation. The general plan and character of the book is the same as before. In fact, the chapter titles are exactly the same as before, and the titles of sections are the same except that three new sections have been added.

The chief differences will now be pointed out. The book has considerably more mathematical theory than the first edition. However, most of this mathematical theory is in small type so that the reader can omit it if he wishes. This additional mathematical theory makes the book much more valuable and transforms it into a higher caliber book more useful for advanced students and research workers. It should be added, however, that the mathematical discussions are never long and extended developments, but succinct and sometimes summarizing the work of various investigators. When derivations are given, they are relatively short and simple. The book is not a book of the mathematical deductive type, in which the effort is made to prove or to indicate the proof of everything from first principles.

Twenty-six new illustrations have been added. New sections have been added on Radiofrequency (Microwave) Spectra, Hyperfine Structure, and Intensities of Electronic Transitions. Other additions have been made in sections contained in the first edition. Among these are a treatment of the Stark effect in diatomic molecules, a discussion of the polarization of resonance fluorescence, and the Hönl-London formulas. The discussion of van der Waals binding has been greatly expanded. A figure showing the simpler symmetric top eigenfunctions has been added; these are available nowhere else in the literature. Many sections have been completely rewritten. Thus the treatment of the theory of rotation and vibration has been improved by the introduction of more mathematical theory.

A very valuable feature in the appendix is a table of the vibrational and rotational constants for the electronic states of all known diatomic molecules. This covers 80 pages and evidently required an enormous amount of work to assemble. The bibliography has been brought up to date and now contains about 1600 references. The book has both a subject and author index. The subject index includes all the more important symbols and quantum numbers as well as all the molecules treated. Thus the book is a most useful reference book, both because of the wealth of material in it and the excellent index.

For anyone from beginning student to research worker this book by an outstanding authority is to be highly recommended. In fact, it is practically indispensable to anyone interested in diatomic molecules and their spectra.

Enos E. Witmer
University of Pennsylvania

Advances in Catalysis, Vol. II

Edited by W. G. Frankenburg *et al.* Pp. 292. Academic Press, Inc., New York, 1949. Price $6.80.

It is not possible to write thirty-odd pages on a particular aspect of catalysis without introducing the flavor characterizing an author, a school, or a piece of specialized research. It is not an easy task to combine nine of these flavors into a tasty book. That is, however, what the editors of *Advances in Catalysis* have done once again in their second volume and their boldness deserves encouragement. The special subjects are well chosen and provide a broad, perhaps slightly fuzzy, scanning of the field. The personal bias of each contributor is readily detectable as it should be in reviews of this kind. It is gratifying to spot the name of a solid-state physicist in the table of contents, but after reading the paper of F. Seitz, the chemist will certainly be disappointed because it treats in a very elementary style the Eyring concept of rate processes. The physical chemistry student of today is perfectly aware that "each atom consists of a central, positively charged nucleus which contains practically all the mass of the atom and which is surrounded by a cloud of electrons." A collaboration between catalytic chemists and solid-state physicists in the realm of solid appears highly desirable and further articles by the latter *on a more advanced level* would be welcome in the *Advances*. G. M. Schwab gives a brief summary of the kinetic relationships encountered in catalytic work. The exposé of O. Beeck is especially interesting because it contains much long-awaited unpublished material, presented in a "pro domo" but highly stimulating fashion. The importance of entropy of adsorption is emphasized by C. Kemball: it gives some indication of the extent to which adsorbed molecules may translate freely on the surface, of dissociation and association in a localized adsorption film and of phase changes. More about adsorption entropy will undoubtedly be heard in the near future so that Kemball's survey comes at the right moment. The more technically minded reader will find much interest in the contribution of L. Schmerling and V. N. Ipatieff, some fifty pages on the mechanism of the polymerization of alkenes. The authors review the different mechanisms which have been proposed for such reactions during the past fifteen years; they favor the carbonium ion mechanism which permits one to systematize a great deal of experimental data; they point out however that in this case "the word ion has a different connotation than it does in inorganic chemistry." No one could give a better idea of the recent progress in hydrogen fluoride catalysis than J. H. Simons whose chapter is complete and critical. Simons discusses the mechanism of HF catalysis in a careful and convincing style: in order to make a point, he even prefers to write 10,000,000,000,000 instead of the less expressive 10^{13}. T. H. James does an excellent job in reminding the catalytic chemist about the rich domain of catalytic phenomena related to photographic development; the work of Hautot *et al.*, at Liége could have been mentioned in this review, especially since it does not appear to be sufficiently known in this country. In their effort to present the many facets of catalytic research, the editors finally include an historical account of multicomponent catalysts by A. Mittasch who played a decisive role in their early study.

Summing up, the book will be a valuable acquisition to the library of an advanced worker in catalysis. It can be fully appraised only if it is considered as a part of "the compilation of papers written by competent specialists," which the editors continue to build up, it seems, with considerable success.

Michel Boudart
Princeton University

Medical Physics, Vol. II

Edited by Otto Glasser, Editor-in-Chief. Pp. 1227, 978 illustrations. The Year Book Publishers, Inc., Chicago, Illinois, 1950. Price $25.00.

In 1944, when the first volume of *Medical Physics* was published, the Editor-in-Chief listed three ideal objectives of the book and described the difficulties encountered in attempting to achieve these objectives. Dr. Glasser and his associates are working toward (1) a compendium of the knowledge in medical physics, including comprehensive bibliographical references; (2) a text for students of medical physics; and (3) a handbook of data for the use of those working on specific problems in the field. When the two volumes are examined, the magnitude of the problem of effective presentation becomes apparent, and the energy, judgment, and breadth of knowledge of Editor and authors are not only apparent, but amazing.

If any doubt the size of the problem, the following physical data on the two volumes of *Medical Physics* may be convincing: Vol. I (1944), 1792 pages each 7¼ by 10¾ in., 1382 illustrations; Vol. II (1950), 1227 pages, 978 illustrations; total weight of the two volumes, more than 12 pounds. Page size, two-column format, type, and jacket are the same for both volumes.

Volume II contains some material published in the 1944 volume, revised to bring it up to date; but the major part of Vol. II is new material comprising articles on subjects not listed in the earlier book and articles that are supplements to those appearing in 1944. Many articles published in the 1944 volume are listed by title in Vol. II to help the reader to use the two volumes together.

The need for Vol. II arises from two circumstances: first, data on some subjects—such as aviation medicine and the production and use of both stable and radioactive isotopes—were known but not available for publication in 1944; and second, the whole field of medical physics has undergone a highly accelerated expansion during the last six years. The range of subjects discussed in *Medical Physics* is extremely broad, including applications of statics, dynamics, electromagnetism, optics, quantum physics, molecular, atomic, and nuclear physics to anatomy, physiology, physical anthropology, physiological chemistry, pathology, and pharmacology; and the interrelation of these applications to medical specialties such as internal medicine, surgery, radiology, physical medicine, neurology, ophthalmology, otolaryngology, dermatology, and urology.

Topics are arranged in Vol. II—as they were in the earlier work—alphabetically, and some closely related topics are kept together by means of subtitles. An example appears at the beginning of of Vol. II. A 10-page article by M. S. Livingston entitled Accelerators: High Energy is devoted to the electrostatic generator, betatron, cyclotron, synchrotron, synchro-cyclotron, linear accelerator, and proton-synchrotron. The article on the betatron by D. W. Kerst and L. S. Skaggs is entitled Accelerators: High energy; Betatron; it occupies 10 pages and it is placed after the above-mentioned article on Accelerators by Livingston. This sounds clear-cut and orderly, but medical physics refuses to fit into a simple pattern. The article on the betatron discusses briefly but clearly the possible uses of the device in therapeutic radiology. To analyze this material effectively the reader may want to look up information on absorption phenomena for high energy x-rays in tissue, depth-dose measurements, positron-electron pair production, and biologic effects of radiation. Each of these subjects is listed in the 36-page index of Vol. II and in the 43-page index of the original volume.

Thus the user of these volumes can learn to find the articles dealing with subjects he particularly wants to investigate, and he finds relatively little duplication of information in articles on related topics. Furthermore, the reader will be amply repaid for the time and effort he devotes to finding out how the books are organized.

The relation of physics to biology and medicine might be likened to the relation of hormones to physiology: the methods of physics have stimulated the solutions of problems in biology and medicine in the most surprising and remotely separated fields. It is not surprising that it is difficult to present medical physics in a manner that is at once brief, simple, and comprehensive.

The Editor and contributing authors are to be congratulated on their notably successful efforts to achieve their objectives. They have worked together to attain two apparently mutually exclusive results: the articles on related subjects are well correlated to avoid unnecessary duplication, yet each author appears to have written independently to present his material as he thinks best. The authors of articles on subjects with which this reviewer has some familiarity are men and women who are not only extremely able investigators but also effective expositors. From this fact, and from the presence in the list of authors of the names of so many well-known scientists in other branches of medical physics, it may be inferred that this happy result has been achieved throughout both volumes.

Extensive bibliographical lists, appended to nearly all articles, and the inclusion in the Name Index of authors of articles in *Medical Physics* and of authors of reference papers in the journals, improve both flexibility and usefulness.

In universities, hospitals, government laboratories, and industry there is a potent and increasingly coherent effort to bridge gaps between the several branches of science. To recognize the strength of this development, and its scope in both the philosophy of science and in research, it is sufficient to note such diverse publications as the lists of papers prepared and issued by the U. S. Atomic Energy Commission, and the book *Cybernetics* by Norbert Wiener. *Medical Physics* is an important exponent of the trend toward interscientific research and development.

University of Pennsylvania

Collision Processes in Gases

By F. I. Arnot. Pp. 104+viii, Figs. 37. John Wiley and Sons, Inc. New York, 1950. Price $1.25.

This little book gave an excellent account of its subject in 1933 and nothing has been added since, although the publisher lists the monograph as "fourth edition, 1950." The last sentence refers to the "neutron recently discovered by Chadwick." For its treatment of atomic collisions up to 1933, however, this reviewer can recommend it.

Walker Bleakney
Princeton University

Wave Filters

By L. C. Jackson, Pp. 107+vii, Figs. 64. Methuen and Company, Ltd., London, and John Wiley and Sons, Inc., New York. First published in February, 1944, second edition in May, 1946, third edition in 1950. This book is one of Methuen's Monographs on Physical Subjects, a "series intended to supply readers of average scientific attainment with a compact statement of the modern position in each subject." Price $1.25.

Chapter I serves as an introduction to the broad subject of wave filters, and includes a brief review of their main applications in the fields of radio, telegraphy, telephony, and acoustics. Chapters II and III present the classical treatment of uniform, lossless ladder structures, "constant *k*" filters and "*m*-derived" filters. Examples of coupled circuits, crystal filters, and coaxial-line filters are briefly discussed in Chapter IV. Chapter V treats the effects of dissipation and of mismatched terminations on the behavior of the filters discussed in Chapters II and III. Practical suggestions regarding the design and construction of filters may be found in Chapter VI. The last chapter discusses the analogy between electrical and mechanical systems, and gives a few illustrative examples of mechanical and acoustical filters. A very brief bibliography is provided at the end of the monograph for those readers who wish to pursue further the subject of wave filters. It is unfortunate that such well-known books as Guillemin's *Communication Networks* and Bode's *Network Analysis and Feedback Amplifier Design*" are not included.

Apart from a few misleading statements, the treatment of the subject is clear and correct. It might provide an introductory (and necessarily superficial) knowledge of wave filters to a reader totally unfamiliar with the subject. This knowledge, however, would be insufficient for the solution of many practical filter problems, even outside the difficult fields of television and telephony. As an example, band-pass ladder structures of the "constant *k*" and "*m*-derived" types cannot be built in many cases because of the impractical sizes of the inductances and capacitances. Appropriate network transformations, which are not discussed in the monograph, need to be employed in such instances in order to obtain satisfactory element values.

The treatment of wave filters presented in this monograph is basically still that of the original papers published by Campbell and Zobel in the early twenties. Truly, some of the most recently developed techniques of filter design are too involved to find place in a short monograph. Still, it would be helpful to many readers to know at least that direct synthesis procedures are available which permit the solution of many practical problems for which the simpler types of filters are inadequate. Moreover, the tremendous progress in network theory that has taken place since the pioneering work of Campbell and Zobel has led to simplifications as well as to involved refinements. For instance, more general and yet simpler treatments of wave filters are possible, which should not require any more space than Chapters II, III, and IV. I am thinking in particular of the use of lattice structures for design purposes, and of the impedance-level and pass-band normalizations which simplify considerably the derivation and the evaluation of the element values.

The monograph by L. C. Jackson is intended to strike a compromise between a catalog of filter designs, and a treatise on network theory. This reviewer feels that an elementary treatment of the general properties of filter networks would constitute a more useful compromise, both as an introduction to a treatise on network theory and as a means of providing sufficient knowledge for the effective use of a filter catalog.

R. M. Fano
Massachusetts Institute of Technology

The Kinetic Theory of Gases: Some Modern Aspects

By Martin Knudsen. Third edition. Pp. 64+vii, Figs. 20. Methuen and Company, Ltd., London, 1950. Price $1.25.

This little book contains principally a clear and pleasing description of the author's own illuminating and important experiments on certain phenomena in gases at low pressures. The topics treated are evaporation and condensation, flow of gases through tubes, resistance to motion, thermal molecular pressure, the author's absolute manometer, and the coefficients of accommodation in relation to the conduction of heat and to mechanical reactions of the radiometer type. The density of the gas is in all cases kept low enough so that the molecules perform individually, with little interference by molecular collisions.

The scant attention paid here to the work of others was appropriate when the manuscript was first prepared in 1933 as a basis for three lectures given at the University of London. The designation of this as the "third edition . . . 1950," however, has converted into an error the author's statement on p. 60 that the radiometer force at high pressures is an edge effect; this surmise as to its nature has been definitely disproved.

The short title used on the cover and on a fly leaf inside, simply *The Kinetic Theory of Gases*, is grossly misleading. The full title is obviously hard to abbreviate concisely; but it seems unfair to prospective readers to imply that the book is a general treatise when in reality it covers only a few selected topics. The introductory remarks on the fundamentals of kinetic theory are adequate for the author's purpose but are very limited in scope.

E. H. Kennard
David Taylor Model Basin

Introduction to Vector Analysis

By B. Hague. Fourth edition. Pp. 122+vi, Figs. 39. Methuen and Company, Ltd., London, and John Wiley and Sons, Inc. New York, 1950. Price $1.25.

This excellent little monograph, first published in 1939, is designed as an introduction to the principles of vector analysis for physicists and engineers, who are interested in obtaining a familiarity with vector techniques and an ability to use them in their own fields. The subject matter is well chosen and well organized, and the presentation is exceptionally clear. As stated in the preface, "the outlook adopted is almost entirely physical; geometrical matters and questions of an exclusively mathematical interest are limited to essentials. Formal proofs of invariance and conditions of continuity in vector processes are replaced by an appeal to physical intuition." This point of view renders the subject matter very much more readable and understandable to students who want only a working knowledge of vector methods.

The book is more likely to satisfy the needs of engineers than of physicists. The latter will regret the omission of some very useful topics, such as a treatment of vector relations in general orthogonal curvilinear coordinates, Green's theorems, the equation of continuity, and perhaps also a brief discussion of wave motion. The section on polar coordinates should be amplified to indicate the ways in which they are applied to the solution of physical problems. Also, a brief treatment of coordinate transformations and the metric tensor would have been a valuable supplement to the chapter on linear vector functions.

It is regrettable, also, that the book does not contain a limited number of well-chosen problems to accompany and supplement the text, since only by working with vectors can readers acquire a working knowledge of vector techniques. Such a set of problems would make the book self-contained for those who are learning vector analysis for the first time, without detracting from its value as a brief and lucid review of the subject for engineers and physicists who need a refresher course. The problem set could also include a number of vector relationships to be verified, thus providing useful additional material for reference purposes.

Because of its clarity and readability this monograph will continue to be a very valuable aid in the teaching of vector analysis.

Simon Pasternack
Brookhaven National Laboratory

Practical Analysis, Graphical and Numerical Methods

By F. A. Willers. Translated by Robert T. Beyer. Pp. 422+x, Figs. 132. (A modified translation of the German edition: *Methoden der praktischen Analysis*, Berlin and Leipzig, De Gruyter, 1928.) Dover Publications, Inc., New York, 1948. Price $6.00.

The translator has rewritten Section 3 to describe the Standard American slide rules. T. W. Simpson wrote Section 6 which discusses thoroughly the features of the three standard (Friden, Marchant, and Monroe) American desk calculators and some of the more important operations that may be performed with them. The remaining 33 sections of Willers' book have merely been translated. Consequently, a large fraction of the material is chiefly of historical or academic interest. In this category can be placed many of the excellent descriptions of graphical methods and mechanical devices. The real worth and usefulness of Willers' book are results of the simply and carefully written sections on numerical methods which are replete with the solutions of illustrative problems from the fields of engineering, physics, astronomy, etc. In many of these examples, the physical data and the work sheets are given in complete detail. Each of the sections was intended to be a unit independent of the rest of the book. For the most part the author has merely separated the sections on numerical methods by interposing sections on graphical methods and mechanical devices. The uncluttered derivation and presentation of the standard formulas together with the abundance of applications make *Practical Analysis* a valuable reference work for anyone who has occasion to do computing.

Chapter I, entitled Numerical Calculation and its Aids, is divided into six sections. The material covered here is: calculation with approximate values (significant figures), graphing functions, the slide rule (with applications), linear interpolation (with a complete analysis of the error involved), nomograms, and desk calculating machines (with many short-cut methods for doing other than routine computations).

In Chapter II, Interpolation, the standard finite difference formulas for interpolation, differentiation, and integration of functions of one or more variables are derived. The discussion starts with a treatment of divided differences and is particularly to be recommended for its clarity and conciseness. In this chapter, except for the Lagrange form of the interpolation polynomial, Simpson's rule (called the Kepler barrel rule on p. 125 and elsewhere) and two formulas for cubature, the principal formulas are presented in finite difference form using only one type of difference notation (Δ-delta, in one variable). The adoption of a simple symbolism is one of the reasons that the book should be useful for reference purposes. The formulas are usually written with the remainder term.

For the most part Chapter III, Approximate Integration and Differentiation, presents the standard formulas for summation and numerical integration in terms of the ordinates of the function. The first section is devoted to a description of Coradi's integraph and of several graphical methods. On p. 170, note 7, a rather cumbersome form of the remainder term in a special Simpson's rule is derived. But, in the next section the author (following Steffensen) derives an elegant form of the remainder term for the closed-type integration formulas. The numerical integration methods of Tschebyscheff and Gauss are carefully explained. The theory of the planimeter is thoroughly developed and several models are described in the last section.

Chapter IV is entitled Practical Equation Theory. In Section 18 several methods for calculating the roots of an equation or system of equations are described (false position, iteration, Jacobi's transformation, and Newton's method). The next section treats special methods for finding the roots of a polynomial (Horner's method and various graphical methods). Section 20 discusses Descartes' rule of signs and the Sturm series for determining the number of roots of an equation. Application of the Sturm series and of various graphical methods to the location of the complex roots of an algebraic equation are made in Section 21. The next section gives a too brief account of Graeffe's method. An elimination method and several graphical methods for solving a system of linear equations is described in Section 23. This work is not especially adapted for the use of desk calculators. Some discussion of the error produced by using approximate coefficients is given. In the last section several iteration procedures for solving a system of linear equations are described.

Chapter V, entitled Analysis of Empirical Functions, is concerned mainly with the theory of least-square approximation by polynomials, harmonic analysis, period analysis, and the representation of a function as a sum of exponential functions. The last two topics are incompletely treated.

Chapter VI, Approximate Integration of Ordinary Differential Equations, is the final chapter. Several graphical methods of integrating differential equations are described and illustrated in the first section. In the next section, the Runge-Kutta and Adams-Bashforth methods are described. The method of iteration is developed with the use of two types of integration formulas. The method of Milne is not described. In Section 24 the graphical and numerical procedures to be used in the solution of differential equations of higher order are described. The last section is devoted to an interesting description of several integrators of first-order differential equations and of the Knorr integrator for equations of second order of a special type.

Each section of the book is followed by a list of references (mainly German) to the literature. There are 132 figures in the text which materially improve its readability. Some of the diagrams suffered in reproduction.

The field of computing and numerical analysis has grown since Willers wrote his book. Many of the modern techniques are therefore not to be found in *Practical Analysis*. However, any book which is well written will prove to be quite valuable until it is replaced by a later well written book. The reviewer knows of no book in the field which can match the spirit and quality of Willers' *Practical Analysis*.

EUGENE ISAACSON
New York University

The Organization of Industrial Scientific Research

BY C. E. KENNETH MEES AND JOHN A. LEERMAKERS. Second edition. Pp. 383+vii. McGraw-Hill Book Company, Inc., New York, 1950. Price $5.00.

Two well-known leaders in the field on industrial research discuss in this 383-page book a subject of utmost importance. The first edition of this book was written by Dr. Mees in 1920 and it is interesting to compare the development of industrial research in this country during the intervening 30 years of the contents, scope, and size of the book. Dr. C. E. Kenneth Mees is particularly qualified, as Director of Research of the Eastman Kodak Company, and as a recognized leader in the field of industrial research, to write on the subject.

The book is divided into three parts. Part I discusses general principles, Part II discusses agencies for the conduct of industrial research, and Part III summarizes the organization and operation of industrial laboratories.

Naturally, the organization of industrial research depends to a considerable extent on the industry it serves. Fortunately, the authors have drawn not only on their own wide experience, but have in addition canvassed numerous large and small industrial laboratories for additional pertinent information. Thus, their conclusions are not based only on the experience of the chemical industry but on that of a number of others. At the same time, their observations are not only limited to the experience gained in this country, but also include that of Great Britain, various countries of continental Europe, and some references to the Soviet Union.

Chapters I and II of Part I trace the whole development of scientific research starting from the dawn of history and concluding with the enormous effort, both in manpower and money, which developed during the Second World War. The gradual growth of industrial research, as distinguished from fundamental or basic research, is discussed in Chapter III.

In Part II the various government research agencies and laboratories are examined in detail. Subsequently, the historical development of such well-known institutes as Mellon, Battelle, and Armour, and the various regional research institutes, which serve the interest of particular regions, such as New England, Industrial Research Foundation, Mid-West, and Stanford Research Institutes are discussed. The structure and progress made at the large industrial laboratories are described in a separate chapter.

The most important part of the book is Part III, where the organization and operation of industrial laboratories are discussed in detail. In some of those chapters the authors were ably assisted by S. W. Davidson and R. Halstead of the Eastman Kodak Company and H. H. Race of the General Electric Company. This reviewer recently had had the occasion to discuss the organization and performance of one of our largest industrial research laboratories with the vice-president in charge of research. The latter outlined some of the difficulties large research organizations are running into at the present time. We have over and over again emphasized the importance of team work in research, putting much less emphasis on leadership as expressed in originality and imagination. This reviewer agrees fully with the authors of the book when they state on p. 204 that: "The efficiency and accomplishment of an industrial laboratory depends to a very large extent upon the director. It may be said of research laboratories, as of other human institutions, that they are the reflex of a man. The large industrial research laboratories have passed through a critical stage in which the founding directors are passing and are being replaced by their successors. Their experience shows to how great an extent the success of a research laboratory is dependent upon the individuality of its director. There are laboratories which have had a distinctly successful career and which, with passing of the directors who organized and developed them, have fallen into obscurity. It is extremely difficult, moreover, to find a suitable man to direct industrial laboratories. The director of an industrial research laboratory must be both a scientist and an executive, and he must have an interest in and a capacity for the commercial operations of the business in which he is engaged. The reason he must be interested in the commercial operations of his company is that he must make his laboratory pay; and if he does not know how to do that, no one else can do it for him."

As our industrial civilization grows in complexity the problems it has to solve become more complicated and intricate and this applies particularly to one of the foundations of this civilization namely, scientific research. It is thus fortunate that those individuals that have both the experience and ability to solve those problems share with us in their experience. Everyone interested in industrial research will find this book a highly desirable text and it is heartily recommended to both the business executive and the research scientist.

A. V. Grosse
Research Institute of Temple University

Mercury Arcs

By F. J. Teago and J. F. Gill. Pp. 107+viii, Figs. 50. John Wiley and Sons, Inc. New York, 1949. Price $1.50.

In this small book which represents a slight revision of an earlier first edition, the aim is to cover the important aspects of mercury arc operation including the electrical, structural, and operational. It is intended as an introduction to the subject which will permit the newcomer to orient himself in the engineering fundamentals without the confusion of detail which must ultimately form part of any thoroughgoing study—an objective which the authors attain adequately.

Their discussion of tube structure and function is illustrated with a few well-labeled drawings which clearly show what an arc tube consists of and why. The useful mercury vapor pressure range and the problem of heat removal both by air and water cooling and the effect of cooling requirements on rectifier size is gone into.

In the examination of the electrical relationships multi-phase operation and grid control are introduced at the beginning. Separate chapters are devoted to grid control of voltage and current, and one chapter examines voltage regulation in the absence of grid control with the current in any one arm assumed to follow part of a sine wave. Then current-voltage characteristics are developed on the more general basis of a sine voltage but a current obeying the usual linear first-order equation for a circuit with inductance and resistance. By a simple extension of the phasing ideas thus far developed, the authors "generalize"— this is the best expression for it—rectification into inversion and show how the two functions can be combined to give regeneration.

There follow chapters on wave-form analysis, transformer ratings, and power factor—the latter explaining the possible meaning to be attached to the term in a multi-phase rectifier circuit. Finally, there is a fairly general over-all treatment of the current and voltage relations in the presence of a load and including the rate of transfer of current from one anode to another due to inductance in each anode arm.

At a few places the book takes on briefly the role of a laboratory manual in giving a detailed description of the calibration of a McLeod gauge and the analysis of two circuits suitable for a Pirani gauge.

The treatment is clear throughout and easily followed. The authors give adequate warning regarding the limited validity of their results because of factors omitted from the calculations at some point. A comparison with actual oscillographic results would have been instructive. The book suffers from what might best be called the engineer's point of view. This shows up in two places. The complicated set of equations developed in the last chapter is solved by an approximation which leads to a minor inconsistency, which "is probably due to the fact that (certain variables) cannot be evaluated exactly." Actually, the method of successive approximations would allow these evaluations to be made as accurately as required. Of more importance is the sad unreliability of the description of fundamental arc processes in the introduction, which would make the book an unsafe starting point for someone who required an understanding of the gaseous conduction—and non-conduction—processes. But as this was not the intent of the authors, this shortcoming can be overlooked. The index is good.

Lewi Tonks
General Electric Research Laboratory

Physical Chemistry of Hydrocarbons. Vol. I

Edited by A. Farkas. Pp. 453+x, Figs. 189, 15×23 cm. Academic Press, Inc., New York, 1950. Price $8.50.

In the words of the editor "the purpose of this book is to summarize the physicochemical basis of the new techniques and methods recently adopted by the hydrocarbons industry, and to help the research worker in exploiting these procedures more extensively and more intensively." This book has the virtues and suffers from the defects of most books which consist of independent chapters written by specialists on their respective fields. The average level is high, however, and this reviewer believes that this volume will be a valuable addition to the library of anyone concerned with the more physical aspects of hydrocarbons, and it will be useful to an even wider circle of readers.

The book starts with a compact and excellently written treatment of the application of quantum mechanics to valence theory by G. W. Wheland. Attention is appropriately centered on bonds between hydrogen and/or carbon atoms and the chapter ends with a balanced presentation of the resonance concept and its use in the interpretation of hydrocarbon structures and energies. A chapter entitled The Molecular Structure of Hydrocarbons as Determined by Spectroscopy and Electron and X-Ray Diffraction by M. H. Jellinek turns out to include much less than its title suggests. The portion devoted to spectroscopy consists of a few paragraphs on infra-red absorption and one on Raman spectra. These are not only grossly inadequate but are so poorly written as to be misleading. It would have been preferable to have omitted mention of spectroscopy, especially in view of the fact that this subject is presented later in the book. The rest of the chapter, dealing with x-ray and electron diffraction, is much better.

J. J. Mitchell contributes a well-organized and quite complete chapter on Mass Spectroscopy in Hydrocarbon Analysis. The subjects of infra-red absorption, Raman, and ultraviolet absorption spectroscopy are treated by N. D. Coggeshall in two chapters, the first of which covers the theoretical and molecular structure aspects while the second is devoted to the analytical applications of these branches of spectroscopy. The title of this latter chapter, Optical Methods of Hydrocarbon Analysis, is too general because *no optical methods except the spectroscopic ones are mentioned.*

In a chapter on Electrical Properties of Hydrocarbons by A. Gemant, emphasis is laid on conductivity, and the dielectric constant and dielectric strength are treated quite briefly. The subject of Solvent Extraction of Hydrocarbons is discussed by A. W. Francis primarily in terms of various types of ternary phase diagrams. A feature of this chapter is the inclusion of two tables, one for references to nearly 600 ternary systems involving hydrocarbons, the other for critical solution temperatures for various hydrocarbons in 422 solvents. A chapter on Solid-Liquid Equilibria of Hydrocarbons by M. R. Cines treats melting points, solid-phase transitions, and associated heat effects. There is a good review of the application of melting point measurements to the determination of hydrocarbon purity by both the static (calorimetric) and dynamic (time-temperature) methods. Purification by fractional freezing or melting is also discussed.

The book ends with a chapter entitled Chemical Thermodynamic Equilibria among Hydrocarbons by F. D. Rossini. The first part of this chapter consists of a concise development of the elements of chemical thermodynamics which will be appreciated by those whose thermodynamic background is a little rusty. The remainder contains a large amount of information, in the form of graphs, on equilibrium constants and concentrations and free energies of formation and isomerization for a number of groups of hydrocarbon isomers, homologues, and compounds otherwise related.

The book is attractively printed and only a relatively small number of typographical errors were noticed.

Sun Oil Company

Dipole Moments

By R. J. W. LeFevre. Second edition. Pp. 117+v, Figs. 23, 10.5×17.5 cm. Methuen and Company, Ltd., London and John Wiley and Sons, Inc., New York, 1948. Price, $1.25.

The object of the series of monographs to which this little book belongs is "to supply readers of average scientific attainment with a compact statement of the modern position in each subject." For the benefit of readers unfamiliar with the first edition, it is desirable to indicate the contents of the book. The first chapter summarizes the theory of dielectric polarization and the methods of calculating dipole moments. An apparent misprint gives the word "Methods" instead of "Moments" in the chapter title in the table of contents. The second chapter describes a heterodyne beat and a resonance method for measuring dielectric constant, gives a number of experimental details, and mentions other methods of measurement. The third chapter gives an excellent summary of the work which had been done upon solvent effect in dipole moment measurements prior to the publication of the first edition. It devotes a brief paragraph to the Onsager equation, which is now regarded as fundamental in the treatment of the dielectric behavior of liquids, and does not mention the important work of Kirkwood on the subject. A good account of the relations of dipole moments to the structures of a variety of molecules is given in the next and longest chapter of the book. Special topics are treated in brief chapters on Intramolecular Rotation and Flexibility of Molecules, and Some Anomalous Dipole Moments, and the book closes with a two-page list of dipole moment values selected apparently from the appendix to the *Transactions of the Faraday Society*, Vol. 30, 1934. Subsequently measured values must be regarded as superseding many of those selected for this short list.

This second edition contains only two literature references later than 1938 and is virtually a reprinting of the text of the first edition. The reader will again note the smoothness, clarity, and authority of the presentation of the material evident in the first edition. The strong emphasis on the valuable work that has been done on dipole moments in England is not unnatural since, in so short a book, only a small fraction of the available material can be treated. Most of the various aspects of the relations between dipole moment and molecular structure are interestingly illustrated. Since, however, many papers in the field have appeared since the publication of the first edition, the very slight alterations introduced in the second edition have been insufficient to make it a wholly satisfactory statement of the modern position in the subject. The book remains, nevertheless, an excellent summary of valuable material which should be useful to readers seeking their first acquaintance with the subject and to investigators not wholly familiar with the field.

Princeton University

Elementary Pile Theory

By Harry Soodak and Edward C. Campbell. Pp. 71+ix, Figs. 21. John Wiley and Sons, Inc., New York, 1950. Price $2.50.

The modest size, scope, and price of this book do not prevent the authors from making a real and significant contribution to the open literature of the neutron chain reaction. The economy of treatment should make this a valuable reference for use within and outside of the atomic energy program.

Reactor theory is developed from first principles of diffusion theory and the physical processes of fission and absorption, to the point of application to a slow neutron reactor with reflector. The general method is to follow a neutron through its life cycle and to introduce each new physical process into the calculations. The diffusion and eventual absorption of thermal neutrons is given. The slowing down of fast neutrons is first described in terms of elastic collision, followed by an evaluation of the probability of the fast neutron reaching thermal energy without absorption. The consequences of a finite diffusion medium are introduced, and finally the complete problem is solved involving slow, fast, and intermediate energy neutrons diffusing in a reproducing medium surrounded by a neutron reflector. Critical dimensions are calculated for four cases: the one-dimensional or infinite slab, sphere, cylinder, and cube. Reflector savings are calculated for a finite aqueous reflector by the one group theory, i.e. considering thermal neutrons only. The method of attach by two groups theory, considering both fast and slow neutrons, is given but no specific calculations are made.

The latter part of the book is devoted to the time-dependent diffusion equations and the kinetics of a reactor. The effect of delayed neutrons on reactor control is developed and the transient behavior of a supercritical reactor is developed.

While the book is more brief and less descriptive than that of *The Science and Engineering of Nuclear Power*, C. Goodman, editor, it is better integrated. It makes no pretense of being complete, but rather follows a single possible line of development. In principle calculations may be made for a low power homogeneous thermal neutron reactor with small excess reactivity. The authors do not always indicate concisely the limitations of the method or the exact postulates on which the development is based.

It is to be regretted that security requirements do not permit the application of the methods to real physical systems. The authors have alleviated this situation as much as possible by taking published and hypothetical values of physical constants and evaluating hypothetical cases.

The average student would benefit by a series of problems and a glossary of symbols.

Lyle B. Borst
Brookhaven National Laboratory

The Mathematical Theory of Communication

By C. E. Shannon and W. Weaver. Pp. 117+v. University of Illinois Press, Urbana, Illinois, 1949. Price $2.50.

This book contains two sections. The first section is essentially a reprint of a paper written by Dr. Shannon and previously published in the *Bell System Technical Journal*. The importance of this work by Dr. Shannon is generally recognized in the communications field. In the second section of the book, Dr. Weaver discusses the general analytical approach to the communication problem.

During the past few years a number of new systems for modulating a carrier for the transmission of information have been proposed and developed. The "Hartley" law set down many years ago was found inadequate for dealing with these systems. The present work provides a more satisfactory method of arriving at an answer to the question of how these various systems compare insofar as the "efficiency" with which they transmit information is concerned. One of the most important results of this work is to show that without noise it is possible to transmit an unlimited amount of information in any given interval of time; with the presence of noise the amount is definitely limited.

Dr. Shannon defines the capacity of a communication "channel" for discrete systems such as the teletype in terms of the amount of choice one has of the messages he can send per unit time; and from this he derives the general formula by which the capacity can be computed for any discrete system. This is followed by a general discussion of discrete sources of information in which the theory of stochastic processes is applied and interesting illustrations are given using the English language in which the separate letters are treated as (discrete) symbols. Thus the concept of the statistical nature of communication is introduced. It is found that a useful measure of the quantity of information produced by a specific source is its "entropy." In this case the entropy is defined by direct analogy to methods used in statistical mechanics in terms of the probability of a particular message.

An important problem involved is that of encoding. In general, a message (in whatever form it may be presented) must be coded for the particular modulation system used, and the coding process can, of course, affect the efficiency of transmission. It is shown that a coding process can be devised which will provide maximum entropy with a given channel, and that in the absence of any noise in the channel it is always possible to encode an information source so that information may be transmitted at a rate which is as close as desired to the capacity of the channel. In the presence of noise, information may be transmitted at the same rate, with, however, a finite probability of errors depending on the amount of noise present. It is possible to transmit this information at a reduced rate with an arbitrarily small probability of errors.

In the case of information which is of a continuous nature (such as a speech wave) it is necessary to determine the probability of a particular wave form, for example a particular voltage given as a function of time, $s=f(t)$. It is well known that if a function $f(t)$ is limited to a band width W it can be represented over a period of time T by properly specifying the value of $2TW$ coordinates. The entropy of a source generating a group of such functions can be expressed in terms of the probability distribution of these $2TW$ coordinates; thus the methods used for discrete sources can be extended to the continuous case.

Finally, a few examples are given for the case of random noise for which quantitative formulas are developed. The application of the method to noises not of random character (such as static) which, incidentally, constitute the major source of interference to radio communications is not entirely clear; it is pointed out, however, that in comparing equivalent levels of random noise and non-random noise the random noise will in general provide a greater amount of interference.

In the second section of the book, Dr. Weaver divides the communication problem into three parts or levels as follows:

Level A. How accurately can the symbols of communication be transmitted? (the technical problem)

Level B. How precisely do the transmitted symbols convey the desired meanings? (the semantic problem)

Level C. How effectively does the received meaning affect conduct in the desired way? (the effectiveness problem)

He points out that the work done so far has been almost exclusively at level A. However, one of his main objectives is to show that there is a close interrelation between studies of the problem at the three levels such that an understanding of the problem at level A (especially as presented in the first part of the book) sheds much light on the problems at levels B and C. This discussion is perhaps shorter than it deserves to be but it contains some stimulating ideas which the communication engineer should find of interest even though, in his immediate problems, he will find his work at level A only. In addition, this part presents a rather detailed summary of the main points of the theory of the problem at level A omitting the mathematical developments and may profitably be read first. Unfortunately, the general problem is sufficiently complex so that a certain minimum knowledge of the analytic methods used is required for understanding the theory.

University of Pennsylvania

Physical Methods in Chemical Analysis. Vol. I

Edited by Walter G. Berl. Pp. 664, Fig. 235, Tables 65, References 875. Academic Press, Inc., New York, 1950. Price $12.00.

This two-volume publication, written for the chemical analyst, is a comprehensive guide-book on the instruments and the techniques for determining the physical constants of substances. Volume I deals with mass spectrometry and the interaction of radiation with matter. During the last quarter century, in particular, knowledge has greatly advanced in these fields. Likewise the problems of the chemical analyst are becoming so increasingly difficult that he must turn to the determination of the physical constants of complex chemical substances to give a complete picture of the material. A knowledge of the molecular arrangement and design of such substances may be of importance equal to, or greater than, the knowledge of only its quantitative chemical composition. Here these new methods are of significant help.

The apparatus required, the techniques of experimentation, and the interpretation of results for such studies are not simple. It is thus appropriate to provide for those persons interested primarily in their use as a tool, a collected, simplified, and directive treatment which will make these new developments available to them.

Volume I does this job quite successfully. It is divided into the twelve sections listed here. Each section is written by different authors. Four of these authors are university professors of physics or chemistry, four are engaged in industrial laboratories, and the others are associated with governmental agencies, such as the Bureau of Standards. At least three of them have published books dealing with the material of their sections and others are authors of papers in scientific journals.

The titles of the twelve sections and their authors are: Absorption Phenomena of X-Rays and γ-Rays, George L. Clark; X-Ray Diffraction Methods as Applied to Powders and Metals, William L. Davidson; X-Ray Diffraction as Applied to Fibers, John A. Howsmon; Electron Diffraction, L. O. Brockway; Spectrophotometry and Colorimetry, Wallace R. Brode; Emission Spectrography, J. Sherman; Infrared Spectroscopy, Harold H. Nielsen and Robert O. Oetjen; Raman Spectra, James H. Hibben; Polariscopic and Polarimetric Examination of Materials by Transmitted Light, C. D. West; Refractive Index Measurement, Leroy W. Tilton and John K. Taylor; Electron Microscopy, Robert D. Heidenreich; Mass Spectrometry, Harold W. Washburn.

As may be expected, the different sections vary somewhat in their approach and completeness. Each section starts with an outline which is indexed giving the page number of the discussion of that part of the subject matter. This is a very helpful time-saving feature. The outline is followed, in general, by a discussion of the development of the knowledge in the field leading to the derivation of working equations. Some of this material, very appropriate in its setting, could also serve as a review for the young physicist. The necessary equipment is described, including in some sections information on the sources of commercial apparatus and the characteristics of this apparatus.

The type and scope of the problems which may be successfully attacked are indicated. Several sections show how to evaluate the data. The copious set of diagrams are carefully selected and the tables are particularly useful guides of more than handbook value.

The cover carries the notation "Enough experimental and theoretical data have been assembled to minimize the need of consulting more specialized texts or the original literature." There is included, however, a large reference list of source material appended to each section, totaling some 875 references. To cover such a large field adequately in one book is an ambitious undertaking—it is most likely that the user will wish to refer also to certain of the references to fill in those gaps which space limitations necessitated.

The reader is impressed with the care and thought put into this book to make it helpful to a wide cross section of scientists. It should be available to the experimentalists in the several physical science fields.

Northwestern University

The General Principles of Quantum Theory

By G. Temple. Fourth edition. Pp. 120+viii. No figs. John Wiley and Sons, Inc., New York, 1948. Price $1.25.

This well-received book in Methuen's Monographs on Physical Subjects originally came out in 1934 and has gone through three editions since 1942. The object is to give an introductory account of the general principles which form the physical basis of the quantum theory. The necessary mathematical background is given in the first chapter on the theory of linear operators. This starts with complex numbers, which it is assumed are well understood by the reader, and the ideas are developed in terms of these familiar quantities. They are used to illustrate the less familiar concepts of operators, proper vectors, and proper values. Projective operators, still a familiar idea, further illustrate the development.

The second chapter on the laws of measurement in atomic physics is the core of the book's treatment and sets up the connection between the experimental observations and the quantities used in quantum mechanics. The states of a system are represented by vectors, the variables are represented by linear operators whose average values give the expectation values of the variable for the states represented by the vectors. This treatment throws light on the physical significance of the operations of quantum mechanics, and is done very smoothly, indeed so smoothly that one is almost persuaded that it is being proved that states can be represented by vectors. The elegance of the treatment notwithstanding, this is still a fundamental assumption of the theory. Furthermore, the fact that the sum of two variables is represented by the sum of the operators representing each variable alone is an assumption although the argument on p. 36 gives the impression that this is being proved. The argument, however, is not conclusive. For example, in the harmonic oscillator the squares of the momentum and the displacement are continuous, but their sum which is proportional to the energy is discrete. The operator $X+Y$ is not known *a priori;* but it may be and is assumed to represent the variable $x+y$. Otherwise Chapters 2 and 3 are a good introduction to elementary quantum mechanics, original and less complicated than the usual treatment. Anyone who will take the trouble to understand these chapters will have a firm foundation on which to build together with an insight into what is involved in quantum mechanics.

The fourth chapter introduces the spin operators including the 16 Eddington Dirac operators and their matrix representation. The last chapter treats systems consisting of more than one particle. Temple is adept at discussing the ideas behind the formalism, with a minimum of mathematical detail. The treatment of perturbation theory is a good example of this. Throughout the book familiar results are obtained with little calculation, e.g., the energy and matrix elements of the harmonic oscillator, the energy levels of the Bohr hydrogen atom, the selection rules for the dipole radiation, and Laporte's rule all fall out without effort. It is not expected that all the questions will be answered. We still do things because they give the right answers. The empirical facts of atomic and molecular structure "can be correlated with the general principles of quantum theory only by assuming that antisymmetry is characteristic of pairs of electrons or of pairs of protons." At least we know where we stand in this statement. Numerous examples for solution by the student are well chosen to illustrate and extend the developments of the theory. Even the difficult ones repay in understanding the effort required to solve them. Most of the misprints of the earlier editions have been removed, but there are still a few especially in the problems.

This excellent little book is highly recommended to anyone seeking an understanding of quantum mechanics. It must be pondered over and digested as it is elementary but abstract in its treatment. It is probably too abstract for the beginner, but it covers the meat of the matter as indicated by the books to which it acknowledges indebtedness: Dirac, Weyl, von Neumann, and Heisenberg.

C. W. Ufford
University of Pennsylvania

An Index of Nomograms

By Douglas P. Adams. Pp. 174+ix. Technology Press of M.I.T. and John Wiley and Sons, Inc., New York, 1950. Price $4.00.

Readers of this very useful *Index of Nomograms* will find references to over 1700 published nomograms in well-known periodicals such as *Aero-Digest*, *Aeronautical Engineering Review*, *American Gas Journal*, *American Machinist*, *American Journal of Physics*, *American Journal of Roentgenology*, *American Society for Metals* (*Transactions*), *Biochemical Journal*, *Civil Engineering*, *Chemical Engineering*, *Chemical Industries*, *Electronics*, *Engineering and Mining Journal*, *Engineering News-Record*, *Electrical Review*, *Food Research*, *Heating and Ventilating*, *Illuminating Engineering*, *Iron and Steel*, *Machinery Journal of Mathematics and Physics*, *Machine Design*, *Metal Progress*, *Journal of the National Cancer Institute*, *Journal of the Optical Society of America*, *Product Engineering*, *Power*, *Public Roads*, *Railway Age*, *Rock Products*, *Textile World*, *Welding Journal*, *Water Works Engineering*, and many others.

Users of the nomograms included in this index will save much time in solving equations involving three or more variables and in the repeated solution of design formulas.

The master list index includes 21 fields, i.e., mathematics, physics, hydraulics and power, aeronautics, machine tools, medicine, food, etc.

Users of the *Index of Nomograms* should examine the sections on mathematics and physics because several of the references include material that might have been listed in one of the other categories. For example, in the section on mathematics, reference 1.11, Hopper Edge Slopes, might also have been included in Section 11—building, structures, etc.

Similarly, in Section 2—physics, references 2.11 and 2.12, might also have been included in Section 5—hydraulics and power.

A brief bibliography could have been included for those readers who would be interested in the theory and design of nomograms.

University of California

Microwave Electronics

By John C. Slater. Pp. 406+xiv, Figs. 91. D. Van Nostrand Company, Inc., New York, 1950. Price $6.00.

Lest any of the following remarks be misunderstood, this writer believes that Dr. Slater's book is an extremely valuable contribution to the understanding of phenomena taking place in microwave circuits and tubes. It is much more than a unified resume of "research in microwave electronics conducted at the Bell Telephone Laboratories and at the Radiation Laboratory of M. I. T.," as the fly-leaf states. It is a logical, thorough, basic and easy-to-understand development of several topics, the understanding of which is indispensable to the serious student or research worker in this field. It is true that the book is written on a rather high level, but a reader familiar with Maxwell's theory and equipped with the mathematical background of a graduate student of physics or engineering will find himself well-prepared for its study. He will, moreover, find it to be a very good introduction to many other branches of theoretical physics. Much of the work is original with Dr. Slater, and represents his personal contributions to the rapid progress which took place in establishing microwaves as a mature branch of science and engineering. Some of this material has been published by Dr. Slater under the same title [see Rev. Mod. Phys. 18, 441–512 (1946)] and in the form of reprints, has been used as a text in graduate courses in microwaves as taught by the late Professor W. W. Hansen and his colleagues at Stanford University. There is no doubt that this book will find much use both as a text and as a reference book.

Perhaps the choice of title for this book is misleading. To this writer, a treatise on the subject of microwave electronics would imply the study of the basic *electronic* phenomena at the very high frequencies. In this category would belong such topics as the mechanism of exchange of energy between electron beams and r-f fields in the presence of space-charge; the theory of space-charge waves with given boundary conditions; the general expressions for density and velocity modulation under transit time conditions as expressed by the Llewellyn-Petersen equations; high frequency random phenomena, such as noise; and other related topics. To be sure, Dr. Slater devotes one chapter to these general problems, and does, indeed, describe the various microwave electronic devices such as the klystron, magnetron, traveling wave tube, etc. But the one chapter on the general subject, and specific topics by way of illustration, do not seem to justify the general title that this book has been given.

The first half of the book is devoted to such topics as: the wave guide with perfect and imperfect walls, standing wave ratio, impedance, and mode concepts, power and energy relations, the analogy between transmission line equations and Maxwell's equations, the theory of resonant cavities, and numerous basic concepts associated with cavities.

It is interesting to note that the treatment in this half of the book no longer begins with a consideration of lumped circuit and transmission line relations. The field concept is used immediately. Impedance, power flow, standing wave ratio, etc., are defined in terms of electromagnetic field components. The powerful tool of expansion of fields in terms of orthogonal modes serves for the analysis of wave guides and cavities. Dr. Slater has not only been pioneering in this field of applying electromagnetic theory to microwave transmission problems, he has also given us an exemplary lucid exposition of this generalization of circuit concepts. Further developments of this circuit theory given in the book include applications to more complex wave-guide circuits and wave-guide discontinuities. The reader is admirably introduced to these subjects and the methods presented may be applied to a wide class of problems. For example, Dr. Slater's analysis of discontinuities in wave guides by application of standing wave solution and the symmetry properties of the structure quickly and simply lead to equivalent circuits; moreover, the analysis predicts what laboratory information needs to be accumulated to establish the constants of these circuits. Several kinds of structure are analyzed in the text, such as an iris in a wave guide, a "T," a "Magic T," coupling loops in cavities, etc. It is not hard for the reader to use these methods to learn and to describe the behavior of other structures. This part of the book appears to be especially useful as a text. The treatment here is, however, not quite as thorough as in the earlier part of the volume. The results could well be complemented by following up the references to some of Bethe's and Schwinger's original work.

The second half of the book is devoted to electronic devices. The klystron, the linear accelerator, the traveling wave tube, the cyclotron, the synchrotron, and other devices are described and analyzed with typical clarity. All the chapters are well written and form an excellent introduction to the various applications of the microwave art. An effort has been made to bring together the various classes of devices which now appear to have a common origin. For example, Dr. Slater points out that the klystron amplifier does not need to be restricted to the conventional form of two or three resonant cavities along an electron beam. More cavities can be used, spaced closely together. This, in the limit of zero spacing between cavities, becomes the problem of continuous interaction of r-f field with a beam thus resembling both the traveling wave tube and the linear accelerator. Thus the reader is made aware from the start of the similarity among several devices which appear, at first glance, to be so radically different and unrelated.

This reviewer believes that a more generous use of references would have been helpful in the second half of the book. Since most of the work in the first half was self-contained, and often original with Dr. Slater, references were not essential. In the second half, however, the descriptions are often brief and necessarily incomplete. Greater reference to the abundant literature would have been helpful, especially where existing parallel analyses have been written from a different viewpoint and lead to conclusions which, at least on the surface, are not identical with Dr. Slater's.

Edward L. Ginzton
Stanford University

Vector and Tensor Analysis

By Harry Lass. Pp. 347+viii, Figs. 101, McGraw-Hill Book Company, Inc., New York, 1950. Price $4.50.

This book is the first to appear in McGraw-Hill's newly projected International Series in Pure and Applied Mathematics and, as such, will be greeted with interest by all those acquainted with the uniform excellence of the familiar companion series in physics.

The book is intended as a text for a course at the first-year graduate or undergraduate senior level, and is liberally interspersed with illustrative examples and with a very great number of problems. A large fraction of the text is concerned with the application of vector analysis to mathematics and to physics, there being two chapters on vector analysis proper, and chapters on Differential Geometry, Integration (Real Variable Theory), Static and Dynamic Electricity, Mechanics, and Hydrodynamics and Elasticity. The last two chapters in the book treat tensor analysis and its applications.

Because of the number of applications of vector analysis, the treatment of each field is brief and concise. Although it would be generally agreed that each of the fields of application treated would be of value to students of mathematics or physics, it would appear that the brevity of the treatments would render comprehension difficult for the average student. There are fundamental conceptual difficulties in each of the fields, and these concepts must be carefully learned before the manipulatory aspects of the field can be intelligently handled. To illustrate the techniques of vector analysis by applications to a number of fields each of which is strange and bewildering to the student would almost certainly result in an identification, in the mind of the student, of some of the mystery and strangeness with the vector analysis itself. Nor may it be expected that the students who use the text are apt to have previous familiarity with an appreciable fraction of these fields. Thus the chapter on Electricity includes such relatively advanced topics as the solution of Laplace's equation in spherical coordinates, introducing Legendre polynomials. It is to be regretted, also, that electrostatic units are used in the Electricity chapter, reversing the almost universal trend to m.k.s. units and placing an additional and unnecessary impediment in the path of those students who have had a prior course in electricity.

The two chapters on tensor analysis introduce the subject in full generality, with the repeated index convention, and in n dimensions. The applications are to differential geometry and to relativity theory. The elements of Riemannian geometry are simply and clearly introduced, and these chapters will afford the young physicist a clear and valuable introduction to this branch of tensor analysis. It is the reviewer's experience and opinion, however, that three-dimensional Cartesian tensors merit separate treatment and are best introduced before consideration of the generalized tensor analysis. Despite the popularity of the more modern fields of atomic physics, the classical fields of elasticity and mechanics are still important branches of the science, and these fields are rendered awkward at best if tensors are avoided. It indeed seems strange and anachronistic to observe the author of a book with the title of this one engaging in all sorts of devious manipulations to avoid the use of tensors in the chapters on elasticity and mechanics. The author is, in fact, essentially forced to introduce tensors prematurely in the section on the dynamics of a rigid body when the moments and products of inertia are written in a square array which, it is pointed out, "will be shown in Chapter 8 to be a tensor." Nevertheless, the whole subject of principal axes and principal moments is treated without benefit of the theory of tensor eigenvalues, and the Euler equations are presented in the complicated and untransparent form required by the avoidance of tensor notation.

Those who are apt to find the book most valuable are seniors and graduate students who happen to have sufficient background in mathematical physics to follow the chapters on applications with some ease and who will use the volume as a reference book in the elements of theoretical physics and perhaps as an introduction to generalized tensor analysis. These students will find the chapters on applications well written and well planned and will find the chapters on tensors clear, understandable, and direct.

H. CALLEN
University of Pennsylvania

Aerials for Centimetre Wave-Lengths

BY D. W. FRY AND F. K. GOWARD. Pp. 172+x, profusely illustrated. Cambridge University Press, London, 1950. Price $3.50.

This book of the Modern Radio Technique Series is a companion volume of one by R. A. Smith on *Aerials for Metre and Decimetre Wave-Lengths*. It is intended to review the wartime developments in microwave antenna technique with emphasis on the radar system requirements, basic design principles, and typical performance data. The mathematical analyses as well as the detailed design information has a fairly complete coverage on microwave antennas developed during the war. It will be a valuable reference book for a radar system engineer.

The first chapter is devoted to the functions and system requirements of microwave antennas. Methods of scanning and types of coverage determined primarily by the tactical needs are reviewed. The electrical and practical requirements are properly covered.

In the second chapter, the basic concepts of the polar diagram theory are discussed. In dealing with microwave antennas where the dimensions are large as compared to the wave-length, two simple and powerful mathematical techniques are commonly used both in analysis and synthesis. The physical optics supply the relationship between the polar diagram and the current or aperture distribution. Whenever one has to deal with divergent waves, the geometric optics usually provide the direct and satisfactory solution.

The rest of the book is divided into three parts: point sources and double-curvature focusing devices, line sources, and cylindrical focusing devices. The chapter on primary point sources is descriptive in nature. The sources are usually designed experimentally, without the benefit of reliable quantitative theory, to feed double-curvature focusing devices such as reflector and lenses. In dealing with focusing devices, emphasis is put on off-axis properties and synthesis. The subjects on line sources and cylindrical focusing devices are treated in the same way.

Many practical considerations on electrical design and construction are given which will be helpful to radar antenna engineers.

L. J. CHU
Massachusetts Institute of Technology

Elements of Heat Transfer and Insulation

BY MAX JACOB AND GEORGE A. HAWKINS. Second edition. Pp. 229+xvi, Figs. 79. John Wiley and Sons, Inc., New York, 1950. Price $4.00.

The first edition of this undergraduate engineering textbook, published in 1942, has been widely adopted; the second edition seems to be an improvement on the first. The approach is a practical one and a great many examples of typical engineering interest are given. The basic concepts involved are satisfactorily developed. A physicist confronted with a practical heat transfer problem would find this book very useful as a first reference. Presumably what is lacking here can be found in the senior author's masterwork, *Heat Transfer* ($12.00).

The new edition differs in that 16 sections have been added or completely revised; the new material is slightly more difficult (or sometimes just more detailed) than that in the first edition. The number of problems has increased from 83 to 220. There are four chapters on conduction (including the unsteady state), three on convection, a considerably revised chapter on radiation, and others on heat transfer in condensing and boiling; combined effects of conduction and convection and of conduction, convection and radiation; experimental determination of conductivities and emissivities; heat transfer in temperature measurements; and heat transfer and fluid friction.

There is a logical stress on graphical and numerical methods, and on dimensionless analysis. Units are more carefully handled than is usual in engineering texts. The British gravitational system is used throughout, save that the authors take some pains to limit their use of the word "slug," preferring instead the pound mass. In this, of course, they do not stand alone. The symbols recommended by the American Standards Association have been adopted. There is a lot of empirical information on properties of materials and the heat transfer characteristics of queerly shaped objects.

Poisson's equation is derived in one dimension and stated in three dimensions. Rigorous solutions for this equation are derived for only a few simple cases; some other solutions are given without proof. The student will need to know the elements of differential equations.

The authors differentiate between a temperature and a temperature difference, using symbols such as °C and C, respectively, for these quantities. The reviewer agrees with the need for such differentiation; perhaps the notation used for many years by the late A. G. Worthing—°C and C°—is better in that it corresponds more closely with the spoken words "degree centigrade" and "centigrade degree."

Among the examples of interest to physicists is a method (Vidmar, 1918) for determining the maximum temperature t_{max} inside a current-carrying coil from measurements of the surface temperature t_s and the mean coil temperature t_m; the latter is easily found from resistance measurements. The simple relationship $t_{\max}=t_s+1.5(t_m-t_s)$ is derived.

University of Pittsburgh

Analytical Absorption Spectroscopy, Absorptimetry and Colorimetry

Edited by M. G. Mellon. Pp. 618+vii, Figs. 281. John Wiley and Sons, Inc., New York, 1950. Price $9.00.

The announced purpose of this book is to present those aspects of absorptimetry and colorimetry that are "of most practical concern in a modern chemical testing and analytical laboratory." Because of the wide range of problems encountered in such laboratories, a wide variety of analytical techniques is needed. It is virtually impossible for one individual to be thoroughly informed on all of them and their associated instrumentation. A comprehensive survey of one of the most useful techniques—that of absorption spectroscopy—is therefore bound to be of value to analytical chemists, whatever their special problems or interests.

The same wide applicability that makes absorption spectroscopy of general interest also makes it difficult for one individual to write authoritatively on all the many ramifications of the subject. (This limitation applies as well to book-reviewers!) The editor of *Analytical Absorption Spectroscopy* has wisely chosen a group of nine specialists in the field to write one chapter each on his specialty. The first, M. L. Moss of the Aluminum Company of America, has written a comprehensive account of the preparation of samples for spectrophotometric or colorimetric analysis. This chapter goes far beyond sample-handling procedures, and includes an extensive discussion of chemical procedures for the development of appropriately colored compounds when the substance to be analyzed is not colored. The chapter includes many examples of these procedures, two valuable tables summarizing methods for analysis of inorganic and organic substances (with references), and a bibliography with nearly six hundred entries.

The second chapter, by the Editor, is devoted to the physical basis of the subject. Terms are defined with care, fundamental physical principles such as the laws of emission and absorption of radiation considered, sources of error are examined in general, and conventions followed by workers in the field are summarized. Then come two chapters on Color Comparimeters and Filter Photometers, respectively, by W. B. Fortune of Eli Lilly and Company, and R. H. Müller of New York University, in which these two types of instruments are treated in detail.

Spectrophotometers for the ultraviolet and visible are the subject of Chapter 5 by K. S. Gibson of the National Bureau of Standards. Here a general discussion of basic concepts, and of the elements of spectrometry and photometry is followed by a survey of typical instruments and methods. Of special value is the detailed consideration of the operating characteristics and practical modifications of two widely used instruments—the Hardy-General Electric spectrophotometer for the visible and the Beckman model DU for the ultraviolet. The chapter is completed with an examination of sources of error and an account of methods of recording data.

Next comes a brief survey of photographic methods, in which E. R. Holiday of the London (England) Hospital pays chief attention to instrumental and optical devices for getting round the many difficulties of photographic photometry. This is followed by an extensive account of the analytical applications of spectrophotometric data by E. I. Stearns of the Calco Division of the American Cyanamid Company. In the reviewer's judgment, Stearns' chapter is one of the most valuable in the book for the analytical chemist. Not only does he consider in detail the very practical aspects of the effects of temperature, concentration, *p*H, solvent, and the like on the use of absorption spectra in analysis, but also gives a remarkably thorough account of the different methods for proceeding from observed absorption data to analytical results. The chapter closes with specific examples of the use of ultraviolet and visible spectra in analysis, especially for certain natural products and dyes.

Chapter 8, Spectrophotometers: Infra-Red Region, by L. J. Brady, Air Reduction Company, is rather heavily weighted with optical and electrical material, and gives very brief treatment of infra-red analytical methods. It appears to the reviewer that when one has a budget of 76 pages to devote to the analytical uses of infra-red spectroscopy, 10 pages on elementary prism optics, and 20 pages on detectors and amplifier circuits are unwarrantedly large amounts of material on these topics. This is especially true if it leads one to devote only one page to non-dispersive infra-red gas analyzers (which are not adequately treated anywhere in the present textbook literature) and two paragraphs and a table to the highly important subject of qualitative infra-red analysis. The subject of quantitative analysis is well handled (20 pages).

The final contribution, on the measurement and specification of color, by D. B. Judd of the National Bureau of Standards, is an interesting and (for the analytical chemist) unusual chapter. It is an authoritative summary of the physiological basis of color specification, and of various practical and short-cut methods of color-specification by material standards. It should give the analyst a clearer quantitative understanding of the physics and physiology of color, and of why these subjects are of direct importance for his own work.

The reviewer has no serious adverse criticism to make. It does appear that the editing of the volume has been rather loose in the sense that the various chapters have been written by the contributors with little concern for integration. There are many instances of this: the analysis of Vitamin A is treated for four or five pages in Chapter 1 and again for four pages in Chapter 7, with no cross-reference other than that afforded by the index. The basic question of optimum solution transmittancy is discussed twice, once in Chapter 7 and once in Chapter 8. The long discussion of prism optics in Chapter 8 is applicable to other regions of the spectrum as well as the infra-red (incidentally the Cauchy index formula 8.22 on p. 450 is not generally correct for the infra-red). A complete section (5.14) of six pages is devoted to filter photometers in Chapter 5, although the preceding chapter presumably covers this topic completely.

There is some evidence that the book has been rather long in the publication stage. Although the references are quite complete up to 1946, very few since that date are cited. No discussion is given of the important Cary recording ultraviolet spectrophotometer, although this instrument has been on the market since 1947 and is in wide current use as an analytical tool. The double-beam version of the Perkin-Elmer infra-red spectrometer is not mentioned, although it was first described in the literature in 1948.

Apart from such minor matters the book is well done, and will be a worth-while addition to the library of the working analytical chemist.

Laboratory and Shop Notes

Stark Effect Absorption Cells for Microwave Spectroscopy*

D. H. Baird, R. M. Fristrom, and M. H. Sirvetz
Mallinckrodt Chemical Laboratory, Harvard University, Cambridge, Massachusetts

July 7, 1950

STARK effect absorption cells in wave-guide form have been extensively used in microwave spectroscopy; the most common type is that introduced by Dakin, Good, and Coles[1] in which the Stark field is applied between the wave guide and a central "tongue." Its principal disadvantage lies in its relatively high attenuation which increases with frequency. We have found that transmission becomes a problem with this type of wave guide at frequencies above 35,000 mc.

For operation at higher frequencies we have tested two new forms of Stark effect wave guides. The two types of guide complement each other in use; the "slotted" type is useful for searching and general work, and the "parallel plate" type is useful for the study of Stark effects.

The slotted guide[2] consists of a section of rectangular guide (usually *K*-size, ½ in. × ¼ in., because of voltage limitation) slotted along the "no current line" (see Fig. 1). The two halves are supported by insulating clamps and the edges of the guide painted with porcelain cement. This allows the two halves to be juxtaposed while still permitting the application of sufficient Stark voltages between the two halves. Transmission of a 6-foot section of this type of guide runs about 90 percent at 25,000 mc. Because of the presence of the slot it is necessary to enclose the guide in a gas-tight glass envelope with mica end plates. It is also advisable to shield[4] completely the system electrically to avoid pick-up in the detecting system.

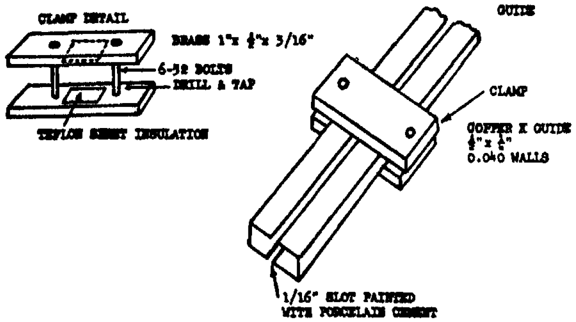

FIG. 1. "Slotted guide" construction details.

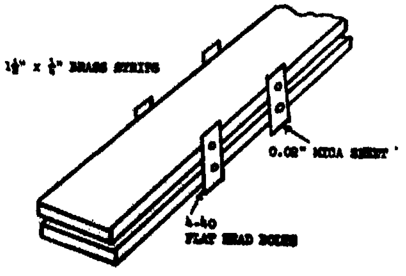
The slotted guide introduces only slight changes in the boundary conditions as seen by the dominant H_{01} mode of the microwaves, and, hence, very long lengths may be used, giving high sensitivity. Unfortunately, this end is achieved only by distorting the applied Stark field to the point where the use of Stark effects for obtaining additional information is completely lost. (At the same time, however, the advantages of Stark effect *modulation* are retained.) This guide has been operated up to 40,000 mc, and it is expected that it will allow operation throughout the millimeter region.

FIG. 2. "Parallel plate" guide construction details.



Another guide of very different physical appearance was first described by Gordy;[3,4] it is the "parallel plate" type which consists of two long flat metal plates separated by insulating posts (see Fig. 2). Microwave energy is fed into the system by means of horns. The horns have been found to transmit more than 75 percent of the energy input and are broad-banded. The most satisfactory method of construction of horns has been an electroforming process in which a form is cut from Woods metal and electroplated with silver and finally with copper until a wall of convenient thickness is formed. The Woods metal is melted out by boiling water and the horn is cleaned with steel wool and mounted. Convenient plate widths and separations (4 cm × 0.1 cm) allow satisfactory operation in the *K*-band, and increase of the width to 8 cm allows operation at 40,000 mc. As with the slotted type of guide a glass envelope should be used with an electric shield. The chief advantage of this type of guide would appear to be in the attainment of high Stark fields (by the use of closer spacings of the plates). We have attained fields as high as 20,000 v/cm and are able to resolve completely the water line at 22,235 mc $(5_{-1}\rightarrow 6_{-5})$. Transmission properties tend to depend rather critically on tuning, and for this reason the parallel plate guide seems less convenient than other types for preliminary searching operations.

We wish to acknowledge the encouragement and advice of E. B. Wilson, Jr., who suggested the work on the parallel plate guides.

[4] A satisfactory shield is a copper pipe completely enclosing the glass envelope grounded to the two horns feeding the system and to the Stark voltage generator.

Apparatus for Cutting Metals Strain-Free

Robert Maddin* and W. R. Asher**
The Johns Hopkins University, Baltimore, Maryland

July 31, 1950

WHEN a metallic single crystal is plastically deformed in tension, the rotations of the slip plane alter the regularity of the lattice. A simple method of measuring this disorientation or strain is to cut a disk from the single crystalline rod parallel to the active slip plane and to measure the strain by means of a glancing-angle x-ray technique.[1-3] The cutting has previously been accomplished by means of a mechanical saw[2,3] which was followed by polishing metallographically and etching to remove the distortion caused by the cutting and polishing. This technique was recently shown to be faulty[3] since, after removal of a large amount of the surface, the strain still remained. It then became apparent that no mechanical means of cutting a metallic disk from a single crystal could eliminate the extremely high local deformation which seemed to penetrate to great depths.

This present note describes a method for cutting a single crystalline disk from a rod by means of chemical attack. The etching cutter is a modification of one which has been used previously.[4] In Fig. 1 may be seen the detailed drawings of the apparatus. Figure 2 shows a photograph of the apparatus arranged for cutting a disk parallel to a specific crystallographic plane.

The unit consists of a specimen holder (1) which incorporates a simple goniometer containing a V-block upon which the specimen rests. The goniometer is so arranged that the specimen, in this case six inches long by one-half inch in diameter, can be rotated

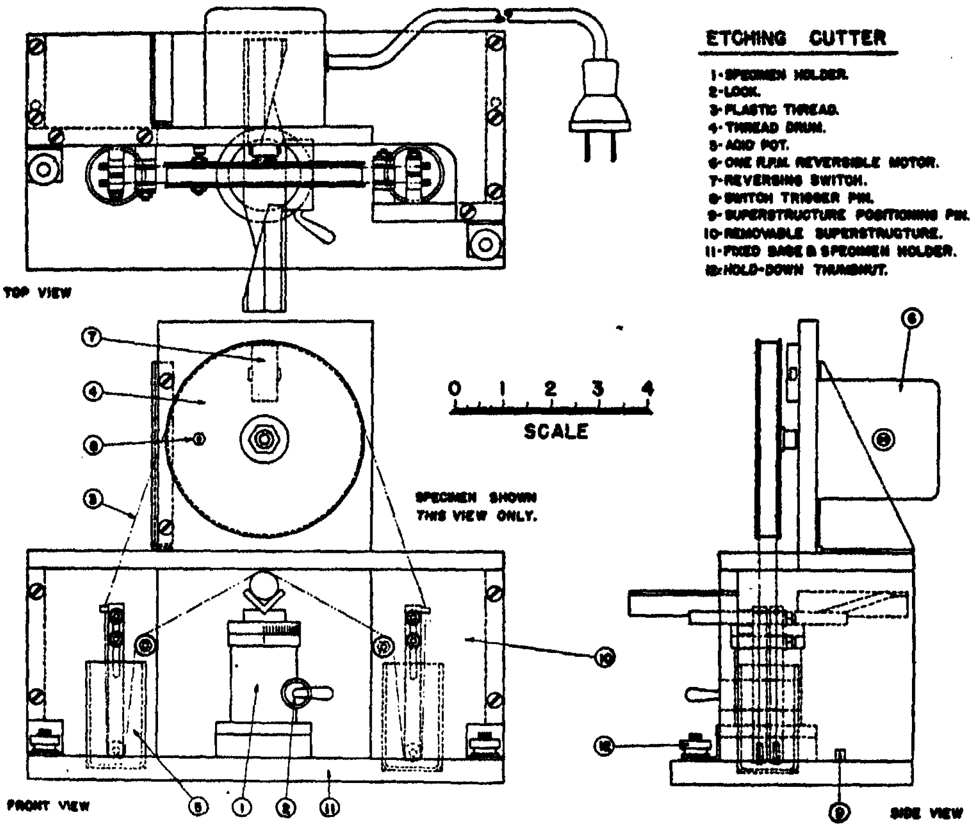

FIG. 1. Drawing for etching cutter.

FIG. 2. Etching cutter arranged for cutting three-eighths-inch disk parallel to octahedral plane of a brass single crystal.

about two axes so that any crystallographic plane may be located. Once the specific plane is located, the goniometer is locked by means of the screw arrangement shown, labeled (2). In the case of brass, a plastic thread (3) (Saran) is wound around a polystyrene drum (4) through a bath containing an eye-pulley down through a bath containing a 1:1 HNO_3 over an idling pulley. The plastic endless thread is led over the specimen over a second idling pulley, through a second tank of HNO_3 and back to the drum again. A second Saran thread is similarly arranged but is kept at a predetermined distance from the first thread by means of slots on the idling pulleys. The superstructure to which the drum is attached contains a 1 r.p.m. reversible motor (6). The drum contains a trigger pin (8) which trips a reversing switch (7) so that continuous oscillating operation may be maintained. The superstructure is composed of plastic and is held in alignment by positioning pins (9) and hold-down thumb nuts.

FIG. 3. Glancing angle photogram of the disk showing sharp Bragg reflection. $\theta = 19°30'$; monochromatic radiation; ten-hour exposure.

To measure the extent of strain induced by this type of cutting, the orientation of a single crystal of brass was determined by the back reflection x-ray Laue method, and a specific crystallographic plane was determined stereographically. The disk was then cut parallel to the $\{111\}$ plane by the apparatus described above. A beam of white radiation impinged on the c-cleavage face of a pentaerythritol crystal. The monochromatic beam was then led through a collimator onto the disk specimen. The disk was set at a theta-angle of 19.5° and was given ten hours' exposure. It may be seen in Fig. 3 that a sharp Bragg reflection results. To insure that a sharper reflection could not be obtained, the disk was annealed for twenty-four hours at 900° C, and another exposure was made. Here again, an extremely sharp Bragg reflection was obtained. This is good evidence to indicate that no strain was induced by this type of cutting.

This work was sponsored by the ONR under Contract Number N6onr 243-21 ONR 031–383.

A High Speed Short Resolving Time Coincidence Circuit for Use with Scintillation Counters

E. F. Shrader
Case Institute of Technology, Cleveland, Ohio

July 31, 1950

The use of non-linear circuit elements in coincidence circuits after the method of Morton[1] and Meyer *et al.*[2] is very attractive, especially when used with the scintillation-type counter. Such coincidence circuits can be made to handle directly the wide distribution of pulse heights which in many cases is characteristic of this type of counter. They can also be made to operate in the pulse voltage range of the photo-multiplier even when the photo-multiplier is operated at conservative voltages. A modification of the Meyer circuit has been developed which realizes these two advantages to a high degree. Because the details of such a circuit have not been widely published, it is felt that a description of one of the many possible variations of this circuit giving its capabilities and limitations will be of value.

The circuit schematic of the coincidence unit is shown in Fig. 1. The input tube (T_1) serves as an impedance changer operating at *essentially unity gain in both input channels.* This provides a high input impedance and insures that the diode bridges will be driven from a source impedance which is not dependent on the input circuitry. The non-linear elements (1*N*34*s*) are incorporated in two bridge circuits which have elements in common. Bridge #1 consists of R_1 and R_3 (R_3 is of course shunted by R_4 and R_2 in series with source #2 impedance) in one side and of D_1 and D_3 in the other side. The other bridge is similar to the first with R_1 being exchanged with R_3 and D_1 being exchanged with D_2. The *grid of the detector tube (T_2) is driven from the diode branch and* the cathode is driven from the resistive branch. Each bridge may be balanced so that there will be no output from the detector for a single pulse applied to either bridge. If, however, the two pulses are applied simultaneously there will be an output because of the non-linear addition of the pulses in the non-linear element D_3. As employed in this circuit the diodes are driven in the forward direction and the coincidence output of the circuit is a positive pulse. The three diodes used are carefully selected and the resistors R_1 and R_3 are matched. The variable resistor R_2 and trimmer condensers (3-12$\mu\mu f$) across the diodes are used to balance the bridges after construction. The balancing is performed using artificial pulses of 0.02μsec. duration. With sufficient care a balance can be achieved such that a single pulse required to give a certain output must be 50 times as large as two equal simultaneous pulses required to give the same output.

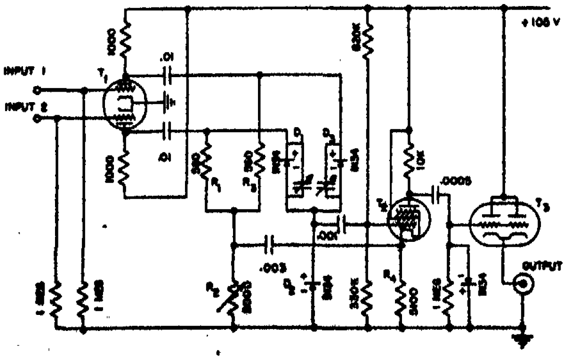

FIG. 1. Circuit schematic of coincidence unit.

In the use of this coincidence unit with the output of a photo-multiplier the scintillation pulses are shaped using the well-known shorted delay line technique. The photo-multiplier output drives a 6J6 cathode follower whose cathode load is a length of RG8U coaxial cable. This cable is shorted at the desired distance beyond the point at which the input pulse for the coincidence circuit is derived. The length of the pulse-shaping line which may be used depends on the time constant of the phosphor and the loss in amplitude of the voltage pulse which may be tolerated.

The output of the coincidence unit is amplified by a wide-band amplifier and registered on a high speed scaling unit (resolving time <0.2μsec.). Figure 2 shows the performance of the unit when tested by the following experimental arrangement. Two 931A photo-multiplier tubes are arranged with an anthracene crystal between them so that real coincidences are observed by the photo-multipliers whenever a scintillation is produced in the crystal by a weak radium source. The coincidence counting rate is plotted against the time delay introduced between the photo-multiplier and the coincidence unit. In each case the time delay required for a 50 percent decrease in counting rate corresponds to twice the length of the pulse-shaping coaxial cable. The curves were normalized to same number of coincidence counts at zero delay.

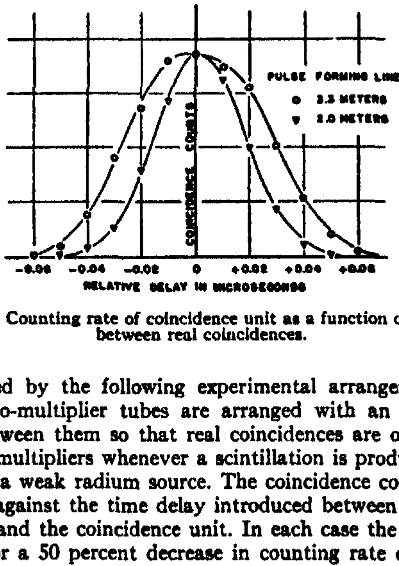

FIG. 2. Counting rate of coincidence unit as a function of delay between real coincidences.

In the above experiment the sensitivity of the over-all system was such that the minimum pulse height excepted was 0.04 volt. By increasing the gain of the amplifier, pulses as low as 0.01 volt can be used with coincidence unit. The amplitude discrimination against single pulses is maintained regardless of the operating voltage range within limits.

The main disadvantages of this type of unit are the difficulties of getting matched diodes and performing the initial balancing. The balancing is made difficult because of the temperature dependence of the diode characteristics. Fortunately, however, thermal cycling does not upset the balance at a given temperature and the stability is good after warm-up period.

This work was aided by the AEC.

Ultraviolet Photon Counting with an Electron Multiplier*

A. H. Morrish, G. W. Williams,† and E. K. Darby‡
Department of Physics, University of British Columbia, Vancouver, Canada

June 23, 1950

THE counting of single nuclear particles using some detecting device such as a Geiger-Müller or scintillation counter, together with electronic pulse counting techniques, has been in general use for years. Recently[1] the decay of some luminescent alkali halides, whose light emission intensity is very weak, was investigated by counting single visible photons. An RCA 5819, which has a large photo-sensitive cathode sensitive to light from 3100 and 6800A, was used together with a conventional pulse amplifier and scaling circuit. It was thought that a photo-multiplier sensitive to the ultraviolet might be useful in certain experiments. A multiplier, whose electrodes were fashioned from sheets of a beryllium-copper alloy after the design of J. S. Allen,[2] was investigated and found to be photo-sensitive to light of wave-length below 2900A. The tube was installed in a metal envelope which had a 3-mm quartz window situated approximately 1.75 in. in front of the first (photo) Be-Cu electrode.

This electron multiplier has been used previously as a particle counter. Allen's paper[2] gives data on its use as an electron counter. J. M. Robson[3] has investigated its use in detecting 10-kev protons and also gives a bias curve for the counting of the gamma-rays from RdTh (2.62 Mev). Several authors have investigated the tube's properties for counting other ions.[2,4] The recording equipment used in this experiment is similar to that used for particle counting, consisting of a pre-amplifier and linear amplifier with maximum gain of 5000. A commercial scale of 64 and mechanical register were used to count the pulses. The first electrode was operated at high negative potential and the collector close to ground potential.

The source of ultraviolet light was the Beckman quartz photoelectric spectrophotometer used as a monochromator with a hydrogen lamp source. Questions of design, slit widths, and stray radiant energy are discussed in papers by Cary and Beckman[5] and by Gibson and Balcom.[6] A Corning No. 9863 Red-Purple Corex A filter is provided with the instrument and was used to remove stray radiation. The filter cuts off below about 2450A.

The beam from the monochromator was fed into the electron multiplier through the quartz window, along the axis of a Bakelite tube. The precaution of using the Bakelite tube proved unnecessary, since the tube was totally insensitive to light above 3000A.

Figure 1 shows the dependence of the counting rate, measured in the scale of 64 per 2 minutes, on the voltage between successive electrodes of the electron multiplier. Light of wave-length 2500A was used. The shape is similar to the one obtained by Allen[2] for electron counting, but the plateau is reached at about 75 volts less per stage, which may be caused by a slightly different condition of the electrode surfaces. Allen found 100 percent efficiency for counting of electrons of 300-500 volts energy, indicating that it is possible to count all electrons emitted from the cathode by the *uv* photons since they are accelerated to the second electrode by a potential difference which can be of this order. With 4000 volts on the tube and the above discriminator and gain setting, the background was approximately 8 counts per minute.

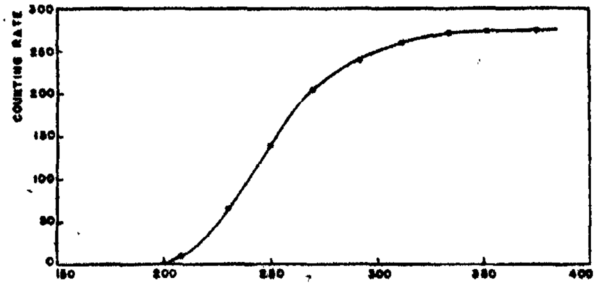

FIG. 1.

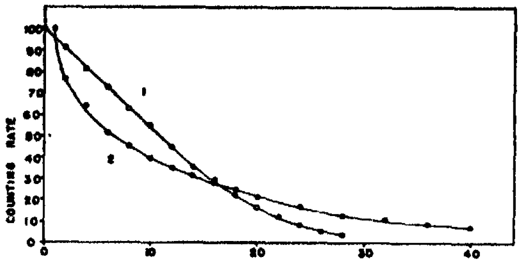

FIG. 2.

Because of the variation of the multiplication ratio for secondary emission there is a wide distribution of pulse size at the output of the electron multiplier. Curve 1 of Fig. 2 shows the counting rate in arbitrary units as a function of discriminator bias. The wave-length of the light used for this curve was 2500A. Bias curves taken for incident light of wave-length 2800A, 2400A, and 2000A coincide with this curve in shape. They, of course, had to be normalized to some point, since the absolute counting rates were different because of the different photo-sensitivity of the tube. This curve is very similar in shape to Allen's curve of the pulse distribution for the counting of electrons.

Figure 3 shows the spectral sensitivity of the tube. The counting rate is plotted on a logarithmic scale as a function of the wave-length of the incident radiation.

The assumption was made that the hydrogen lamp emitted the same number of photons in a given frequency interval from 2000 to 3000A, inasmuch as the intensity distribution from a hydrogen lamp in this region has not been determined very precisely.[7]

The curves at the right are upper edges of the sensitivity curve multiplied by a factor of 100. The dashed curves appear to show that appreciable counting rates are obtained above 3000A. This was shown to be caused by scattered radiation below 2400A, because when the red-purple filter was used the solid black curve was obtained at long wave-length settings. This curve fitted into the curve taken without the filter just below 2700A.

Fused quartz was used as the window to the multiplier, and in the Beckman, and, since quartz varies considerably in its absorption properties below 2200A, the drop in the sensitivity curve below this wave-length may have been caused by this and the assumption of constant number of photons emitted from the H_2 lamp rather than lowering of the sensitivity of the Be-Cu cathode.

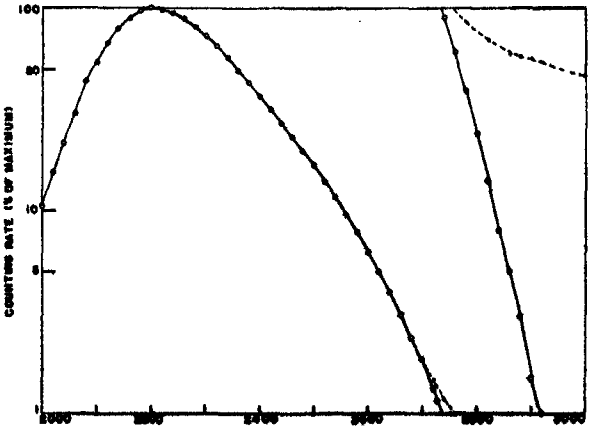

FIG. 3.

By using the value of the threshold obtained from this experiment, the work function of Be-Cu is determined to be 4.2 volts.

In order to obtain the quantum efficiency of the tube in the ultraviolet region, its response was measured using a source of thermal radiation. The light from a hot platinum wire was collimated and directed at the first electrode. The temperature of the wire was measured with an optical pyrometer. The quantum efficiency was found to be about 7×10^{-4} at the wave-length of maximum sensitivity, 2000A. The efficiency at other wave-lengths is proportionately less as indicated by Fig. 3.

The efficiency and pulse distribution for high energy photons was investigated using gamma-rays (1.17 and 1.33 Mev) from Co^{60}. A lead collimator was constructed, and the gammas were directed at the first electrode of the multiplier. From a knowledge of the strength of the source and the solid angle, the efficiency at zero bias was calculated to be 0.1 percent.

Curve 2 of Fig. 2 shows the pulse-height distribution curve for the gammas. It is similar in shape to that obtained by Robson[4] using a RdTh source of gammas (2.62 Mev). The efficiency he obtained was 0.2 percent for these gammas.

Comparison of the bias curves in Fig. 3 shows a number of pulses, caused by the gammas, bigger in amplitude than those caused by the *uv* photons. Also, there are more small pulses. Since the efficiency for the *uv* photons of 2200A and for 1.2-Mev gammas is about the same, and the bias curves are markedly different, it seems that the mechanism for the production of electrons in the two cases is different. Since the *uv* photon bias curve is similar to that obtained for electron counting, it suggests that single *uv* photons are being counted. While *uv* photons accomplish electron emission because of the photoelectric effect, those caused by the gammas are obtained by Compton collisions. The scattered electron evidently is capable of knocking out several electrons in some cases, and this will account for the large pulses. The smaller pulses may be caused by scattered gamma-rays striking electrodes other than the first and giving rise to a smaller pulse, since then a smaller number of electrodes are available for amplification of the signal by secondary emission.

It was found that the decay of luminescent CaF_2 could be detected with the tube. A CaF_2 crystal was irradiated with 55-kv 3 ma x-rays at room temperature at a distance of 4 cm for 15 minutes.

The observed counting rate was plotted as a function of the time after irradiation. The decay observed was of the form $I=at^{-n}$, where n is 1.17 in this case.

In view of the great amount of literature concerning mitogenetic radiation,[8] and conflicting views on its existence, a preliminary attempt was made to detect ultraviolet photons from onion roots. Counting rates with and without a bundle of onions placed before the quartz window were determined for the same period of time. In one experiment the counting rate was 158 counts in 16 minutes with the onion roots as compared to 152 counts without the onions in the same period of time, so that, within the limits of the sensitivity of the tube, apparently no mitogenetic radiation was observed. The authors wish to thank Professor O. Blüh for suggesting the experiment on mitogenetic radiation, and for preparing the samples of onion roots.

No suitable phosphor was found for use with the tube as a scintillation counter.

Preparation of Carbon Targets

G. C. Phillips and J. E. Richardson
Rice Institute, Houston, Texas

July 7, 1950

In investigating the $C^{12}(d, n)N^{13}$ and $C^{12}(d, p)C^{13}$ reactions in this laboratory, it was found necessary to prepare thin, pure carbon targets on light silver foils. A thin backing was needed to prevent the positrons from the N^{13} from backscattering and to enable observation of the long-range protons in the forward direction. Targets prepared by depositing soot or by evaporating ceresin on silver foils were found unsatisfactory as the composition and the thickness of the soot is unknown, and the ceresin was found to evaporate under bombardment when deposited on a thin foil.

We have devised a method of cracking benzene on silver which produces a pure, uniform carbon target free from the abovementioned difficulties.

A Hubert's Model 22 Deluxe oven was used to produce the temperature necessary to crack the benzene. A three-mil silver foil was mounted on a silver disk and placed in a Vycor tube which was sealed at one end. The open end was connected to a bottle of benzene and a vacuum pump. The Vycor tube was evacuated and the pump was then applied to the benzene until all air over the benzene had been removed. The hose to the pump was closed, and the benzene vapor was allowed to fill the tube. Then the hose to the tube was closed, and the target end was inserted in the oven which had been pre-heated to 1500° F. With the oven held at this temperature, any number of targets can be prepared simultaneously in six or seven minutes. The target thickness, of course, depends upon the amount of benzene used and the time in the oven. Care must be taken that the temperature of the target has dropped below that at which carbon burns before air is admitted to the tube.

We have prepared several targets in this manner which were found to be very uniform. This uniformity was checked by comparing the observed width and shape of the $C^{12}(d; p, \gamma)C^{13}$ 1.435-Mev gamma-ray resonance[1] to the width as calculated from the thickness determined by the yield. The thickness of a target was determined by comparing its yield with that from a thin ceresin target of known thickness and with a thick graphite target. These targets were found to have a carbon deposit of about 25 μg per cm^2. This corresponds to a thickness of 8 kev for 1.4-Mev deuterons.

Isotopically enriched C^{13} targets were prepared from methyl iodide which was purchased from the Eastman Kodak Company of Rochester, New York. The methyl iodide had been enriched to 48 percent C^{13}. As the methyl iodide was quite expensive, a more efficient method of preparation than that described above was devised.

A $\frac{1}{32}$-inch thick nickel disk of 1-inch diameter was supported in a Vycor tube by means of a quartz support. The Vycor tube was placed inside a single-turn induction coil of a Model 1-A l RCA Electronic Power Generator with the disk at the center of the coil. A sylphon-bellow Hoke valve was placed between the Vycor tube and the vacuum system which included a diffusion pump and a liquid air trap. Two similar valves placed between the Vycor tube and the methyl iodide allowed known amounts of methyl iodide vapor to be sent into the tube. All vacuum seals were made with rubber "O" rings which were found not to be as readily attacked by methyl iodide as was ordinary vacuum hose. The inner seal of the methyl iodide glass container was broken by an iron cylinder which itself was sealed in a glass envelope.

After attaining a vacuum of about 5 mm of mercury, the nickel disk was thoroughly degassed by heating with the induction heater. The valve to the pump was closed, and the desired amount of methyl iodide vapor was sent into the Vycor tube. The induction heater was tuned to heat the nickel disk to red-orange heat which is sufficient to obtain a carbon deposit from the methyl iodide vapor. The cracking process actually commences at about red heat. The iodine was found to deposit on the cooler parts of the Vycor tube, but starch tests showed no traces of iodine on the targets. An additional inner sealed tube was attached to store the unused methyl iodide. The liquid was transferred to the new container by immersing the tube in liquid air.

Seven targets of different thicknesses have been prepared. Of these targets the thickest have a carbon deposit of about 60 μg per cm². Calculations show that about 30 percent of the carbon in the methyl iodide vapor is cracked onto the blank. It was found necessary in the preparation of these targets to freeze the methyl iodide by immersing the tube containing the methyl iodide in liquid air and then pumping off oxygen which was apparently sealed in the tube with the methyl iodide.

A Scintillation Counter for Fast Neutrons*

H. B. Frey
Servomechanisms Laboratory, Massachusetts Institute of Technology, Cambridge, Massachusetts

June 5, 1950

A SCINTILLATION counter, using two type 931 photo-multiplier tubes and a coincidence circuit, in combination with a zinc sulfide phosphor on Lucite sheet, has been used previously as a detector of fast neutrons.[1] A more sensitive instrument is now desirable because the recommended fast-neutron tolerance level has been recently reduced from 200 to 20 neutrons per square centimeter per second. The present tolerance level corresponds to only 0.38 count per minute on the earlier detector. The newer type 5819 photo-multiplier tube with its large photo-cathode on top of the tube makes greater sensitivity possible and allows more of the light from the phosphor to be collected, thereby increasing the signal-to-noise ratio and making a two-channel coincidence circuit for noise suppression unnecessary.

Two drops of thickened polystyrene coil dope[2] were placed on the cathode end of a type 5819 photo-multiplier tube and zinc sulfide powder[3] was mixed with the dope until a stiff white paste was formed. This mixture was spread over the entire photo-cathode area and allowed to dry. An aluminum foil reflector was placed over the phosphor, a Mumetal magnetic shield slipped over the tube, and the assembly enclosed in a light-tight box.

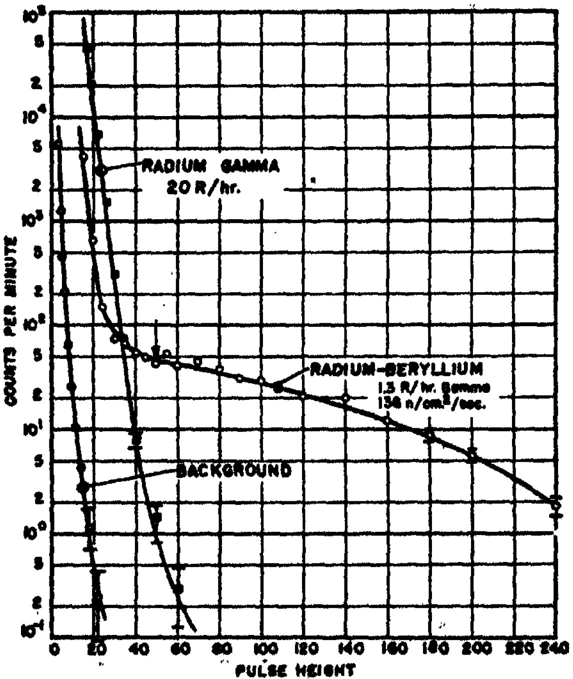

FIG. 1. Integral bias curve for fast-neutron scintillation counter. Arrow indicates pulse-height setting for normal operation.

A linear amplifier and discriminator[4] followed by a pulse counter was used to obtain the integral bias curves shown in Fig. 1. The background curve includes amplifier noise, photo-multiplier dark current, and actual gamma-counts from other sources stored nearby. When data for the radium-gamma-curve were taken, the radiation intensity at the phosphor was approximately 20 roentgens per hour. The radium-beryllium curve was obtained with the phosphor in a neutron flux of 136 neutrons per square centimeter per second and a gamma-radiation intensity of 1.3 roentgens per hour. The radium-beryllium source used had been calibrated against the standard pile at Oak Ridge National Laboratory. With a pulse-height setting of 50, a flux of 20 neutrons per square centimeter per second would correspond to an easily measured counting rate of 7.4 counts per minute.

Making Small Metal Tubes by Electrodeposition on Nylon Fibers

Rolf J. E. Gezelius
Research Institute of National Defense, Stockholm, Sweden

July 7, 1950

METAL tubes with diameters from 1 mm down to 0.1 mm or less are often useful in electronics and instrument techniques. Biological injection needles, eyelets, and indirectly heated cathodes for electron tubes are examples. These small tubes are generally made either by drawing down larger tubes or by electrodeposition on a mandrel. The first method must generally be used for alloy tubes, i.e. stainless steel but the difficulties are considerable in using this method to obtain very small diameters. The electrodeposition method can be used for pure metals but in the deposition on waxed or oxidized threads it is difficult to pull out the mandrel without destroying the tube, especially with very thin walls and small diameters. A variation of the older electrodeposition method of making small metal tubes makes use of the excellent mechanical properties of the Nylon fiber as a mandrel. Drawn Nylon fibers of high strength and with very smooth surfaces are obtainable in exact dimensions.

The first step in making tubes is the silvering of the Nylon fiber by the Brashear or rochelle salt method as used for glass.[1] A better adhesion between Nylon fiber and the silver coating is obtained if the Nylon fibers before the silvering process are dipped in a solution of 1 g $SnCl_2$ in 1 liter of distilled water and then rinsed in two (not more) baths of distilled water. The silvered Nylon fiber is then plated to the necessary wall thickness with the metal desired. In order not to destroy the thin silver coating the electric circuit must be closed before the fiber is immersed in the electroplating bath. Further details on such electroplating work are given elsewhere.[2,3]

The Nylon mandrel may be removed from the metal tube by holding one end of the tube with tweezers and drawing on the free end of the Nylon fiber. The fiber will then contract without breaking and free itself from the inside surface of the tube. It can easily be drawn out. If it is necessary the thin silver coating inside the tube can be removed by short dipping in dilute nitric acid.

Tubes of several inches in length with inside diameters as small as 0.05 mm can be made in this way. Metals such as copper, silver, and nickel have generally been used. It is also possible to make hard and corrosion-resistant tubes of a nickel-cobalt alloy by simultaneous electrodeposition of these two metals.

Volumetric Displacement Flask*

S. D. Snyder, C. J. Craven,** and D. B. Trauger
K-25 Laboratory, Carbide and Carbon Chemicals Division, Union Carbide and Carbon Corporation, Oak Ridge, Tennessee

July 10, 1950

Although many similar displacement flasks have been devised, the authors have not seen one which incorporates all of the features of the flask presented here. This unit has proven particularly useful where very precise gas volume flow measurements are required. Flasks having volumes of ½, 2, 5, and 12 liters have been constructed.

In using the flask shown in Fig. 1, the flow to be measured is first by-passed through stopcock 1 and the liquid drawn into the flask and bulb by closing stopcock 2 and opening stopcock 3 to vacuum. (Dibutyl phthalate is a suitable liquid for many gases.) After reversing the setting of cocks 2 and 3, cock 1 is turned to direct the flow into the flask simultaneously with starting a timer and the collection interval is timed until the image of the leveling point meets the leveling point as viewed from below. The damping tube prevents bubbling at the intake from creating disturbances which blur the leveling point image. Although the pressure in the flask varies throughout the collection, the inlet pressure remains nearly atmospheric and constant since the right side of the trap is open. Pressure variations of no more than ¼ cm of water are observed at the source at the beginning and throughout the collection if the bulb and arms are proportioned as indicated and the collection time exceeds two minutes. Proper leveling of the bulb is obviously important and it is recommended that it be given permanent mounting on a stand. In the larger sizes, it was advantageous to locate the arms and leveling point in a short cylindrical section of reduced diameter which was added to the bottom of the flask. (The volume of the bulb is determined by weighing the displaced liquid.)

Each of the flasks used has been compared with those of adjacent sizes using a constant source of nitrogen from a cylinder and regulator, Moore Products Regulator and critical orifice in series. When the collection time was greater than 2 minutes, the greatest difference in flow measurement was 0.1 percent. The liquid must be completely saturated with the gas if maximum accuracy is to be obtained.

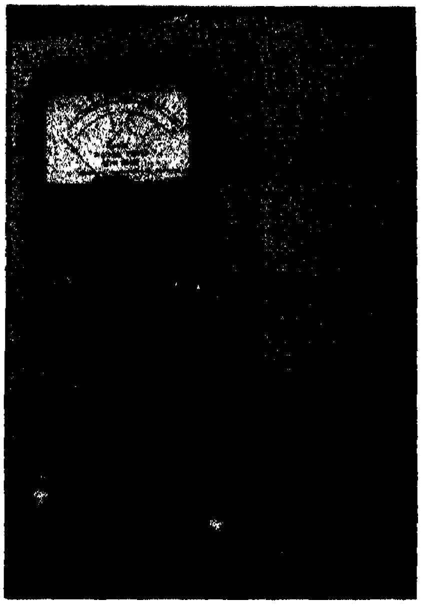
New Instruments

W. A. Wildhack: Associate Editor
in Charge of this Section
National Bureau of Standards, Washington, D. C.

These descriptions are based on information supplied by the manufacturer and in some cases from independent sources. The Review *assumes no responsibility for their correctness.*

Power Level Indicator

For the measurement of non-sinusoidal or otherwise erratic wave forms, a thermocouple or other thermoelectrical device is usually employed. However, a small, robust, and portable instrument using *no* thermocouple, yet giving a similar, true r.m.s. reading regardless of wave form has now been announced.



A new circuit comprising a temperature-limited diode, d.c. amplifier, and feed-back loop will maintain constant power in the diode filament. Accordingly, an unknown current introduced into the filament produces effects which depend only on its heating ability, and a root-mean-square voltmeter can be built having the accuracy associated with feed-back devices. A mathematical approximation involving an error of the order of one percent allows construction of an r.m.s. voltmeter carrying a linear scale in watts. Full-scale measurements of 1 mw, 10 mw, 100 mw, 1 w, and 10 w into 600 ohms are available in the instrument, and accurately corresponding r.m.s. voltage scales are also provided.

The portable instrument, now in production, has a case size of 6×7×12 in., and is suitable for 150-v, 50- to 60-c.p.s. operation. Rack-mounted and special types are also available, including instruments giving a true oscillographic record of power *vs.* time. Applications of this device are the measurement of noise, both the audio- and radiofrequencies, and underwater sound work.—Reed Research, Inc., *1048 Potomac Street, Washington 7, D. C.*

Laboratory Coating Unit

This instrument, designated Type 3108, is designed to meet the following requirements: (1) pump down to shadow-casting pressure (1×10^{-4} mm Hg) in ½ hr. (2) a sales price "below $1000" to be gained without loss of quality by good design, and (3) versatility and ease of operation with special emphasis on filament adjustments.

The individual requirements of various users are so diversified that it was concluded the best way to meet individual demands was to present a base unit with all of the essentials for shadowcasting and to furnish accessories for special requirements.

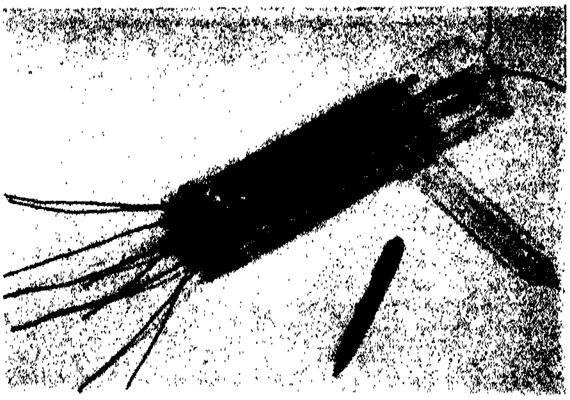
The basic unit consists of a neat table-top cabinet with a 9-in. glass bell jar and a pumping system using a National Research Corporation H-2-P purifying-type three-stage oil diffusion pump, offset from the bell jar by a water-cooled gooseneck manifold, to reduce oil migration into the bell jar to a minimum. This pump is capable of reaching a blank-off vacuum of 2×10^{-7} mm Hg absolute.

A mechanical pump is included in the base unit, as well as a high voltage discharge which acts as a cleaner and degasser for surfaces within the bell jar. The high voltage discharge also serves as an order of magnitude vacuum gauge to indicate when evaporation can take place. A set of high current feed-thrus is furnished with the base unit and they are connected to a 100-watt low voltage transformer for heating the filament.

The basic unit is capable of pumping down to 1×10^{-4} mm Hg in less than ½ hr. If a high vacuum valve and roughing line are added, a reduction in cycle time of 15 min. can be achieved. Two sets of filaments can be provided with the unit and adjusted to move on straight line loci 90° apart, which intersect at the center of the bell jar. The height of the filaments is also adjustable. These two adjustments permit complete control of the oblique angle used for shadowcasting. The filament holders use a new spring design which permits expansion and contraction of the filament during the evaporation cycle. This facilitates filament changes so that longer life and less breakage can be expected.—National Research Corporation, *70 Memorial Drive, Cambridge, Massachusetts.*

R-F Mass Spectrometer Tube

New progress in the field of radiofrequency mass spectrometry has been reported. Improved three-stage tubes of the design of Dr. W. H. Bennett are now commercially available, and complete spectrometers will become available soon.



A new model of the Bennett r-f tube is shown in the accompanying photograph. The tube consists of filament, sixteen grids, and a collector plate, together with the necessary leads and supports, enclosed in an evacuated glass envelope. Masses are sorted by the principle of velocity selection, as described previously [Rev. Sci. Inst. **21**, 578 (1950)].

The grid-holding disks are drawn Nichrome V with grids of knitted ½-mil tungsten wire. Because of the large number of grids, fine wire and an open grid structure must be used to allow large usable beam currents. In the model shown only about 50 percent of the tube cross section is blocked by grid wires.

Insulation for voltages as high as 2000 v and more is provided by glass tubes, running along the outside of the grid structure to each set of grids. Grid-spacing dimensions are held to a tolerance of 0.001 in. by carefully ground spacers. In early models glass spacers have been used, but glass is being replaced by Alumina to improve resistance to shock and vibration.

New models of the tube use monel metal envelopes with ends sealed by screw caps and gaskets. Not only are these tubes less sensitive to shock and vibration, but they can be easily disassembled for inspection, adjustment, and cleaning.

The filament used in this model is a tungsten spiral coated with catephoretically deposited thoria. Emission currents of 1 ma are sufficient to get the usable beam currents of 10^{-7} to 10^{-8} amp. Signal currents from 10^{-9} to 10^{-10} amp. are readily obtained.

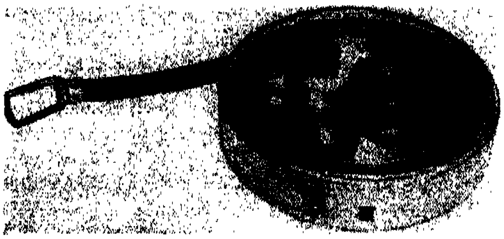
R-f voltages in the order of 5 v at frequencies from 0.1 to 10 Mc represent typical operating conditions. D.c. voltages from 50 to 1000 v are used for ion acceleration.

This tube shows a sensitivity of helium in air of one part in 200,000. Resolution to about mass 40 is possible with suitable circuitry. In operation the tube is apparently sufficiently stable for chemical analysis work, with low background currents. Pressure, emission, and d.c. voltage must be carefully regulated.

Uses of the new r-f mass spectrometer tubes include leak detection, process control, and analytical work. These Bennett tubes have been placed on the market to encourage various laboratories to build and test different types of r-f mass spectrometers, thus contributing to the advance of the entire field of r-f mass spectrometry.—General Electric Company, *1 River Road, Schenectady, New York.*

Spring Motor

New latitude in devising spring motors for cameras, time recorders, mechanical recording instruments, automatic reels, antibacklash mechanisms, and balancing devices is offered to design and development engineers through the Neg'ator—a new type of elastic member made from prestressed flat spring stock. Spring motors designed around the Neg'ator are characterized by two inherent attributes: (1) a constant output torque, and (2) a long running time (large numbers of turns) on a single winding.



The basic Type B Neg'ator spring motor, is made up of three basic parts: the Neg'ator spring itself and two spindles or spools. The Neg'ator band coils on both spindles in opposite rotational direction.

The unusual feature of the Neg'ator which permits the design of such spring motors is its ability to exert constant—or even decreasing—force with increasing deflection. This is in contradistinction to accepted principles of design which suppose that increasing deflections of elastic members can only be accomplished by exerting greater force. This is possible because only a small increment of length of the long Neg'ator coil is being deflected from its natural position at any instant, whereas the entire length of a conventional power or spiral spring is always involved in generating that spring's torque.

Energy is stored in a Neg'ator by deflecting each increment of length—in succession—from its natural radius to a larger radius. Therefore, if a Neg'ator with a natural radius of curvature R_1 is mounted on a spindle of the same radius and forcibly wound onto a spindle of larger radius R_2, the Neg'ator will subsequently run from the larger spindle onto the smaller one when the external restraining force is released. The greater the difference in the radii of the two spindles, the greater will be the torque at the output spindle. Maximum output torque in minimum space is achieved by back-bending the Neg'ator from one spindle to the other (involving the concept of a negative radius). Neg'ator motors can be used for linear motion, recoiling, balancing, and backlash-elimination. For example, hand-power tools on an assembly line can be spring-supported without requiring the operator to fight strong retracting forces while using the tool.

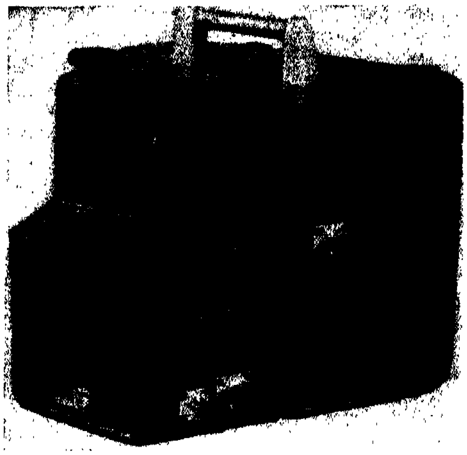
The 50-ft. steel measuring tape illustrated is retracted by a single Neg'ator "B" motor that has the following specifications: small bushing radius, ¾ in.; large bushing radius, 1⅛ in.; blue tempered stock is 0.005 in. thick, ⅜ in. wide, and 250 in. long; life is 5000 cycles.—NEG'ATOR DIVISION, *Hunter Spring Company, 1 Spring Avenue, Lansdale, Pennsylvania.*

2000-M.P.H. Timing Equipment

Velocity and acceleration of objects moving at 2000 m.p.h. can be recorded and measured in a single optical image by a new Beckman & Whitley temporal sequence system based on slit-type camera techniques.

To measure optical phenomena, a slit camera records time sequence in a vertical plane passing through the optical axis of the lens. Besides photographing the event, this equipment automatically records—on the same film—numbers showing elapsed seconds and hundredths with intermediate pips spaced at thousandths of seconds. Printer dials accumulate 1000 seconds per turnover. Longer time periods are handled by an independent tally of the total number of such periods. External time-standard pulses can also be applied to synchronize the timer with events occurring elsewhere. Continuously variable film speed in either direction permits recording events progressing in either direction and at speeds up to 2000 m.p.h. Higher speeds can be accomodated with modifications.

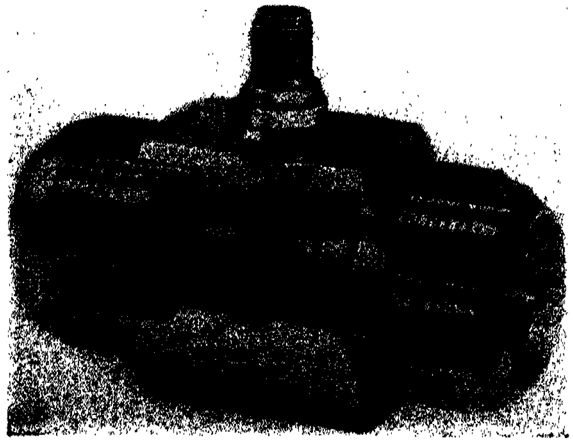
Used optically in this manner, the camera produces a strip picture looking like a conventional stop-action photograph of two-dimensional space. Because it is made with a vertical slip instead of a shutter, the image is actually a geometric plane figure of generation with the horizontal coordinate in terms of time rather than space. Events taking place vertically in the slit plane are expanded horizontally—coordinated with the calibrated time scale. The camera can also be used to make conventional time-and-position intermittent sequence photographs indoors if the object is illuminated with a stroboscopic lamp.



For non-optical events, electrical pulses can be fed to the system and recorded on the film in a specified relation to the printed time sequence. In addition to measuring the velocity and acceleration of high speed objects such as missiles, projectiles, etc., the apparatus is useful for the recording of oscillograph traces and other oscillations taking place vertically within the slit plane, for example, machinery parts.—BECKMAN & WHITLEY, Inc., *936 San Carlos Avenue, San Carlos, California.*

Electronic Flowmeter

The Potter electronic flowmeter comprises a flow-sensing unit having a dynamically balanced rotor and magnet rotating within a non-magnetic housing, and an external pick-up coil connected to an electronic integrator, or totalizer, or both. It features a high efficiency, free-flowing rotor, which the manufacturer claims eliminates such troubles as bearing maintenance, friction drag, and large pressure drop. Fluid flow around the rotor establishes upstream thrust components which exceed the downstream drag factor. This tends to move the revolving rotor axially upstream into an intermediate operating position where no thrust is exerted upon either upstream or downstream supports. This feature eliminates the need for thrust bearings and permits the use of a small-diameter rotor shaft and short guide bearings to journal the



rotor. Fluid from the line is admitted into each bearing through a small vent, so that the rotor actually revolves on a film of liquid.

This design also results in an exceptionally low pressure drop through the meter. One of the major factors which influence pressure loss is blade loading. Since blade loading has been eliminated, the pressure drop is directly related to Venturi efficiency, which can be made quite high.

The housing of the sensing unit is compact (usually a standard AN fitting). It is no larger than the line into which it is installed. Three circular spring clips at each end maintain the guide bearings for the rotor shaft in center. Fluid passing through the housing turns the rotor at a speed determined by velocity of the liquid and pitch of the rotor blades. A cylindrical permanent Alnico magnet within the rotor sets up a rotating field which generates a.c. current in the pick-up coil. Frequency is equal to the speed of the rotor when the magnet is two-pole. A four-pole magnet provides twice this frequency. A single, shielded wire conducts the a.c. current to an electronic unit which either integrates it into d.c. current for operating a rate-of-flow meter, or counts and totals the cycles on an electromechanical counter of the Veeder-Root type.

Since the sensing-element output is an electrical frequency, only flow factors which affect the speed of the rotor can affect the accuracy of the meter. As long as the rotor maintains its balanced position, its blades operate no-slip. Therefore fluid viscosity, pressure, temperature, and specific gravity have very slight effect upon the volumetric flow rate.

Operating temperatures range from 4° A. to 1000°F. Standard housings withstand pressures up to 5000 p.s.i. Special housings can be supplied for pressures up to 20,000 p.s.i.—POTTER AERONAUTICAL COMPANY, *87 Academy Street, Newark, New Jersey.*

Oscilloscope Camera

The F-284 Fairchild-Polaroid oscilloscope camera adapts for oscilloscope recording the Polaroid-Land principle of a "photographic print in one minute." Because of the speed with which prints become available it offers a convenient method of recording oscilloscope traces for immediate study or future reference. No special photographic skill is required to obtain good pictures.

The complete unit consists of an adapter which can be attached to any 5-in. cathode-ray oscilloscope, a light-tight hood which automatically provides the correct focus for the camera, and a standard Polaroid-Land camera body which is equipped with a specially designed high speed *f*2.8 lens and suitable between-the-lens shutter. The camera body is also fitted with a special two-position, spring-actuated shift device which permits two images to be recorded on each photographic print. Each print is 3¼×4¼ in. in size and the recorded image is one-half the size of the scope image. Traces with speeds up to 1 in./μsec. at 3000 v have been recorded.—FAIRCHILD CAMERA & INSTRUMENT CORPORATION, *88-06 Van Wyck Blvd., Jamaica 1, New York.*

Electron-Diffraction Camera

Electron-diffraction cameras are used for the investigation of the structure of matter and particularly for the study of thin films, surfaces, and gases. The process is particularly suitable for the study of surface phenomena, due to the small penetrating power of the electrons. The ease with which electrons are scattered results in an intense diffraction pattern, and therefore exposure times of the order of seconds may be used, as compared with the hours frequently necessary with x-rays.

The Finch-Edwards electron-diffraction camera obtains a constant accelerating voltage with relatively simple equipment. Since a change in accelerating voltage alters the wave-length and consequently the diameter of the diffraction ring, the high tension system must be designed so that the accelerating voltage is highly stable. To secure stability advantage is taken of the fact that the gas pressure and current in the cathode tube and the accelerating voltage are interdependent. The gas pressure is therefore maintained constant by employing a special leak system, while a constant current is ensured by employing the saturation characteristics of a diode. The discharge pressure in the cathode chamber

is maintained at a constant value by a small diffusion pump and a fixed leak from a "leak chamber." The leakage rate is controlled by the leak chamber pressure, which can be raised by adjusting a needle valve or lowered by opening a valve to an evacuated reservoir. Cold-cathode discharge is used to give a beam of high current density, which can be employed for accelerating voltages of 15 to 80 kv.

The usual attachments are provided, and three types of plate holders are available, one of which enables three plates to be exposed without breaking the vacuum, while the second is fitted with a shutter so that the two halves of a plate can be exposed independently for comparison purposes. The third is a single-plate holder for taking one exposure only. Separate diffusion pumps are provided for the discharge and camera chambers with a common backing rotary pump. Both the rotary and diffusion pumps can be isolated from the camera while changing plates, so that only a few minutes are necessary to restore the vacuum afterward. A Pirani gauge head is provided for indicating the pressure conditions and carrying out leak detection.—W. EDWARDS & COMPANY, LTD., *Worsley Bridge-Road, Lower Sydenham, London, S. E. 26, England.*

Manufacturers' Literature

Fast Pulse Amplifier—Hewlett-Packard Journal, Vol. 1, No. 11, July, 1950, describes a new hp Model 460B amplifier, which is designed for a maximum output level of 125 volts open circuit—high enough to permit viewing on a cathode-ray tube.—HEWLETT-PACKARD COMPANY, *395 Page Mill Road, Palo Alto, California.*

Photo-micrographic Camera—Pamphlet GI-27 presents the Model "U" (Universal) camera, which features extreme versatility and convenience of operation. It can be used for micro, low power and macro work, copying, and projection. A great number of accessories are available, including a line of six objectives ranging in focal length from 20 to 250 mm, macro stage, light box for large objects, enlarger head, etc.—GAMMA INSTRUMENT COMPANY, INC., *P.O. Box 532, Great Neck, Long Island, New York.*

Magnetic Amplifiers—Bulletin, entitled "Magnetic Amplifiers—Circuits, Characteristics, Types," introduces three new types now being made available to industry: The High Performance Series, with output powers ranging from milliwatts to 385 watts, the High Gain Series, with outputs from ½ to 1200 watts, and the High Power Series, for 65 to 3660 watts.—VICKERS ELECTRIC DIVISION, *1815 Locust Street, St. Louis 3, Missouri.*

High Power Pulse Transformers—A design manual for pulse transformers, used in magnetron circuits, comprises one section of a report by Armour Research Foundation discussing the theory of pulse transformers and the Armour interleaved winding design. The design manual section permits the development of a pulse transformer to meet within narrow limits given operation requirements. Procedure for all design steps is given, and the calculations for a typical sample design are described for illustrative purposes. PB 100 478, *High Power Pulse Transformer Design and Development*, 229 pages including diagrams, graphs, and tables is available at $8 in microfilm, $28.75 in photostat. Optical Quartz

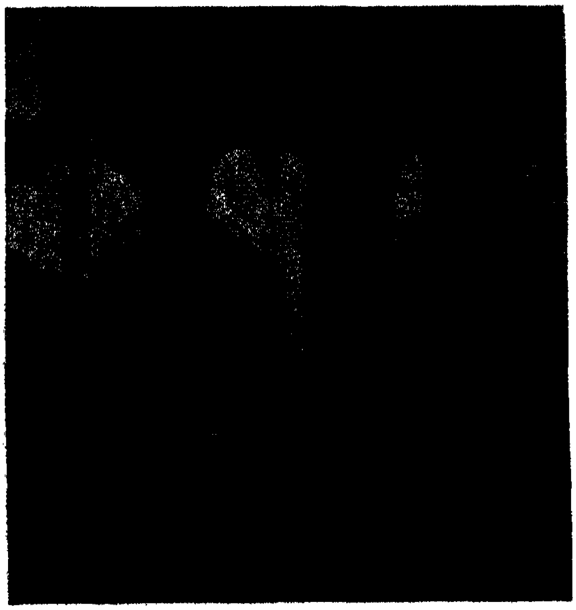
Your editor has received a letter from which the following excerpt is quoted.

"Enclosed is a picture of a remarkable piece of optical quartz which I have recently acquired. It weighs 1000 pounds, and represents the central portion of a crystal which originally weighed four tons. This piece is flawless and wholly free of such optical defects as blue needles, Tyndall effect, bubbles, seeds, Chuva, phantoms, smokiness, or other defects visible in an arc lamp. Due to its enormous size, it has been impossible to examine it in polarized light to determine optical twinning, but as Brazilian quartz, in the



large sizes, is notably free of optical twinning near the center of the crystal, I have every hope that this piece is clean in this respect as well.

"It is my intention to saw this crystal into slabs some 6 to 12 inches thick, measuring parallel to the optic axis, and to examine these slabs in polarized light to detect optical twinning, after which the slabs will be marked off as to the clear portion and sold on the basis of such clear portion.

"This crystal is, in every way, unique and I wish to use it in the most efficient possible manner, both for the sake of monetary return and because such a crystal represents, in a sense, a trust for the benefit of the optical industry. I should, accordingly, like to enlist your help in publicizing its availability so that users who require pieces of quartz of unusual size or purity may be apprised of the availability of this piece. I hope, in this manner, to be able to cut slabs of such thickness as can be most efficiently used by the optical companies concerned."—Dan E. Mayers, *214 East 18 Street, New York 3, New York.*

Flaw Detection

Dy-Chek is an assembly of a red dye, a white liquid developer, and a cleaning and dye-removing liquid, to detect surface cracks and flaws in metal parts. In application the surface is prepared with the cleaner, the dye is applied and then removed with the cleaner and finally the developer is spread over the surface. Flaws show up as red markings where the dye has penetrated and has not been removed by the cleaner. These markings show up in sharp contrast to the white background of the developer. The liquids can be sprayed or brushed on a surface or can be applied by dipping.—Dy-Chek Company, *1513 East Broadway, Hawthorne, California.*

Vibration Isolation

Met-l-flex unit mounts are designed for mounting equipment subject to vibration or shock. They are of all-metal construction and are unaffected in spring rate or damping by extreme temperatures (−80 to 250°C), oil or moisture. High damping is provided by inter-wire friction in the woven-wire cushion, which reduces amplification at resonance and affords greater structural stability in the mounting system. Drift or permanent set in this cushion is negligible.—Robinson Aviation, Inc., *50 Industrial Avenue, Teterboro, New Jersey.*

Abrasion-Resistant Plastic

Enrup is a mixture of nitrile rubber and a thermosetting plastic which can be made in varying degrees of flexibility, and which is described as bridging the gap between soft and hard rubber. It is stated to be a high strength material which is resistant to abrasion and to chemicals and which can be formulated with physical characteristics to meet varying requirements. Tensile strength (varying with hardness) averages 4200 p.s.i.; specific gravity is about 1.3; water absorption is low; and the safe operating range is from 0 to 250°F. It has been used in high strength, low-cost gears which can be molded to close tolerances. In such applications, it is reported that Enrup gears have been in operation for more than a year where metal gears have failed within a few weeks. Other suggested applications include fuel-pump parts, battery cases, valve seats, bearings, tote boxes, electrical insulators and automotive parts. The material is available in the form of sheets, rods, tubes, gear blanks, and as molded parts.—United States Rubber Company, *Rockefeller Center, New York 20, New York.*

Decontamination

Radiacwash is a solution designed for the cleaning of surfaces contaminated by radioactivity. A number of actions, combining the physical and chemical principles of decontamination, contribute to the removal of radioactive contaminants from exposed surfaces. The liquid acts as a detergent, emulsifier, solvent, ion-extractor, surface wetter, and carrier. The maker states that in a laboratory test the radioactivity of a beaker contaminated with radio phosphorus was reduced to a value corresponding to a reading of 4.5 mr for a particular geometrical configuration of object and detector, by repeated scrubbings with water and a strong detergent. Under identical conditions the reading was reduced to 0.25 mr after 3 min. of agitation in the new cleaner.—Atomlab, *489 Fifth Avenue, New York 17, New York.*

Plastic Packing

Super-Seal plastic packing is now made with a securely vulcanized tape back as an integral part. This increases packing flexibility and permits the spiral to be twisted down to small shaft sizes and then cut into rings without breakage. Packing is available in six different styles to cover various ranges of operating conditions, which are clearly marked by different colors on the tape back for identification. These packings are resilient and homogeneous, and are composed of asbestos, antifrictional metal particles, flake graphite, and special binders. They do not harden at elevated temperatures and need not be removed as wear occurs. An added ring in the stuffing box is sufficient to maintain leakproof service. Full service recommendations are included in a booklet available from the manufacturer.—Crane Packing Company, *1800 Cuyler Street, Chicago 13, Illinois.*

Radiant Glass Panels

Pyrex 7740 heat-resistant glass is coated on one surface with a transparent conducting film for radiant heating. Backed by a metal reflector behind the film the panel will radiate 80 percent of the energy input through its uncoated surface. Mounted in a suitable frame it may be used for space heating, process drying, and electrostatic charge dissipation. A $12\times12\times\frac{7}{32}$-in. panel is available in 500- to 1500-watt rating at 110 volts and 1000 watts at 220 volts. Element temperatures range from 410 to 640°F in free air. A $16\times24\times\frac{7}{32}$-in. panel is made for 1000 and 1500 watts on 110-volt input, and 1000 to 3500 watts on 230 volts, with temperatures in free air from 356 to 600°F. Manufacturer's bulletin B-86 *Pyrex E-C Radiant Glass Panels* gives further information and data.—Corning Glass Works, *Corning, New York.*

Front-Surface Mirrors

Zeno-Kote is a process for producing front-surface mirrors having unusual durability and tarnish resistance. The reflecting surface is produced by evaporation of a special aluminum alloy under high vacuum. The reflecting surface is then protected by the deposition of an extremely hard transparent film which does not affect the reflectivity of the mirror but which permits it to be dusted or wiped without injury to the surface. Mirrors produced by this process have a reflectivity of about 93 percent in the visible spectrum, and can be made to meet any optical or dimensional tolerances. Further details can be obtained from the manufacturer.—Zenith Optical Laboratory, *123 West 64 Street, New York 23, New York.*

Metal Cleaning Sponge

A metal cleaning sponge, made of a continuous ribbon of curled monel metal, is now available. It is stated to be soft and flexible to handle, designed so that it will not splinter and injure the hands, and hard enough to insure long wear. Being rust and corrosion resistant, it can be used where other metallic or non-metallic cleaning pads might not serve. Because of its springiness and flexibility it will withstand repeated stretchings and rinsings, and the ease with which it may be cleaned helps to prevent the introduction of metallic impurities into equipment where contamination must be avoided.—Kleenette Manufacturing Company, *1269 West North Avenue, Chicago 22, Illinois.*

Low Expansion Steel

No. 430-ELC is a new stainless steel developed to have essentially the same expansion as glass. As a result it is particularly suited for use in products such as glass-steel television tubes. This steel is characterized by its relatively low cost as compared to previous compositions developed for the same purpose.—Armco Steel Corporation, *701 Curtis Street, Middletown, Ohio.*

Magnetic Tape Recorder for Very Low Frequency Phenomena*

PAUL E. GREEN, JR.
Research Laboratory of Electronics, Massachusetts Institute of Technology, Cambridge, Massachusetts

(Received June 23, 1950)

An apparatus is described for the recording of electrical signals of frequencies below 100 cycles per second on magnetic tape for subsequent playback. A system of wide deviation frequency modulation of an audio frequency carrier has been employed to eliminate the difficulties normally encountered in the direct recording of low frequency and d.c. signals.

GENERAL DESCRIPTION

IN certain investigations it is necessary to have permanent records of electrical signals whose frequency spectra lie below 100 cycles. Pen recorders, oscillograph cameras, and the like have provided a means of obtaining such records, but are useless when the need for playback arises. Conventional disk or tape recording procedures suffer from the inability to handle such low frequencies.

In this laboratory the problem arose as a need for a device which could record brain wave signals (1–100 cycles) and then reproduce them later as a function of time for statistical analysis by electronic means. It is the purpose of this paper to describe the equipment built for this purpose.

It was decided to use magnetic tape because of ease of handling and editing, and the possibility provided by such tapes of playing fairly long records repetitively using an endless loop arrangement. Because the analyzing equipment into which the playback output is to be fed can perform its analysis more quickly with higher frequency inputs, a speed step-up on playback is used. Two independent identical channels are provided so that two signals can be simultaneously recorded and their relative phase relations preserved.

Since the frequencies to be used are too low for direct recording, they are used to modulate a carrier of a higher, more convenient frequency. Amplitude modulation proved to be impractical because of excessive playback amplitude variations due to non-uniformity of the magnetic properties of the tape. For this reason, the recorder described here uses frequency modulation. A system somewhat similar to this has been described previously,[1] but it is felt that the details of the present equipment are sufficiently different and simplified to be of interest.

The f-m signal recorded on the tape has a center frequency of 1000 cycles per second with deviations from this of plus or minus 55 percent on modulation peaks. These large frequency swings are desirable in order that spurious tape speed variations shall not have appreciable influence. Linear tape speed is 3.0 inches per second during recording. The tape is played back at 15 inches per second into the demodulator circuit and the original signal, with all its frequencies multiplied by 5, is recovered at the output.

The tape-handling unit is an Amplifier Corporation of America Type 808-A twin track chassis modified for the new speeds and for simultaneous operation of both tracks. Conventional one-quarter-inch tape is used.

A block diagram of one of the two channels is shown in Fig. 1, with the corresponding detailed circuit diagram in Fig. 2.

RECORDING SECTION

Of the various means available for producing frequencies proportional to voltage, the most satisfactory one for the present purpose appeared to be the variable-bias multivibrator.[2] By varying the voltage to which both grids of a simple multivibrator are returned, it is possible to make the frequency vary almost linearly over a wide range, as shown in Fig. 3. (Circuit values

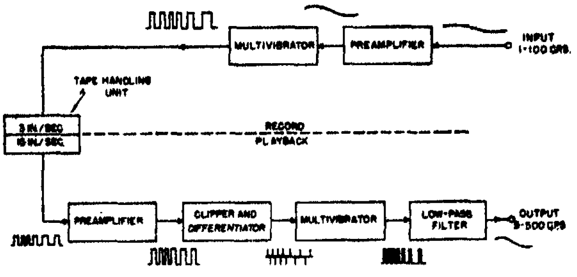

FIG. 1. Block diagram of f-m magnetic tape recording equipment.

and connections are those shown in Fig. 2.) Although the frequency *versus* voltage characteristic is steeper when the grid bias is negative, the improved linearity and convenience of power supply connection for the positive grid case made it more desirable.

The violently non-sinusoidal nature of the wave form produced by the multivibrator is of no consequence in this application, since, as will appear later, demodulation amounts merely to counting the rate at which the wave crosses the zero axis. Tape biasing and equalization are also unnecessary for the same reason. As shown in Fig. 2, the recording-playback head is energized directly by one of the plate circuits of the multivibrator. The resulting assymmetry of the multivibrator wave form has no effect.

The varying multivibrator bias voltage is obtained from the input signal by a preamplifier consisting of one stage of amplification and a cathode follower. In the present recorder, it was not necessary to have response down to d.c., so these two stages were made RC-coupled. It would be a fairly simple matter to provide for recording the d.c. level as well by substituting direct-coupled circuits instead, but then additional problems of long-time stability are encountered.

PLAYBACK SECTION

As shown in the lower halves of Figs. 1 and 2, the playback section consists of two amplifier stages, followed by a clipping and differentiating circuit, a multivibrator, and a low pass filter. The clipper is a bistable circuit which can be adjusted to change from one state to the other each time the input wave crosses the zero axis. The large rectangular pulses produced are differentiated to feed sharp triggers to the monostable multivibrator. This multivibrator generates a constant-width and constant-height pulse for each positive trigger, that is, for each cycle of the incoming f-m signal. By passing the multivibrator output through a low pass filter whose cut-off frequency is lower than the lowest excursion of the carrier, only the average value of the pulse train remains at the output. This is proportional to the instantaneous carrier frequency and corresponds therefore to the desired signal originally impressed on the carrier (with all frequencies multiplied by a factor of five due to tape speed-up).

Figure 4 shows the frequency relations involved in the demodulator circuits. The carrier center frequency is 5000 cycles, with maximum and minimum frequency excursions to approximately 7750 and 2250 cycles respectively. The low pass filter is designed to reject all components of the f-m spectrum, yet to pass modulation frequencies up to 500 cycles (corresponding to an input of 100 cycles—approximately the upper limit of the brain waves of interest here).

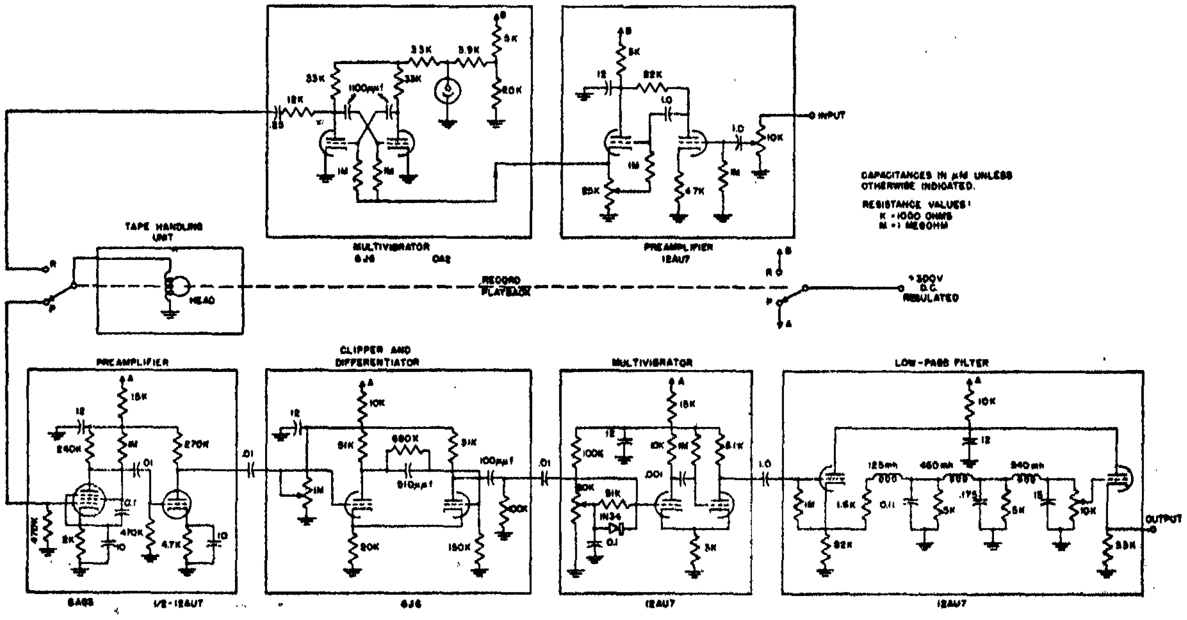

FIG. 2. Schematic diagram of tape recorder.

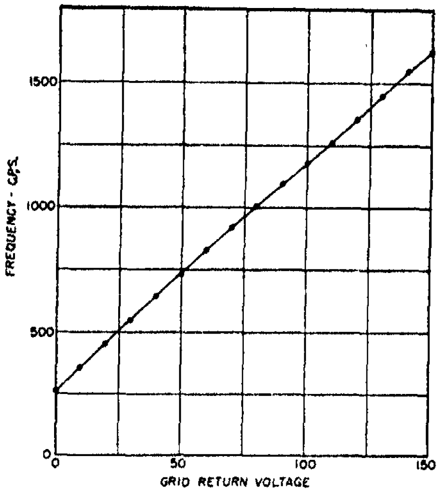

FIG. 3. Recording multivibrator frequency *versus* grid bias.

By using a recording multivibrator of five times the frequency used here, the playback could be performed at the same tape speed as that used for recording.

PERFORMANCE

The upper curve in Fig. 4 indicates the over-all frequency response of the system. The high frequency attenuation is seen to be due to the filter characteristic, whereas at low frequencies, attenuation occurs in the RC coupling circuits in recording preamplifier and demodulator multivibrator output.

Flutter in the tape transport mechanism as used is about 0.5 percent. This represents an unwanted noise component in the output giving a signal-to-noise ratio for the maximum (55 percent) carrier swings of 100 to 1, or 40 db.

The recorder is operated in conjunction with conventional electroencephalographic equipment, which is customarily employed to make pen recordings of the incoming signal.

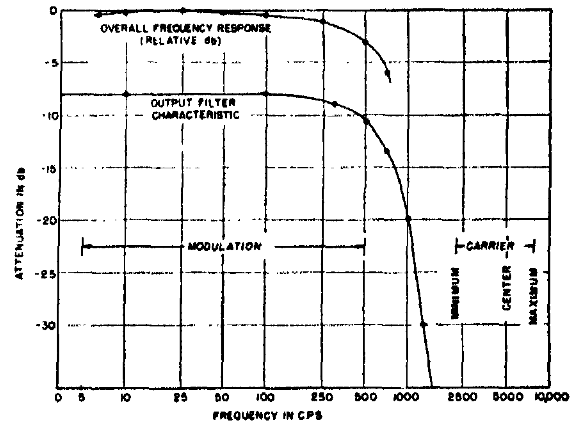

FIG. 4. Over-all frequency response and output filter characteristic.

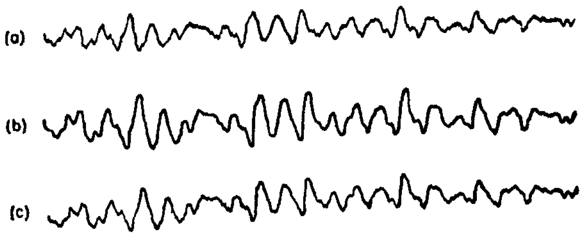

FIG. 5. Performance of one channel of the recorder with a brain wave signal. (a) Electrical input to both pen recorder and tape recorder. (b) Record made by conventional pen recorder. (c) Playback from tape recorder.

Figure 5 shows a comparison between simultaneous brain wave records made by such a pen recorder and the magnetic tape recorder described here. Aside from a loss of frequency components above about 100 cycles the system is seen to provide faithful reproduction of the original input. The frequencies above 100 cycles are usually attributed to muscle activity and are not of particular interest here. The duration of traces (a) and (b) is 2.3 seconds, and that of (c), 0.46 seconds, due to increased tape speed on playback.

ACKNOWLEDGMENT

The author wishes to express his appreciation to Professor J. B. Wiesner and Dr. O. H. Straus of the Research Laboratory of Electronics for their aid and supervision, and to Mr. James Casby of Massachusetts General Hospital for his assistance in obtaining the data presented in Fig. 5.

An Apparatus for the Study of Electrets

LARRY A. FREEDMAN AND LOUIS A. ROSENTHAL
Rutgers University, College of Engineering, New Brunswick, New Jersey

(Received June 23, 1950)

An apparatus capable of continuously measuring and recording electret strength is described. It consists of a mechanically driven condenser whose induced voltage, due to the electric field of the electret, is filtered and amplified before being applied to a recorder. Some experimental observations of the transition from heterocharge to homocharge are presented.

INTRODUCTION

THE majority of electret strength measurements have been confined, in the past, to the charge transfer method. The effective electret surface charge is transferred to a charge sensitive instrument such as the electrometer, electroscope, or low capacity electrostatic voltmeter.[1,2] This method is quite tedious when numerous measurements are desired for the various time studies of electrets. Strength characteristics with time under normal conditions or with variations in temperature, pressure and humidity are of considerable interest at present. The apparatus herein described serves the obvious need for a completely automatic measuring system.

THE MEASURING APPARATUS

The measuring apparatus consists of a mechanically driven capacitor in which the electret is mounted. The voltage output of the capacitor is passed on to the associated equipment shown in block form in Fig. 1. The equipment includes a high input impedance cathode follower with a 60-cycle twin "T" filter, a standard amplifier and rectifier unit,[3] and a recorder.[4] Continuous visual indication of relative electret strength is given by the recorder.

An assembly drawing of the driven capacitor is shown in Fig. 2. It consists of a frame, a solenoid mounting and an electrode mounted on flat springs. It is designed to give electrode motion of about one-hundredth to one thirty-second of an inch at 120 cycles per second.[5] The springs are designed so that their natural resonant frequency is well above the 120 cycles per second operating frequency. They consist of 1 by $\frac{1}{8}$ in. steel 4 in. long and are fastened rigidly to the frame which is made of $\frac{1}{2}$ in. steel 4 in. wide. This gives enough mass to prevent vibrations of the whole device and is at the same time light enough to be easily portable. The solenoid is mounted on the overhead part of the frame. A brass rod is inserted at the ends of the springs with a brass collar and nuts for rigid mounting. Fastened at the top of the rod with a screw thread and nut is the iron plunger, while at the bottom is the brass electrode. The electrode consists of a circular brass disk $1\frac{5}{8}$ in. in diameter and $\frac{1}{8}$ in. thick with a collar for mounting on the brass rod.

The plunger is centered axially in the solenoid[6] and adjusted so that it is just below is normal centered-position. When it is positioned in this way, a relatively small amount of current is necessary for a usable amplittude of oscillations. The solenoid is fed with 60-cycle a.c. voltage. This voltage is controlled with a variac and may be varied over a relatively wide range. For satisfactory operation however, 100 volts is sufficient.

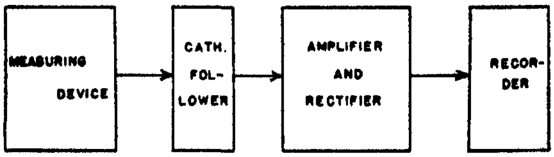

FIG. 1. Assembly drawing of the mechanically driven condenser. The solenoid is not shown, but is mounted on the upper frame for correct motion of the electrode structure.

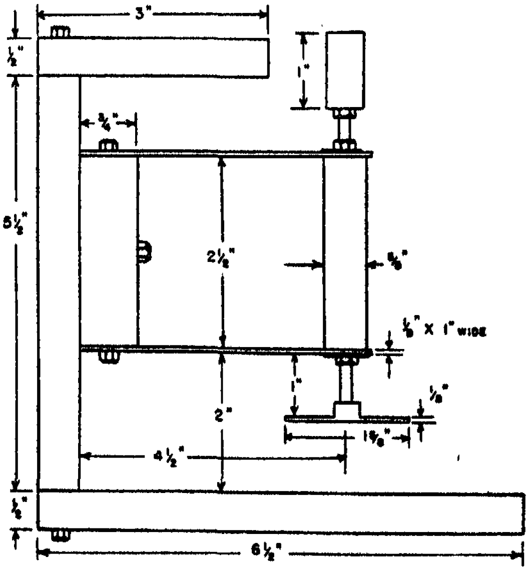

FIG. 2. Block diagram of measuring apparatus.

[4] Esterline-Angus Company—1 ma 1600 ohms.

[5] For a 60-cycle per second applied voltage, there will be a maximum field in the solenoid twice in each cycle. The plunger will be drawn toward the center position in the solenoid twice for each cycle and 120-cycle motion of the plunger will result.

[6] Solenoid from General Electric Company circuit breaker CN-1 for 110 volts a.c.

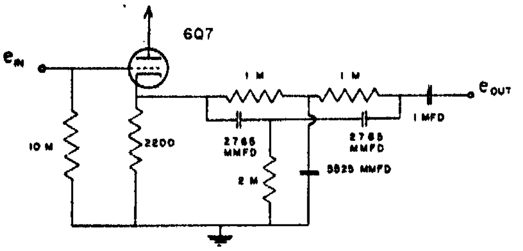

FIG. 3. The cathode follower with filter to eliminate stray 60 c.p.s. pickup.

When measurements are made, about $\frac{3}{4}$ in. of insulating material, such as polystyrene, is placed on the base of the device and on this is placed an electrode consisting of a thin sheet of aluminum or tin foil. The electret is then placed on this electrode, and the upper electrode and the frame are grounded. The lower electrode on which the electret is placed is the electrode of varying potential, and to this is attached the pick-up lead. It has also been found that copper mesh used for electrostatic shielding, when placed around the springs and the electrodes, prevents an excess of stray pick-up.

The action of the oscillating electrode above the surface of the electret is similar to the vibrating plate of the condenser microphone. As the electrode is displaced sinusoidally in the field of the electret, the potential induced on this plate varies. If a constant gradient is assumed for a very small amplitude of vibrations, the variation in potential on the plate will be sinusoidal. Stray pick-up is a serious problem so that the frame and the oscillating electrode are grounded. This causes the potential at the bottom surface of the electret to vary and it is from this surface that the variations in potential are passed on to the associated equipment.

Because of the small voltages and correspondingly small currents associated with the device, it is necessary to use an amplifier with a very high input impedance. Since the induced electret voltage is 120 c.p.s. and 60 c.p.s. pick-up may be large, it is desirable to filter the output before amplifying and recording. Since an input impedance of the order of megohms is not easily attainable with a filter a cathode follower stage was constructed with the filter across the output, as shown in Fig. 3. The triode section of a 6Q7 was employed so that a short lead could be used to the grid cap, and at the same time an input resistor of ten megohms could be used. The twin "T" filter attenuates the 60 cycle by 25 db while passing the 120 cycle with negligible attenuation.

The output of the cathode follower was fed to a standard amplifier-detector unit available in the laboratory. The amplifier had a maximum sensitivity of 100 microvolts per milliampere which gives a full scale meter reading of one milliampere for an input level of 100 microvolts. The meter and recorder movements both had a one milliampere full scale deflection so that the amplifier output could be read, or switched to the recorder for the same indication. The recorder speed is readily changed so that speeds of 0.75 inch per 15 seconds, per minute, per 15 minutes, or per hour may be used. For most long time recordings a speed of 0.75 inch per hour was used.

EXPERIMENTAL RESULTS

An electret mixture of 40 percent carnauba wax, 40 percent rosin, and 20 percent beeswax was used for testing purposes. This composition has good mechanical strength as well as the desired electrical properties.

Figure 4 is a typical recording obtained with the apparatus. Zero time represents the electret strength immediately upon removal from the charging electrodes. An apparent heterocharge is present at this point which gradually decreases to zero charge after about five hours. The zero signal level indicates a null in the electret charge.[7] This is followed by a more gradual rise after which the maximum signal level is reached in about fifteen hours. This signal level represents a homocharge and is the final strength attained by the electret; no change being evidenced in a month's time.

It is interesting to note that the transition from heterocharge to homocharge appears to take place in

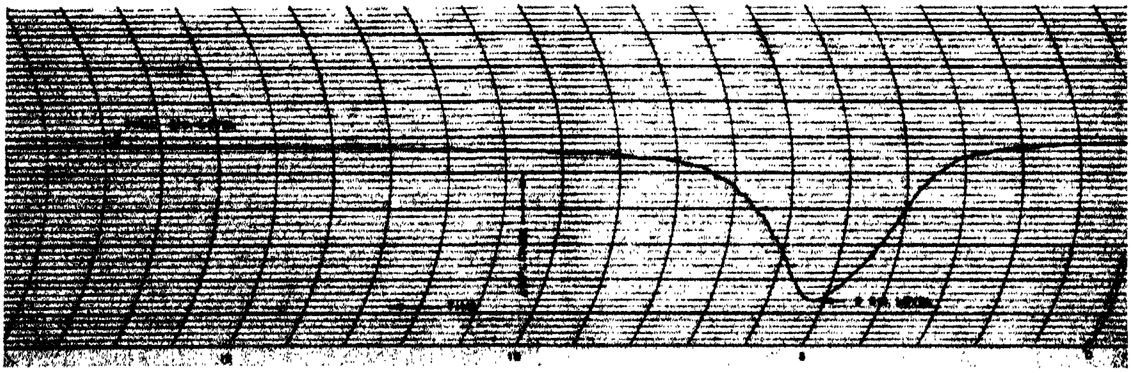

FIG. 4. The recorded strength of a newly formed electret with time. The electret was made with a field of 10 KV/cm and the chart speed is 0.75 in./hr.

---

[7] Since the detector is not polarity sensitive, the heterocharge and homocharge are recorded in the same direction.

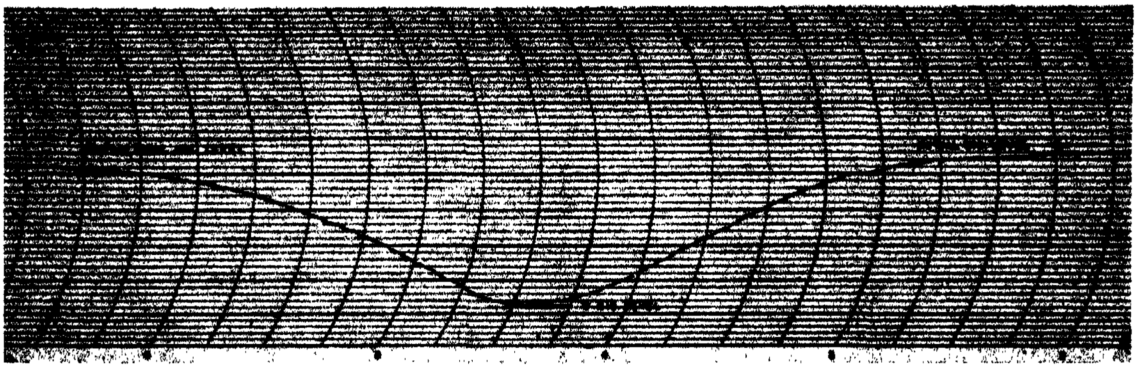

FIG. 5. The transition region is expanded by increasing the recorder speed. The electret is identical to that of Fig. 4; the chart speed has been increased to 3 in./hr.

discontinuous steps. Figure 5 shows the transition region using a faster recording speed. A speed of three inches per hour was used while only three quarters of an inch per hour was used in Fig. 4. The duration of the transition is about the same in either case but the discontinuities are more apparent at these higher recording speeds.

Other interesting and informative experiments on electrets may be performed with the aid of the apparatus described. Such variables as pressure, temperature, and humidity may be controlled and the electret strength measured. It is hoped that the device will afford a valuable tool to the experimenter in electrets.

The authors wish to acknowledge the aid and cooperation received from Professor J. L. Potter of the Electrical Engineering Department.

Transmission of Beta-Rays by Nylon and Formvar*

R. B. HELLER, E. F. STURCKEN, AND A. H. WEBER
Saint Louis University, St. Louis, Missouri

(Received June 29, 1950)

The percent beta-ray transmission by thin Nylon and Formvar films (windows) was studied to obtain experimental "absorption" corrections to be used with G-M counters employing such thin windows. It was found that window "absorption" included (1) energy loss of electrons traversing the films and (2) scattering of incident electrons by the film (a geometry effect). The results are plotted in several ways to exhibit the various factors involved and to permit easy use in applying the corrections. It was found that scattering of transmitted electrons was a factor of considerable importance, whereas the energy lost in traversing the film was not very important for the range investigated. The electron energy range investigated was limited to the region in which the "absorption" correction was considerable for the window thicknesses used. A scintillation counter was used as the detector, and the source of monoenergetic electrons was an electron gun with electrostatic focusing.

I. INTRODUCTION

THE problem of "absorption" of low energy electrons in thin end-window G-M counters has become an important one, and experimental correction factors for these effects should be made if any accurate measurements are to be obtained in low energy beta-ray spectroscopy where these counters are employed for detection.

It was found in the present investigation that, for a given beta-ray energy and film (window) thickness, the apparent absorption of the window was a function of (1) the scattering of the incident electrons by the window and (2) the energy lost by the electrons in traversing the window.

The method of window thickness correction in G-M counters ordinarily applied[1] consists in extrapolating to zero window thickness (for various constant beta-energies) an experimental counting rate *vs.* window thickness curve. This method is always questionable because of the uncertainty of the extrapolation in the region of very thin films. Also, to apply such a method with the apparatus used in this investigation (scintillation counter plus electron gun with electrostatic focusing) would require maintaining constant the electron beam current, which would be difficult.

Solid triangles at joints indicate soft solder, open triangles silver solder. *A*, end plate to receive electron gun, with 6 holes spaced every 60° tapped for ¼-20 bolts; *B*, Pyrex insulator, sealed to Kovar, to separate second and third anodes; *C*, flexible Cu bellows with three thumb screws and springs for adjusting the electron gun; *D*, Pb diaphragm to block light from filament of electron gun; *E*, Al button for mounting films; *F*, C-7140 photo-multiplier tube; *G*, electron gun (C. T. Keogh and A. H. Weber, J. App. Phys. 19, 1077 (1948)). *H*, current collector or film holder; *I*, glass and Kovar insulator with *O*-ring sealed brass rod through center screw hole at the end of the rod for attachment of *H*; *J*, pump-out stack to oil diffusion pump; *K*, coaxial lead for photo-multiplier tube voltage; *M*, coaxial lead for output of photo-tube; *N*, brass cap for electrical shielding of output lead wires; *O*, mu-metal shield to minimize magnetic effects; *P*, shield for lead to electrometer (not shown); *Q*, end plate; *L*, polystyrene lead-through vacuum-tight bushings; *CR*, $CdWO_4$ crystal mounted on inside of mu-metal shield; *R*, lead to ground; *S*, lead to anode of photo-multiplier tube; *T*, space for resistor housing.

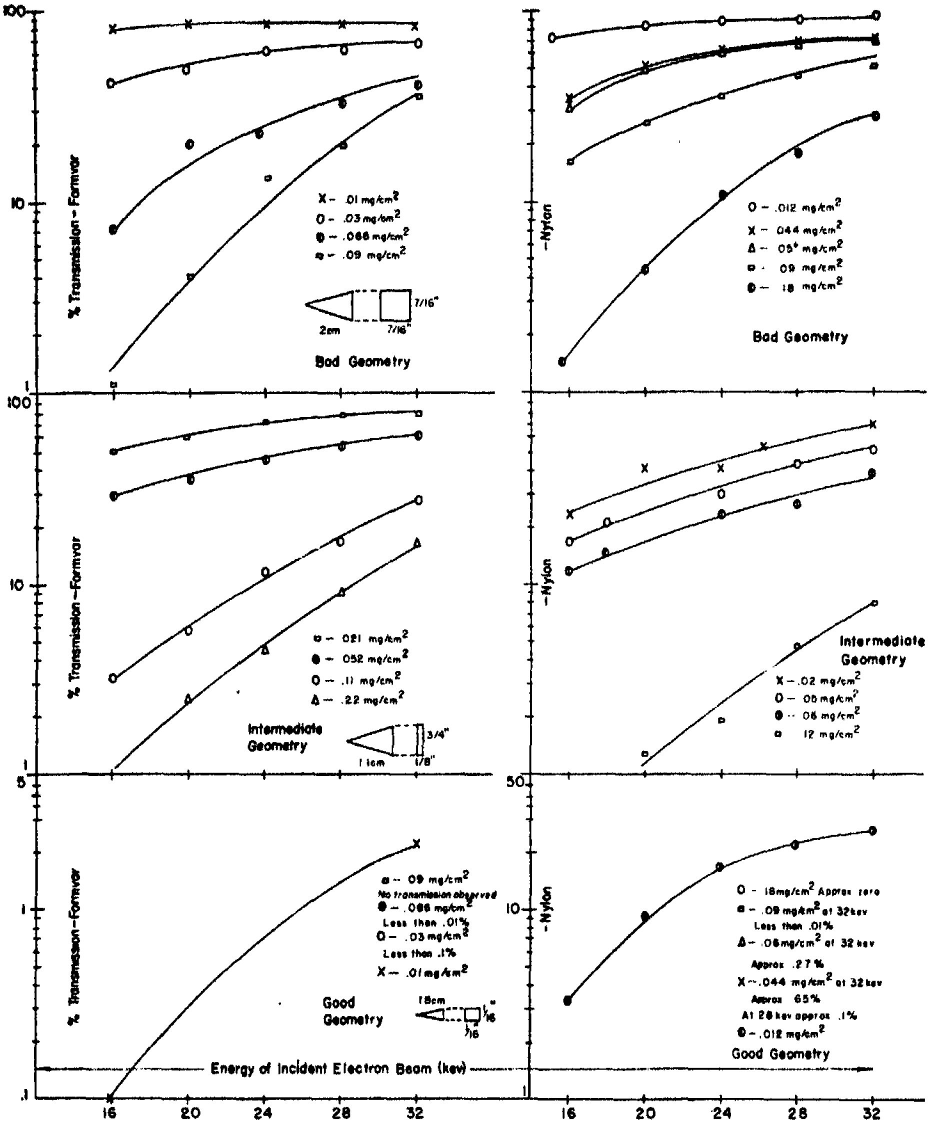

FIG. 2. Percent transmission *vs.* electron beam energy for films of Formvar and Nylon of different weights. The scaler pulse-height discriminator was set at zero for all readings. Electron gun filament current operated in the neighborhood of 1.5 amp. The geometries (*Bad*, *Intermediate*, *Good*) are defined by the diagrams so labeled; area and shape of crystal surface and distance from film are specified. Bad and good geometry data were obtained with a cadmium tungstate crystal and C-7140 RCA photo-tube; intermediate geometry data were obtained with a calcium tungstate crystal and a 1P21 RCA photo-tube.

To avoid the use of a detector which already had a window in the determination of "window corrections" and to eliminate the necessity of maintaining constant the electron beam current, it was decided to use a scintillation detector which is a "windowless" counter. The effect of scattering was studied by determining the percentage transmission[2] through thin Nylon and Formvar windows as a function of geometry (size of the crystal and its distance from the window) at distances such that the area presented by the scintillating crystal to the radiation was the important factor. The effect of energy loss on the "absorption" correction was studied by determining the change in counting rate due to a change in electron energy alone, so that the above measurements of counting rate for the transmitted beam intensity can be corrected to the same energy as the incident beam intensity and the I and I_0 measurements will be for the same energy.

It was found that scattering of transmitted electrons by the windows gave rise to a considerable part of the "absorption" correction. The electron energy range investigated is limited to the region in which the corrections are considerable for the window thicknesses used.

At approximately 50 kv the corrections considered here are negligible; extrapolation of the curves of Fig. 2 from 32 to 50 kv appears justifiable. In all transmission experiments the estimated error is at most ten percent.

II. EXPERIMENTAL

The monoenergetic electron beam was obtained from an electron gun, G (Fig. 1), using electrostatic focusing.

---

[2] The percentage transmission is defined as the ratio of the transmitted beam intensity I (the counting rate with sample minus background) to the incident beam intensity I_0 (the counting rate without sample minus background). The background was found to be negligible (less than 0.01 percent) in all cases.

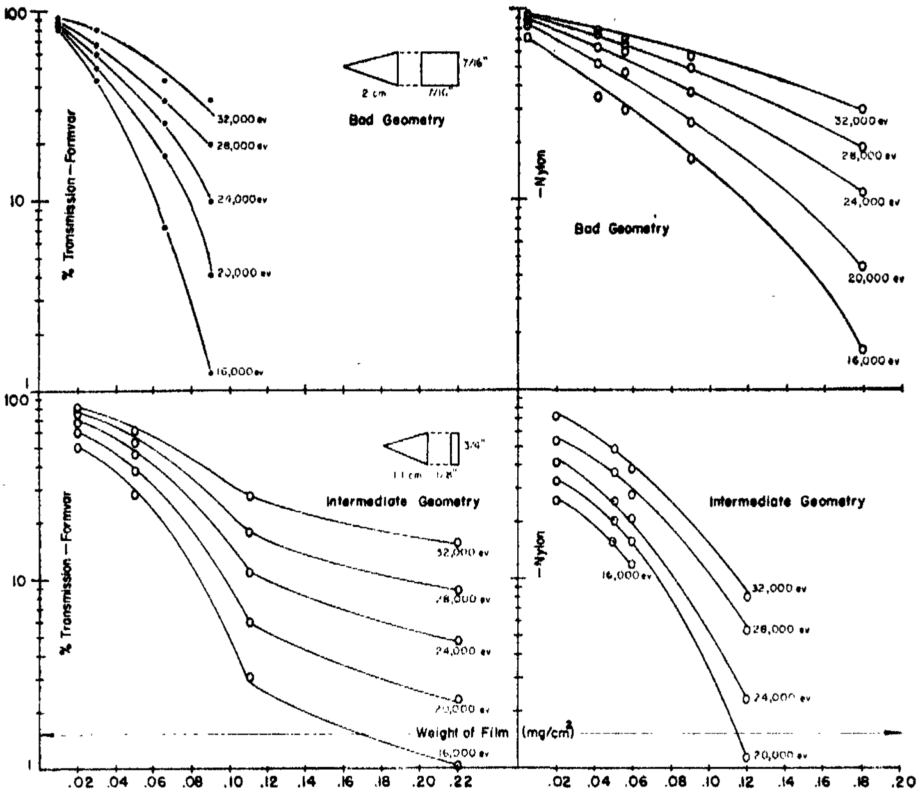

FIG. 3. Percent transmission *vs.* film weight at constant electron beam energy. These curves were plotted from the data of Fig. 2.

The voltage was varied from 16 to 32 kv in steps of 4 kv. To minimize spurious counts caused by light from the filament, four things were done: (1) the electron gun filament was operated at a temperature which would assure adequate electron emission along with minimum light output, the latter to minimize counts due to filament light; (2) a metal shield was placed around the photo-tube leaving a small hole only exposing the crystal (fluorescent[3] material was placed around the hole to facilitate locating the beam on the crystal); (3) the beam was focused off the crystal and brought on with a magnet when a run was taken (this procedure also minimized charging of the crystal); (4) a circular lead plate with a small hole, *D* (Fig. 1), was placed in the chamber. The arrangement of Fig. 1 was employed for the bad and good geometry experiments.

The intermediate geometry experiments employed the apparatus of Fig. 1, with the exception that a 1P21 photo-multiplier tube with a calcium tungstate crystal[4] mounted directly on the window of the photo-tube was used. The crystal was polished and, because of the high refractive index of calcium tungstate, was coated with evaporated aluminum[5] on parallel long sides to prevent loss of light from total internal reflection and scattering. The crystal was Aquadaged around the edges and grounded to minimize accumulation of charge.

The Nylon and Formvar windows were inserted in and out of the electron beam with an O-ring sealed probe, *H* (Fig. 1). Three- to ten-sec. counting periods were used (to avoid charging the crystal), and the average value of I_0 was controlled to give a probable error in counting of less than 0.2 percent.

The Nylon films were prepared in the usual manner.[6] Clear films 25 cm² in area were obtained by this method. A uniform piece about one cm² was selected from the film and mounted in a holder, *E* (Fig. 1), which was fastened to the end of the O-ring sealed probe for the experiment, *H* (Fig. 1). The method of preparation of Formvar films was the same as that of Nylon with the exception that ethylene dichloride was used as a solvent.

It was reported[7] that calcium tungstate had a serious "afterglow" following exposure to extreme radiation intensities, so cadmium tungstate[8] was used in the good and bad geometry experiments which were performed after the intermediate geometry experiments. An area of $\frac{7}{16}\times\frac{7}{16}$ in. of the crystal was used for the bad geome-

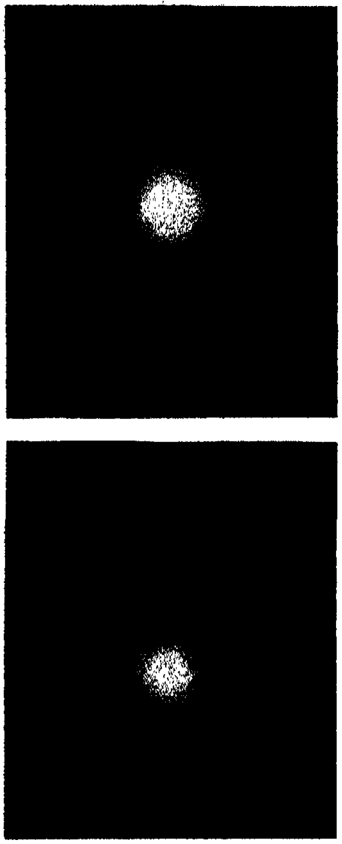

FIG. 4. Electron diffraction patterns of Formvar (lower) and Nylon (upper) films. The films were 0.01 mg/cm^2 in weight. The accelerating voltage was 20 kv. In the printing of the positives from the negatives, the exposure was varied to bring out each individual ring.

try, and the arrangement was changed to good geometry by the placing of a carbon button with a $\frac{1}{16}$-in. square hole directly in front of the crystal. The procedure for taking data was the same as for the intermediate geometry experiments, with the exception that three-sec. counting periods were used always and the beam was focused on the crystal but deflected magnetically until a reading was taken. The large surface of the C-7140 photo-tube insured good light collection.

The change in counting rate due to a change in energy alone, that is, the response of the photo-tube *vs.* electron beam energy with constant electron beam current, was measured for the 1P21 and C-7140 photo-tubes. The apparatus of Fig. 1 was used for these experiments. A current collector in the form of a brass cup coated with Aquadag replaced the holder, *H*, of Fig. 1, and an electronic electrometer connected through *P* (Fig. 1) with a sensitivity of 2×10^{-13} amp./division was used to maintain a constant beam current for various beta-ray energies. Calcium tungstate was used as the scintillator. The detailed results of these experiments are not reported here; but it was found that the energy loss of electrons in traversing the films contributed a maximum of ten percent to the "absorption" correction, and this was within the experimental error of the transmission experiments. However, for energies lower than 16 kv, the energy lost in traversing the windows would become a considerable part of the "absorption" correction and would have to be applied to the transmission curves. To estimate the energy lost in traversing a thin window, the aluminum equivalent of the window was employed in conjunction with the curve of specific energy loss for singly charged particles *vs.* kinetic energy.[9,10]

III. RESULTS

The results of the transmission experiments are shown by Figs. 2 and 3. The window thicknesses used were selected on the basis of those to be employed in G-M counters. It is to be noted that the measured transmission varied most markedly in the region of the electron energies employed in these experiments; the curves (except for good geometry) extrapolate to 100 percent transmission as the energy is increased beyond 50 kv. It is observed that Formvar and Nylon have different transmission properties. In an attempt to explain this fact, electron diffraction patterns of Nylon and Formvar windows (Fig. 4) were obtained. These patterns show that (1) Nylon has a more regular structure than Formvar and (2) there is greater incoherent scattering in Formvar than in Nylon. With these considerations it would not be expected that Nylon and Formvar would have the same transmission properties.

For the good and bad geometry experiments a magnetic shield was used; however, in the intermediate geometry experiments the beam was deflected on the crystal with a magnet and a shield was not used. Graves[11] has reported that magnetic fields affect the response of scintillation counters. In this investigation all measurements were on a relative basis, and (since the magnetic field was present in both the I and I_0 readings) the results of the transmission experiments were not affected.

It is hoped that these results will permit investigators in this field to make experimental window "absorption" corrections.

Somewhat similar experiments to those here described were performed by Schonland[12] with Au and Al films (thinnest foil 0.15 mg/cm^2, approximately). The results are also similar to those of the present work.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 11 NOVEMBER, 1950

A Pulse Generator for the Millimicrosecond Range

R. L. Garwin
Institute for Nuclear Studies, University of Chicago, Chicago, Illinois

(Received June 16, 1950)

A description is given of a laboratory pulse generator producing pulses with rise and decay times less than 2×10^{-10} sec. at a repetition rate of 120/sec. Three simultaneous outputs are available, variable in amplitude from 100 microvolts to 100 volts and accurate to a few percent.

INTRODUCTION

The considerable interest evoked by a pulse generator constructed here last year has prompted publication of this paper. This instrument has proved invaluable in the testing of distributed amplifiers and very fast coincidence circuits, and in calibrating fast electronic equipment.

DESCRIPTION

The heart of the pulser is a switch which is incorporated into the center conductor of a coaxial line and is operated at 120 cycles by the 60-cycle magnetic field from a coil external to the outer conductor. In Fig. 1 both the lower flexible "reed" and the longer upper contact are ferromagnetic, so that the reed snaps from its rest position as indicated in the figure to make contact when an axial magnetic field is applied.[1]

The reed is so constructed that the contacts are continuously wet with mercury by capillary action from a drop of the metal at the base of the capsule. The liquid serves the important purpose of bridging mechanical chatter and so completely eliminates multiple pulses. A 10-atm hydrogen filling keeps the mercury clean and increases the sparking potential to some 8 kv.

If now the copper shield diameter is so chosen as to make an approximate impedance match with some common high frequency cable, and if a short open-ended section of the cable is attached to the upper contact and charged to potential V, and an essentially infinite or matched length is connected to the reed, then on closing the switch a rectangular pulse of amplitude $V/2$ and duration twice the electrical length of the pulse forming line is propagated into the infinite line.

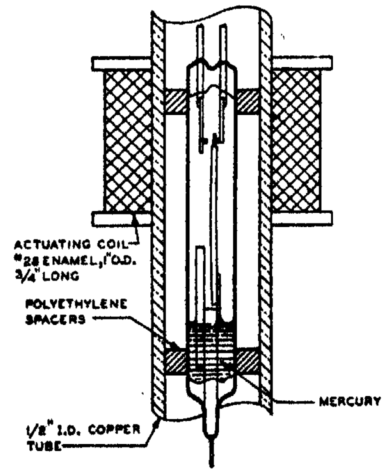

FIG. 1. Rapid coaxial switch.

The circuit of the instrument (Fig. 2) is thus clear: a connector is available to which to attach various lengths of pulse forming line (Pulse widths from 5×10^{-10} to 10^{-6} sec. are obtained from lines ranging from 5 cm to 100 m long). The relay is actuated by 6.3 v.a.c. applied to a coil wound on the copper shield. The voltage regulator tubes and the switches allow full scale output voltages from 100 v to 0.001 v in decimal steps, while the wire-wound potentiometer allows one-percent accuracy in setting pulse heights. The tee which splits the output pulse into three introduces an attenuation of a factor 3, so that the line must be charged to 600 v to produce output pulses of 100-v amplitude. The reversing switch allows either positive or negative pulses to be obtained.

TECHNIQUE

The indicated pulse heights hold, of course, only if the system is matched in impedance at each point. Thus, if an output is not being used, it must be terminated in its characteristic impedance to avoid reflections. The system impedance used in the pulser here constructed is 75 ohms, for which no constant-impedance connectors are available. Accordingly, the AN-83 series connectors

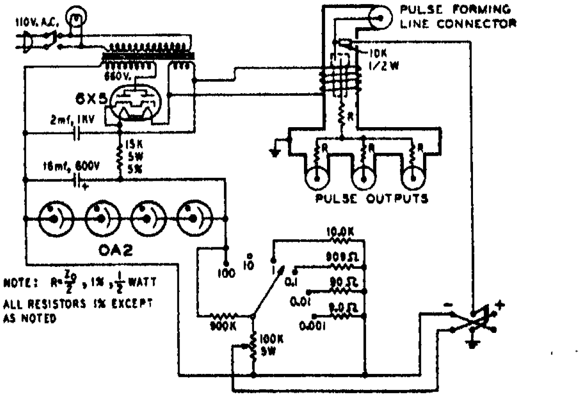

FIG. 2. Pulser schematic.

---

[1] The glass-enclosed switch is taken from a Western Electric D-168479 synchronous relay.

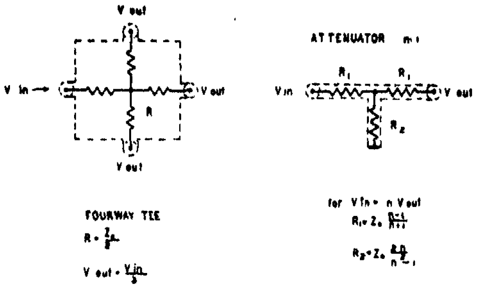

FIG. 3. Very high speed elements.

were used, introducing a time constant about 10^{-11} sec. at each junction. (The 50-ohm type *N* connectors will match a 50-ohm line into the microwave region.) It can be shown theoretically and has been observed that a connector of impedance Z and of electrical length (time) t, short compared to the pulse rise time τ, will introduce in a system of impedance Z_0 a fractional voltage reflection $t(Z-Z_0)/\tau(Z+Z_0)$. In the present instrument this is ~ 2 percent. In using this instrument it is necessary to have several connectors with resistors carefully soldered in to terminate properly non-infinite lines. Open circuited lines are approximated by the noncontacting weatherproofing plug, while shorted terminations are most conveniently obtained by inserting into the plug a small metal cylinder which efficiently shorts the line. While disk resistors have been used in some cases, it has been found that the Allen-Bradley ½-watt carbon resistors have good characteristics for rise times about 2×10^{-10} sec.

For convenience some matched tees and attenuators for a system of impedance Z_0 are shown in Fig. 3. It is best not to take an attenuation greater than 10:1 in a single attenuator as the shunt resistance becomes so low that the inductive impedance is important. In the range above 10^{-10} sec. it has been found sufficient to maintain minimum inductance by the use of closely fitting metal shields to which the connectors are attached. For higher frequencies at least two approaches are obvious: to use rod and disk resistors as the elements, or to use a lossy line.

PERFORMANCE

The operation of the pulser is perhaps best illustrated by the measurement of its apparent rise time. A long length (10 m) of 75-ohm cable was used as pulse forming line, while two other lengths led two output pulses to the intensity grid and the sweep trigger of a fast oscilloscope (a Du Mont K 1033 tube operated at a writing rate of $c/6=5\times 10^9$ cm/sec. by a triggered hydrogen thyratron). The pulse to be observed was delayed 0.15 microsecond and led to the coaxial vertical deflection plate. The rise was fully observable at 120/sec. and was from 10 percent to 90 percent in 1.5 cm, so 3×10^{-10} sec. The shape of the rise, however, checks with what one expects for the distortion of a step function through 0.15 microsecond of the cable used. It is hoped to use air dielectric delay line for a better determination of the switch characteristics. The sweep calibration in the region of interest was established by removing and adding 6-cm lengths of coaxial cable.

SUMMARY

The pulser has proved to be a very helpful accessory. A minor limitation is the impossibility of triggering the artificial pulse at an arbitrary time, but this does not decrease appreciably the utility of the instrument.

A Method for Measuring the Thermal Conductivity of Small Samples of Poorly Conducting Materials such as Optical Crystals*

STANLEY S. BALLARD, KATHRYN A. MCCARTHY, AND WILLIAM C. DAVIS†
Department of Physics, Tufts College, Medford, Massachusetts

(Received June 29, 1950)

Thermal conductivities of from 2 to 500×10^{-4} c.g.s. units are measured by comparing the flow of heat through a given sample with that through a standard material. On the basis of repeat runs and checks with literature values, an accuracy of about five percent is estimated for this method. The dimensions of the apparatus limit the face size of both the unknown and standard samples to a maximum of 10 millimeters square; thicknesses of 2 to 10 millimeters are suitable. Values at average temperatures between 30°C and 75°C are reported for nine materials:—sodium chloride, potassium chloride, potassium bromide, calcium fluoride, lithium fluoride (both air-grown and vacuum-grown), silver chloride, thallium bromide-iodide, thallium bromide-chloride, and fused silica.

IN the course of a program of measuring the physical properties of crystalline optical materials of importance in infra-red instrumentation,[1] it became apparent that there was no readily available method for measuring the thermal conductivity of small samples of such materials. Very often only small samples are available for test; this is especially likely to be true for new crystals which are being grown in experimental lots. Therefore it seemed that an equipment was needed which could give acceptable accuracy for samples as small as one centimeter square and a few millimeters thick. These materials are neither good conductors of heat such as the metals, nor are they very poor conductors such as insulating substances, but rather they fall into an intermediate class, with thermal conductivities in the range of 2 to 500×10^{-4} c.g.s. units (cal. sec.$^{-1}$ cm^{-1} °C^{-1}). This article describes a simple device for making these measurements, lists a few of the values that have been determined, and reports comparisons with available literature values.

The method is comparative rather than absolute in that there is a constant heat flow maintained through a standard crystal and the crystal under test, and the temperature gradients necessary to maintain this equal flow through the two crystals of unequal thermal conductivity are measured. As illustrated in Fig. 1, the two crystal blocks are placed one above the other between a heat source and a heat sink. In preparing for each measurement the heat is passed through the crystals for a sufficient time so that a steady-state condition exists. The interface temperatures T_1, T_2, and T_3 are then measured. Under these conditions the quantity of heat, Q, which flows through each material in a given interval of time is the same, and by definition of the thermal conductivity, k,

$$Q=(kA\cdot\Delta T)/t.$$

Equating Q for the standard and unknown crystals,

$$\frac{k_sA_s(T_2-T_3)}{t_s}=\frac{k_uA_u(T_1-T_2)}{t_u},$$

where k_s and k_u, A_s and A_u, t_s and t_u are the thermal conductivity, surface area, and thickness, respectively, of the standard material, s, and the unknown, u. All quantities can be measured except k_s which is taken from the literature, and k_u which is being determined.

The materials selected for use as standards in this comparative method must of course have well-established thermal conductivity values which lie in the appropriate range. Crystalline quartz, whose thermal conductivity at various temperatures has been extensively reported, is used as a basis of comparison for crystals in the upper part of the range of values being investigated. The quartz crystals are Z-cut, so the values of conductivity employed are those for heat flow parallel to the optic axis. Values from −252°C to 100°C are listed in the International Critical Tables,[2] and values from 100°C to 475°C have been determined by Knapp.[3] Plexiglas and Pyrex are used as standards in the lower part of the optical crystal range. The thermal conductivity of Plexiglas, manufactured by the Rohm and Haas Company of Philadelphia, is about one-fiftieth that of crystalline quartz; H. E. Robinson of the National Bureau of Standards has measured samples of this material using an 8-inch guarded hot-plate appa-

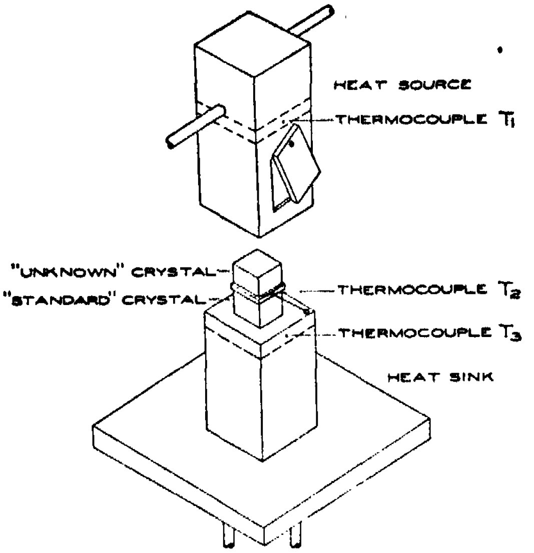

FIG. 2. Apparatus for measuring the thermal conductivity of small specimens.

ratus. The thermal conductivity of Pyrex No. 7740, as supplied by the Corning Glass Works of Corning, New York, is about one-tenth that of crystalline quartz. Stephens[4] has measured the thermal conductivity of Pyrex at temperatures from −200°C to 250°C, and reports data which are presumed to be reliable.

In the actual apparatus, which is diagrammed in Fig. 2, the heat source is a brass box with a copper bottom which is heated by steam passed through the box—copper is of course used because of its high thermal conductivity. The heat sink is a brass box with a copper top which is cooled by a stream of tap water. The heat source is located at the top of the apparatus and the sink at the bottom, so as to minimize convection currents along the sides of the crystal pile. A thin copper plate is placed between the two crystals to keep the heat flow through the crystals parallel when the crystals do not have the same cross-sectional area, and to facilitate the measurement of the interface temperature. The thermocouples are made of 32-gauge copper and constantan wire; one thermocouple is soldered in the approximate center of the copper plate between the crystals, and the other two are soldered near the surfaces of the copper plates which constitute the heat source and heat sink. A shield extends from the upper box to make thermal contact with the lower box; the air enclosed in the space between the crystal pile and the shield is thus expected to have a temperature distribution similar to that of the crystal pile. A small door is provided in the side of the shield for the inspection of the crystal pile after the apparatus has been assembled. A preliminary run of about ten minutes is generally sufficient to establish a steady state condition, with constant temperature readings.

When the copper plates are in good contact with the surfaces of the crystals, the temperature distribution over the conducting areas of the crystals is assumed to be uniform, and the flow of heat through the pile is assumed to be linear and unidirectional from the heat source at the top to the heat sink at the bottom. A possible source of error exists at the interfaces between the copper plates and the crystals, where good thermal contact must of course be established. Glycerin or vacuum-pump oil is used between the surfaces to eliminate air spaces caused by surface roughness, and weights are placed on top of the steam jacket to assist in maintaining better thermal contact. The differential heat losses from the sides of the crystal pile appear to be negligible. To study this possible source of error, tests were made in which crystalline quartz plates served both as the unknown and as the standard samples. Tests were made first with the "unknown" quartz sample in contact with the heat sink; then the crystal pile was reversed, and runs were made with the "unknown" quartz sample in contact with the heat source. The values of thermal conductivity obtained for the "unknown" quartz sample at two different average temperatures checked very closely with the literature values for those temperatures. If an appreciable amount of heat were being lost from the sides of the crystal pile, the conductivity measured at a given average temperature should not have agreed with the literature value for that temperature.

Measurements have been made only within the comparatively small range between the temperatures of steam and tap water, and the actual runs reported here have been made at average temperatures for the unknown sample of between 30°C and 75°C. By using samples of different thickness and by interchanging the positions of the unknown and the standard crystals, it is possible to obtain different interface temperatures and thus to measure values of thermal conductivity for a number of average temperatures within the range available. The face size of both the unknown and the standard materials is limited because their conducting surfaces must fit within the edges of the center copper plate, which in the present apparatus is 10 millimeters square. Sample thicknesses in the range 2 to 10 millimeters have proven satisfactory. A sample must be of constant cross-sectional area throughout its depth, and the contacting surfaces must be plane and parallel.

The materials tested to date are listed in Tables I and II. The experimental value of thermal conductivity given for each material was determined from several runs made with approximately the same temperature gradients existing. The temperature which accompanies each conductivity value in the tables is the mean of the temperatures at the two conducting surfaces of the material being tested. The test samples of the materials given in Table I are single crystals synthetically grown from the molten salt, according to the method of Bridgman and Stockbarger, by the Harshaw Chemical

---

[4] R. W. Stephens, "The temperature variation of the thermal conductivity of Pyrex glass," Phil. Mag. 14, 897 (1932).

Company of Cleveland, Ohio. Comparison of our values with those reported by other investigators[5,6] is difficult because of possible differences in the source of the crystals, some being naturally-occurring crystals, and others being synthetically grown. However, the results obtained agree with most values reported by other investigators to within five percent, except that the measurements on the synthetic lithium fluoride supplied by Harshaw differ greatly from values reported by Knapp for samples which were presumably grown synthetically by the same general method. The conductivity measured for air-grown lithium fluoride differs significantly from that measured for vacuum-grown lithium fluoride; this appears to be consistent with the differences in certain elastic properties reported by Combes and Ballard[1,7] for these two materials.

In Table II values are given for five materials whose thermal conductivity has not been previously reported, at least for the synthetic crystals. The silver chloride tested was cut from a sheet rolled from a single-crystal ingot, and supplied by Harshaw. In order to prevent the corrosive action of silver chloride on copper, the conducting surfaces of the samples were coated by evaporation with a thin protective layer of silver. The mixed crystals *KRS*-5 (thallium bromide-thallium iodide) and *KRS*-6 (thallium bromide-thallium chloride) were supplied by the Engineer Research and Development Laboratories, Fort Belvoir, Virginia. The fused silica listed in Table II is of the high optical homogeneity variety "Homosil," manufactured by the W. C. Heraeus Company of Hanau, Germany, and since its thermal conductivity has not been reported previously, it is listed with the new values.

TABLE I. Thermal conductivity of some optical materials.

Material	Experimental value c.g.s. units	Temperature °C	Literature value c.g.s. units	Temperature °C	Source
Sodium chloride	147×10^{-4}	35	167×10^{-4}	0	Eucken[a]
	130	70	150	30	Eucken[a]
Potassium chloride	156	42	167	0	Eucken[b]
	153	72			
Calcium fluoride	232	36	250	0	Eucken[a]
Lithium fluoride (air-grown)	249	36	61.3	105	Knapp[c]
Lithium fluoride (vacuum-grown)	280	34			

[a] See reference 5.
[b] See reference 6.
[c] See reference 3.

TABLE II. New values of thermal conductivity of optical materials.

Material	Experimental value c.g.s. units	Temperature °C
Potassium bromide	115×10^{-4}	46
Fused silica (Heraeus)	28.2	41
Silver chloride	27.1	52
Thallium bromide-iodide	21.3	54
Thallium bromide-chloride	17.1	56

Samples of crystals additional to those listed in Tables I and II have been obtained, and are being measured. Of particular interest are non-cubic crystals, such as sapphire and rutile, with which a study can be made of thermal conductivity as a function of crystal orientation. Plans are underway to construct a variation of the present apparatus which will make possible the extension of the thermal conductivity measurements down to temperatures well below 0°C.

The authors wish to thank David W. MacLeod and Gustave A. Larson of the Research Laboratory of Physical Electronics of Tufts College for their assistance in the construction of the apparatus and the preparation of samples, and Professor Gordon B. Wilkes of the Massachusetts Institute of Technology for his encouragement and assistance in the early days of the project.

Synchrotron-Oscillation Resonance*

NELSON M. BLACHMAN
Brookhaven National Laboratory, Upton, Long Island, New York

(Received June 16, 1950)

The frequency of phase oscillation in a synchrotron is so low as to make possible resonances with harmonics of the power-supply frequency. The interaction may take place through ripple in the magnetic field or in the frequency or amplitude of the accelerating voltage, the first two interacting very strongly and the third moderately. Thus, a small ripple in the magnet power supply output, though it produces only an extremely small ripple in the magnetic field because of the magnet's inductance, may tend to cause large phase oscillations. The detuning effect of the fall in phase oscillation on frequency with increasing amplitude limits the resulting amplitude, however, and may even reduce the amplitudes of initially large phase oscillations. The ripple in the accelerating field is unlikely to be sufficient at a resonant frequency to cause trouble. In addition to ripple, there will be noise which, particularly through modulation of the frequency of the accelerating field, may result in time in considerable phase oscillations because the noise contains a wide range of frequencies, one of which is always in resonance throughout the acceleration cycle.

I. INTRODUCTION

ALTHOUGH resonances among the frequencies of vertical and horizontal betatron (free) oscillation and of revolution in a synchrotron have already been studied,[1-3] the possibility of resonance in the phase (synchrotron) oscillation has received less attention.[†] The frequency of the latter is much lower than those of the former three; in the Brookhaven proton synchrotron it will vary from 2620 to 1800 c.p.s., and resonance may occur with harmonics of the power-supply frequency. The Brookhaven magnet is powered by a nominally 60-cycle generator and 12-phase rectifier, having significant output components at multiples of 720 c.p.s.; the third gives cause for concern with phase-oscillation resonance.

II. DIFFERENTIAL EQUATIONS OF PHASE OSCILLATION

The differential equations of small phase oscillation are[3]

$$\omega d(e/\omega)/dt=-A\theta \tag{1}$$

and

$$d\theta/dt=Ke-Ch+w, \tag{2}$$

where e is the energy excess of the particles over that of the equilibrium particle, θ is its phase-angle excess, h is the amount by which the magnetic field exceeds the field H required to keep a particle of the equilibrium energy at the equilibrium radius R, and w is the amount by which the radian r-f exceeds the angular velocity of ω of the equilibrium particle. A, K and C are the slowly varying positive constants

$$A=-\partial(dE/dt)/\partial\theta=(\omega/2\pi)\epsilon V|\cos\phi|, \tag{3}$$

$$K=-\partial\omega/\partial E=\frac{\omega}{E(E^2-E_0^2)}\times\left[\frac{E^2}{(1-n)(1+4L/2\pi R)}-E_0^2\right], \tag{4}$$

$$C=\partial\omega/\partial H=\omega/[H(1-n)(1+4L/2\pi R)], \tag{5}$$

with E the total energy of the equilibrium particle, of rest energy E_0 and charge ϵ, V the amplitude of the accelerating potential, ϕ the equilibrium phase angle ($\pi/2<\phi<\pi$), n the index of the fall-off of the magnetic field with radius, and $4L$ the total length of straight sections.

If the amplitude of the r-f voltage should be excessive by the amount aV, i.e., by fraction a, Eq. (1) must be modified to read

$$de/dt=-A\theta+Da, \tag{6}$$

in which the two ω's have been canceled because the change in ω during a passage through resonance will be negligible;

$$D=V\partial(dE/dt)/\partial V=(\omega/2\pi)\epsilon V\sin\phi. \tag{7}$$

Combining (2) and (6), we get

$$\ddot{\theta}+\Omega^2\theta=-C\dot{h}+\dot{w}+\Omega^2|\tan\phi|a, \tag{8}$$

where $\Omega=(AK)^{\frac{1}{2}}$ is the radian frequency of phase oscillation.

III. FORCED OSCILLATION

The right side of (8) is a forcing term, causing θ to oscillate. For example, if h is varying sinusoidally with radian frequency W and amplitude h_0, its time derivative will have amplitude Wh_0, and θ will be forced to vary with the same frequency and amplitude

$$\theta_0=CWh_0/|\Omega^2-W^2|. \tag{9}$$

Likewise, if the accelerating frequency varies sinusoidally with frequency W and amplitude w_0, θ will be forced to oscillate with amplitude

[3] N. M. Blachman and E. D. Courant, Rev. Sci. Inst. 20, 596 (1949).

† N. M. Blachman, Phys. Rev. 80, 125 (1950).

$$\theta_0 = Ww_0/|\Omega^2 - W^2|, \tag{10}$$

while if the r-f voltage is amplitude modulated at frequency W with modulation index a_0, a forced phase oscillation of amplitude

$$\theta_0 = \Omega^2 |\tan\phi| a_0/|\Omega^2 - W^2| \tag{11}$$

will result.

The amplitude of forced phase oscillation (10) or (11) is of the same order of magnitude as the amplitude-modulation index or the ratio of frequency swing to phase-oscillation frequency, respectively, unless the modulating frequency resonates with the phase-oscillation frequency. However, because C is of the order of ω/H and ω is of the order of a thousand times Ω because the particles' energy gain per revolution is of the order of a millionth of their kinetic energy, a large phase oscillation (9) will result from only a very small wobble of the magnetic field. Ordinarily, though, the ripple in the magnetic field will be of a still smaller order of magnitude on account of the filtering effect of the magnet's inductance on the ripple in the magnet-supply voltage.

If the amplitude of the latter is m times the d.c. voltage, the rate of change of the ripple magnetic flux must be m times the rate of change of the d.c. flux. Assuming that these two fluxes are distributed similarly in space, we conclude that $Wh_0 = m\dot{H}$, whence

$$h_0 = m\dot{H}/W. \tag{12}$$

Substituting (12) and (5) into (9), we obtain

$$\theta_0 = m\omega\dot{H}/[H|\Omega^2 - W^2|(1-n)(1+4L/2\pi R)], \tag{13}$$

which is of the order of magnitude of m unless the ripple and phase-oscillation frequencies are nearly equal. In the latter case, because Ω is changing, it must pass through W, and resonance will occur.

IV. RESONANCE

Since the effect of Ω passing through W will be practically the same as that of W passing through Ω at the same rate while Ω remains constant, the solution to

$$\ddot{\theta} + \Omega^2\theta = f(t) \tag{14}$$

may be written

$$\theta = \Omega^{-1} \int_{-\infty}^{t} f(t') \sin\Omega(t-t')dt'. \tag{15}$$

We may write the forcing term, assumed to have amplitude F, as

$$\begin{aligned} f(t) &= F \sin\left\{ \int_0^t [\Omega + (\dot{W} - \dot{\Omega})t]dt + \psi \right\} \\ &= F \sin[\Omega t + \tfrac{1}{2}(\dot{W} - \dot{\Omega})t^2 + \psi], \end{aligned} \tag{16}$$

substitute it into (15), and then write the product of the two sines as the difference of two cosines, one having the frequency difference multiplying t' and the other the sum. The resonance occurs in the former term, which we retain, the integral of the latter being negligible so that we drop it:

$$\theta = (F/2\Omega) \int_{-\infty}^{t} \cos[\Omega t + \psi + \tfrac{1}{2}(\dot{W} - \dot{\Omega})t'^2]dt'. \tag{17}$$

Expanding the integrand as the cosine of a sum, we obtain two terms, a cosine times the Fresnel integral C and a sine times the Fresnel integral S. However, by setting $t = \infty$ and using Peirce's integral No. 487, we can find the total effect of passage through resonance without reference to Fresnel integrals, *viz.*,

$$\theta = (F/\Omega)(\tfrac{1}{2}\pi/|\dot{W} - \Omega|)^{\frac{1}{2}} \sin(\Omega t + \psi - \pi/4). \tag{18}$$

Therefore, the amplitude of the phase oscillation resulting from passage through resonance at the rate $|\dot{W} - \dot{\Omega}|$ will be

$$\theta_0 = (\tfrac{1}{2}\pi/|\dot{W} - \dot{\Omega}|)^{\frac{1}{2}} Ch_0, \tag{19}$$

$$\theta_0 = (\tfrac{1}{2}\pi/|\dot{W} - \Omega|)^{\frac{1}{2}} w_0, \tag{20}$$

$$\theta_0 = (\tfrac{1}{2}\pi/|\dot{W} - \dot{\Omega}|)^{\frac{1}{2}} |\tan\phi| \Omega a_0, \tag{21}$$

or

$$\theta_0 = (\tfrac{1}{2}\pi/|\dot{W} - \dot{\Omega}|)^{\frac{1}{2}} m\omega\dot{H}/[\Omega H(1-n)(1+4L/2\pi R), \tag{22}$$

corresponding to (9), (10), (11), and (13), respectively. The effective time interval during which the ripple resonates with the phase oscillation equals twice the square root appearing in (18) to (22). Following this period of build-up, the resulting oscillations continues, damping very slowly. These phase oscillations are limited in the amplitude to which they can build up in a way not taken into account above by the fall in phase-oscillation frequency with increasing amplitude, which hastens the passage through resonance. Thus, the danger is not from the oscillations themselves but from the protons' decreased phase stability and consequent increased vulnerability to such disturbances as noise. Ripple is able to push particles past the limits of phase stability only to the extent that Ω^2 is not $\gg\Omega$, i.e., the number of cycles of phase oscillation during resonance is finite and the growth of their amplitude is not smooth.

Sufficiently large ripple can even reduce the amplitudes of initially large oscillations by locking in their frequency. Since the phase-oscillation frequency falls with time as well as amplitude, it can remain constant and equal to the ripple frequency only if the amplitude falls. For this locking in to occur, the product of the partial derivative of the phase-oscillation frequency with respect to amplitude, $\partial\Omega/\partial\theta_0$, times the amplitude of the incremental phase oscillation produced per unit time by the ripple at resonance, $|F|/2\Omega$, must be many times the rate of change with time of the phase-oscillation frequency, $\dot{\Omega}$. In this case, there will be a stable phase-oscillation phase and amplitude, the latter falling with time, which maintains approximate equality of ripple and phase-oscillation frequencies until the amplitude has fallen to the point where $\partial\Omega/\partial\theta_0$ is no longer sufficient ($\partial\Omega/\partial\theta_0=0$ for $\theta_0=0$); then the oscillation will go out of resonance without increasing in amplitude.

An oscillation larger in amplitude than the stable amplitude would have a lower frequency and so get behind in phase. An oscillation behind in phase would be reduced in amplitude faster than the stable amplitude because it would be closer to 180° out of phase with the incremental oscillation due to ripple. Thus, particles executing phase oscillations with other than the stable phase and amplitude will oscillate in phase and amplitude about these values provided that there is sufficient ripple and amplitude dependence of the phase-oscillation frequency. To determine the latter, it is necessary to integrate the equation of finite phase oscillation[3] numerically over a cycle of oscillation.

V. APPLICATION TO BROOKHAVEN PROTON SYNCHROTRON

In the Brookhaven proton synchrotron[4] the phase-oscillation frequency will pass through resonance with the nominally 2160-c.p.s. power-supply ripple with $\Omega/2\pi=2055$ c.p.s. at the time the field $H=8500$ gauss, $\omega/2\pi=4.0$ mc/sec., $\dot{H}=14750$ gauss/sec., $\dot{\Omega}/2\pi=-1600$ c.p.s./sec., and $\dot{W}/2\pi=-100$ c.p.s./sec. on account of the slowing down of the generator due to the conversion of rotational energy into magnetic. With $m=0.5$ percent r.m.s. for this ripple, we find on substituting into (22), taking $n=0.6$ and $4L/2\pi R=0.2122$, that $\theta_0=0.64$ radian $=36°$ in amplitude, which is not small. It may be compared with the phase acceptance range of 199° corresponding to the equilibrium phase angle $\phi=152.8°$ at this resonance. The resonance will effectively last 26 msec.

The amplitude of the incremental phase oscillation produced per unit time by the ripple at this resonance is 0.64 radian/0.026 sec. = 25 radians/sec. Numerical integration of the equation of finite phase oscillation shows that for an equilibrium phase angle $\phi=150°$ the frequency of phase oscillation varies approximately as $(1-0.10\theta_0^2)$ for small θ_0. The frequency becomes zero for oscillations touching the limit of the region of phase stability. Thus, $\partial\Omega/\partial\theta_0$ is about $-411\theta_0$ c.p.s./radian, which gives a product of $-10{,}300\theta_0$ c.p.s./sec., to be compared with $\dot{\Omega}-\dot{W}=-1500$ c.p.s./sec. The former is larger in magnitude over most of the range of θ_0 during the resonance, but not sufficiently to bring about any considerable locking in of the oscillations set up by the resonance. The chief effect of the amplitude dependence of the phase-oscillation frequency in this case is to hasten the passage through resonance, reducing the resulting amplitude θ_0 to about 0.41 radian $=23°$.

From (12) we find that $h_0=0.0057$ gauss r.m.s., which is indeed small! Balancing terms on the right side of (8) to get zero, we find that this h_0 may be compensated by an appropriately phased 2055-cycle amplitude modulation with a peak swing of 7.8 c.p.s., which is equivalent to a 0.22° phase modulation. This f-m should be supplied automatically by the frequency-control system, which is designed to keep the frequency appropriate to the magnetic field, however the latter may wobble. Just as this variation in frequency of two parts in a million is enough to balance out a 23° phase oscillation, so such a variation could cause one. However, no ripple in the frequency of this order of magnitude is expected in the range of phase-oscillation frequencies. It is expected that the 2-kc amplitude modulation of the accelerating voltage will not exceed 0.1 percent, which would produce only a 5° phase oscillation.

VI. NOISE

In addition to ripple modulation of the accelerating voltage and ripple in the magnetic field, there will be modulation by the noise in the r-f control system of the frequency and amplitude of the accelerating voltage and noise in the magnetic field due to noise in the magnet supply voltage. Although this noise has no discrete frequencies like ripple to resonate with the phase-oscillation frequency, it contains components of a wide band of frequencies, including the entire range over which the phase-oscillation frequency varies. Thus, instead of resonating only during a brief passage through resonance, a part of the noise is effective throughout the acceleration cycle. The various spectral components are not coherent but produce only statistical effects much smaller in magnitude than if they were coherent like a discrete frequency; but because of the longer time of interaction, noise can produce considerable phase oscillations.

Noise may be considered to be made up of many discrete components of random phase and amplitude, the latter obeying a Rayleigh distribution (of the shape $xe^{-x^2/2}dx$) with its mean-square value given by the spectral intensity. We may resolve the noise into components whose frequencies change in the same way as the phase-oscillation frequency, so that there is one that remains in resonance throughout the acceleration cycle. It represents all components that remain coherent for this period of time, say T. They in effect occupy a band width about the phase-oscillation frequency of $2\pi/T$ in radians/second.[5] Note that ripple components at multiples of 60 cycles which are more or less uniformly small in amplitude may be regarded as noise since their effects on the particles will not be coherent.

Considering (8) again in the form (14), we suppose that $f(t)$ is a noise with spectral intensity $\Phi(\Omega)$ in the neighborhood of the phase-oscillation frequency Ω. Φ is the mean-square value of that part of $f(t)$ lying within a

---

[4] Livingston, Blewett, Green, and Haworth, Rev. Sci. Inst. 21, 7 (1950).

[5] If an undamped harmonic oscillator of resonance frequency Ω is driven by a sinusoidal force of frequency W nearly equal to Ω for a long time T ($\Omega T\gg 1$), the resulting amplitude, which is proportional to T at resonance, is readily found to be $[\sin\frac{1}{2}(\Omega-W)T]/[\frac{1}{2}(\Omega-W)T]$ times as large when $W\neq\Omega$. If the forcing frequencies W are distributed uniformly in the vicinity of Ω, the effective band width is

$$\int_{-\infty}^{\infty}[\sin\tfrac{1}{2}(\Omega-W)T]^2/[\tfrac{1}{2}(\Omega-W)T]^2dW=2\pi/T.$$

frequency band of unit width (1 radian/sec.). Thus, the mean-square value of the effective component of $f(t)$ is $2\pi\Phi/T$, and its r.m.s. amplitude is $(4\pi\Phi/T)^{\frac{1}{2}}$. Such a resonant driving force, acting for time T, excites oscillations of θ of amplitude $T/2\Omega$ times the amplitude of the driving force, i.e., phase oscillations of r.m.s. amplitude

$$\theta_0 = (\pi\Phi T/\Omega^2)^{\frac{1}{2}}, \tag{23}$$

since there is very little damping of the phase oscillations.[6] As is shown in the Appendix, the r.m.s. phase-oscillation amplitude due to noise builds up with time as $(\pi\int_0^t \Phi dt/\Omega^2)^{\frac{1}{2}}$; hence, if $\Phi(\Omega)/\Omega^2$ is not constant, its mean value must be used in (23), due account being taken of the dependence of Ω on amplitude. At the end of the acceleration cycle the amplitudes due to noise of the phase oscillations of the various particles will have a Rayleigh distribution of r.m.s. value (23), since those starting with different initial phase oscillation amplitudes will, on account of their different phase-oscillation frequencies, respond to different noise components. The particles that would execute oscillations exceeding the limits of phase stability are, of course, lost.

Noting that the spectral intensity of a derivative is the square of the angular frequency times that of the original quantity, we see that the r.m.s. amplitude of phase oscillation due to a random variation with time of the magnetic field of spectral intensity η in gauss²/(radian/sec.) is

$$\theta_0 = C(\pi\eta T)^{\frac{1}{2}}. \tag{24}$$

If the accelerating frequency varies randomly, e.g., because of noise in the r-f control system, with spectral intensity ν in (radians/sec.)²/(radian/sec.), which may be given by the spectral intensity of the latter noise times the mean-square sensitivity of the frequency-control system, the r.m.s. amplitude of the resulting phase oscillation is

$$\theta_0 = (\pi\nu T)^{\frac{1}{2}}. \tag{25}$$

If the accelerating voltage has random amplitude modulation which, expressed dimensionlessly (in percent), has spectral intensity α in (radian/second)$^{-1}$,

$$\theta_0 = \Omega|\tan\phi|(\pi\alpha T)^{\frac{1}{2}}, \tag{26}$$

while (24) in terms of noise in the magnet supply voltage which, similarly expressed, has spectral intensity μ in (radian/sec.)$^{-1}$ is

$$\theta_0 = C\dot{H}(\pi\mu T)^{\frac{1}{2}}/\Omega, \tag{27}$$

which is of the order of magnitude of $\Omega(\pi\mu T)^{\frac{1}{2}}$ and may be compared with (26).

VII. APPLICATION TO BROOKHAVEN MACHINE[4]

Values of μ or α corresponding to 0.1 percent magnet-supply noise or noise modulation, respectively, in a 10-kc frequency band correspond to a θ_0 of about a tenth of a radian for the Brookhaven machine, which should do little harm. However, the synchrotron is very sensitive to frequency modulation, because a slight change of accelerating frequency introduces an equal rate of change of particle phase (see Eq. (2)) that is effective for a time of the order of the period of phase oscillation and produces a net change of particle phase of the order of a thousand times $(=\omega/\Omega)$ the fractional change of accelerating frequency. The great sensitivity to variation in the magnetic field is due to the same effect, the relative frequency change this time being due to the shift of the equilibrium radius.

With $T=1$ second and an r.m.s. oscillator sensitivity of about 25 kc/v, 100 μv of noise in a 10-kc band feeding the frequency-control circuit along with the 0- to 300-v control voltage will result in phase oscillation of r.m.s. amplitude 0.11 radian = 6.4°, which will have only a slight effect on the life expectancy of the protons. Over half of the effect of the noise f-m, however, will have appeared by the time the protons reach 50 Mev, where the radial oscillations still require all available aperture. On reaching relativistic energies these phase oscillations will damp slowly in their customary way.

VIII. ACKNOWLEDGMENT

I want to acknowledge discussions of the present problem with Dr. Ernest D. Courant and other members of the Accelerator Project of this laboratory.

APPENDIX

Another derivation of (23) from (14). White fluctuation noise may, without loss of generality, be assumed to result from a sequence of impulses (delta-functions) that occur at random times going through a low pass system that smears out and conceals the individual impulses. We have seen that the frequency response of a particle to the driving force $f(t)$, our noise, is very sharp and would do so much of its own smearing as to hide the effects of any low pass filter. Hence, we suppose that $f(t)$ consists of a sequence of delta-functions occurring at the random times t_i.

Thus, after t_1 and before t_2, θ is given by the indicial response of (14), $\theta = \Omega^{-1}\sin\Omega(t-t_1)$. Ignoring the rather small damping of the phase oscillations, we find that after a large number N of impulses

$$\begin{aligned}\theta &= \Omega^{-1}\sum_{i=1}^{N}\sin\Omega(t-t_i)\\ &= \Omega^{-1}\sin\Omega t\sum_{i=1}^{N}\cos\Omega t_i - \Omega^{-1}\cos\Omega t\sum_{i=1}^{N}\sin\Omega t_i\\ &= \Omega^{-1}\Big[\Big(\sum_{i=1}^{N}\cos\Omega t_i\Big)^2 + \Big(\sum_{i=1}^{N}\sin\Omega t_i\Big)^2\Big]^{\frac{1}{2}}\sin(\Omega t+\psi)\\ &= \Omega^{-1}\Big[N+2\sum_{i>j=1}^{N}\cos\Omega(t_i-t_j)\Big]^{\frac{1}{2}}\sin(\Omega t+\psi),\end{aligned}$$

whence we see that the r. m. s. amplitude of oscillation of θ is $\theta_0 = N^{\frac{1}{2}}/\Omega$, for the mean value of the summation over i and j is zero. If the number of impulses per second is b, $N = \int_0^T bdt/\Omega^2$, whence

$$\theta_0 = \left(\int_0^T bdt/\Omega^2\right)^{\frac{1}{2}}. \tag{28}$$

From the fact that the Fourier transform of the delta-function is $1/\pi$ (radian/sec.)$^{-1}$, it follows that the spectral intensity of the integral of its square is $1/\pi$ sec./(radian/sec.). Hence, the power spectral intensity of the sequence of delta-functions coming at the rate b per second is b/π (radians/sec.)²/(radian/sec.), which is what we called Φ. Therefore, $b = \pi\Phi$, and (28) becomes (23).

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 11 NOVEMBER, 1950

An Electrostatic Beta-Spectrograph*

DONALD R. HAMILTON AND LEONARD GROSS†
Palmer Physical Laboratory, Princeton, University

(Received June 16, 1950)

A beta-ray spectrograph has been constructed in which electrons move radially outward against a retarding electric field, and the current due to those electrons having more than any given energy is measured. Momentum resolution is one-third percent. The insensitivity of current collection, as compared to single particle detection, is compensated by a large tolerable source area and a large useful solid angle subtended at the source by the detector.

I. INTRODUCTION

THIS article is concerned with the design and operation of an electrostatic beta-ray spectrograph which has been used to investigate the low energy portion (0–30 kilovolts) of the spectrum of sulfur 35, as reported elsewhere.[1] Instead of single-particle detection this spectrograph uses current detection, thus obviating difficulties with the thin windows of counters. Use of electrons leaving the source in a large solid angle increases the intensity as is necessary in going to the less sensitive method of current detection. This spectrograph is thus complementary to the magnetic spectrograph and, among other things, may be used in the low energy range to test the Fermi theory[2] of beta-decay, which has proven so robust and in such good agreement with the observed spectra at all other energies.

II. DESIGN OF APPARATUS; RESOLVING POWER AND INTENSITY CONSIDERATIONS

The increase in intensity requisite to current detection is obtained by having electrons move radially outward against a spherically symmetric retarding electric field; one measures the relative number of electrons able to surmount the retarding field, i.e. having more than a given energy. The spectrum measured is thus an integral spectrum from which the

[2] E. Fermi, Zeits. f. Physik 88, 161 (1934).

customary spectrum is obtained by differentiation. Such an instrument is not mentioned in the literature although it has apparently occurred independently to various individuals. Electrostatic spectrographs described in the literature, in which electrons move at right angles to a cylindrically symmetric electric field,[3,4] have no particular advantages over magnetic types.

The simplest electrostatic spectrograph of the present general type, consisting of two parallel planes as source and collector, is practically useless since only a small component of the initial electron momentum is on the average parallel to the retarding field. This fault is easily remedied by having a small spherical source, radius r_0, concentric with a spherical collector of radius r_2; from conservation of angular momentum it follows that a mono-energetic electron source would have an apparent total relative energy width $(r_0/r_2)^2$. This width is unaffected if the radial dependence of the spherically symmetric field is altered, as by a spherical grid of radius $r_1 (r_0<r_1<r_2)$ intermediate in voltage and space between source and collector. In particular the apparent energy width is unaffected if such an intermediate grid be at source potential and have a radius comparable to that of the collector. In addition, this last condition minimizes edge effects which arise if the collector subtends at the source a solid angle considerably less than 4π steradians.

The latter features are incorporated in the practical spectrograph shown in Fig. 1. Here the grid G_1 is maintained at the same potential as the source S. Electrons from S travel initially in a field free space and meet the retarding field between G_1 and G_2. Electrons having enough energy to pass G_2 are collected by P; since G_2 is biased 90 volts negative with respect to P, no slow secondary electrons leave P. Electrons turned back between G_1 and G_2 return toward S and are absorbed in B with, as will be discussed later, the production of very few secondaries. Electrons not initially emitted toward G_1 likewise terminate their career suddenly at B. Confinement of the retarding field to the region G_1G_2 is necessary for the prevention of electrical stress on the thin film source S; and of course since the source must for practical reasons be non-spherical and non-conducting, any retarding field which extended up to the source would be considerably distorted by the latter. The possibility of insertion of B as an electron trap is one advantage of the hemispherical arrangement of Fig. 1 over the idealized spherical arrangement; the principal additional advantage is mechanical simplicity.

In addition to the general limits set by convenience, the dimensions in Fig. 1 are set by a number of factors:

(1) The G_1G_2 spacing must be large enough to reduce sufficiently any strong-field emission of electrons from G_2 toward G_1. (2) The G_1G_2 spacing must be small enough, relative to the radii of G_1 and G_2, to keep down edge-effect distortions of the retarding field. (3) The G_1G_2 spacing must be large enough, relative to the size of the holes in G_2, to minimize loss of resolving power from coarseness of G_2. (4) The detector sensitivity sets the minimum source strength, which in turn, for a minimum source thickness, sets a minimum source area; as this area increases relative to G_1 area, resolving power gets worse.

The considerations involving resolution warrant more detailed discussion. By "resolution" we shall mean the apparent relative momentum width, $\Delta p/p = 1/2(\Delta V/E_0)$, for a source of non-relativistic monoenergetic electrons of energy E_0; here ΔV is the differential width of the range of retarding voltages within which electrons reach the collector. Hereafter V denotes retarding voltage between G_1 and G_2.

It has already been noted that for concentric spherical source and collector of radii r_0 and r_2, $\Delta V/E_0 < (r_0/r_2)^2$; a more detailed estimate for the arrangement of Fig. 1, bearing in mind that for practically all electrons the shortest distance from line of flight to center of symmetry is less than the radius of the source, gives

$$(\Delta V/E_0)_s = A/9R^2, \tag{1}$$

using the subscript s to refer to an effect arising from the source. Here A is the area of a plane circular source, R the mean radius of G_1 and G_2.

At G_2, coarseness and opposing electric fields on opposite sides of the grid mesh result in a potential barrier of variable height for different electron trajectories. The maximum variation of the barrier height from point to point, a new ΔV, could be calculated exactly. With relative dimensions of the order of magnitude of those used here, ΔV will be proportional to the separation of adjacent grid wires; several methods of estimating ΔV give

$$(\Delta V/E_0)_{G_2} = 1/10(G_2 \text{ grid wire separation}/G_1G_2 \text{ separation}) = 10^{-3}.$$

Coarseness of G_1 causes a transverse deflection of an electron passing through G_1; since the radial component of momentum is not altered, no $\Delta V/E_0$ results.

It should be noted that the values of ΔV indicated above do not combine error-wise. The finite-source effect makes monoenergetic electrons appear to have less energy, the G_2 effect more energy, than they actually have.

The resolving power of the spectrograph was checked experimentally with a monoenergetic source of electrons, provided by a wire mesh diode plate through which passed electrons accelerated from a tungsten filament by a d.c. voltage E_0 ranging from zero to 15 kilovolts. Results are summarized in Fig. 2 which shows the differential current distribution (slope of the directly observed integral spectrum) as a function of normalized retarding voltage V/E_0. The curve has a

[4] J. G. Backus, Phys. Rev. 68, 59 (1945).

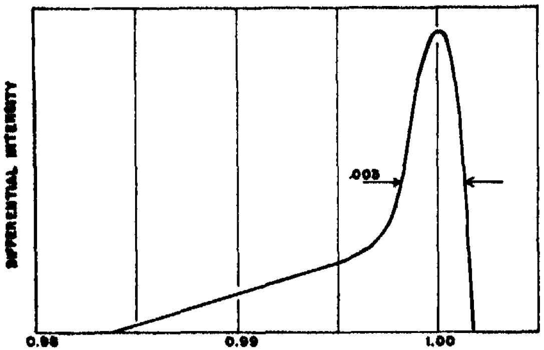

FIG. 2. Apparent momentum distribution of monoenergetic electrons.

relative voltage width at half maximum of 0.006, or a resolution $\Delta p/p=1/2(\Delta V/E_0)=0.003$, of which one-third is contributed by the region $V>E_0$(G_2 effect). These widths are about twice those calculated by the same method as above, assuming a beam 1 cm in diameter. The factor two in the finite-source effect would be explained if, as is very possible, the effective source were a quarter-inch off center.

The question of intensity is complementary to that of resolution, and is particularly important here; how much can the loss in intensity in going to current detection be compensated by the increased solid angle utilized at the source? A quantitative figure of merit involving intensity and resolving power is provided by the product

$$F\equiv(A\Omega/n)(p/\Delta p) \tag{2}$$

in which Ω is the solid angle utilized at the source, relative to 4π, and n is the detector background in electrons per second. In the present spectrograph, as in most types, F is independent of source area A since $p/\Delta p$ is proportional to $1/A$; taking A_0 as the effective sensitive area of the detector (i.e. the area of P) and $\Omega=A_0/4\pi R^2$, then by Eq. (2) $F=1.4A_0/n$. For the specific apparatus of Fig. 1, for which $A_0=430$ cm^2 (actual area times factor 2/3 for grid shadow) and $n=1000$, $F=0.6$ cm^2. The Columbia solenoidal spectrograph,[5] which seems to be the best magnetic type with respect to this figure of merit, yields about the same value; here $A=1$ cm^2, $n=1/2$, $p/\Delta p=25$ and $\Omega=0.04$, giving $F=2$ cm^2.

III. BACKGROUND ELECTRONIC EFFECTS

In addition to the primary electron current at P, a number of secondary sources of current exist and give rise to spectrum distortions. Among the masking secondary effects to be considered are secondary electron emission from electrodes, positive ion formation, and strong field emission from G_2. These will be considered in the order just given.

Secondary Electron Emission

In general this effect has been minimized by geometry and by coating all sheet-nickel surfaces, such as B and the mounts for G_1 and G_2, with aquadag (colloidal graphite). The following discussion is of necessity somewhat general since detailed effects depend on the energy spectrum of the primaries. The necessary information on secondary emission ratio (ratio of secondaries to primaries) and on energy spectrum of secondaries has been taken from a number of sources.[6-10]

(a) *Secondary Emission from Collector P*

The -90 volt bias of G_2 prevents the escape from P of the slow secondaries (<90 volts energy) which comprise at least 90 percent of the secondaries produced in carbon by primaries of less than 50 kilovolts energy. (The total secondary emission ratio from carbon varies from approximately unity at low energies to <0.1 for primary energy >70 kilovolts.) Electrode geometry is such that about one-half of the fast secondaries (>90 volts) which are not held back by G_2 can escape from P; the fast secondary emission ratio for carbon drops from 0.1 at ≤ 2 kilovolts to 0.01 at 40 kilovolts and then rises to 0.03 at 170 kilovolts. All told, secondaries from P may diminish the primary spectrum by amounts ranging from several percent to less than one percent.

(b) *Secondary Electrons from Backstop B*

Here, just as at P, the slow but not the fast secondaries are irrelevant. The geometry of this electrode is such that most secondaries are trapped; for a source one inch in diameter less than eight percent of the secondaries should be able to escape. Hence secondaries from B, as compared to those from P, have small effect.

(c) *Secondary Electrons from G_1*

Slow secondaries are irrelevant. This grid is stainless steel, 0.009-inch wire, 16 mesh, open area 73 percent. By geometry, ≤ 0.2 of the fast secondaries from G_1 head toward G_2. The fast secondary emission ratio is ≤ 0.3 for 40–100 kilovolt primaries, less for slower primaries. All told these secondaries will make at most a two percent contribution to the current at P.

(d) *Secondary Electrons from G_2*

All slow secondaries, even those initially heading toward P, will be pulled toward G_1 and are irrelevant. Although the mesh of G_2 is quite open (0.001-inch wire, 50 mesh, open area 90 percent) this is counteracted by the fact that the fast secondary emission ratio for tungsten is high, approximately 0.4–0.5 for 40–100 kilovolt primaries. Also, because of the finer mesh a larger fraction (≤ 0.4) of the fast secondaries can see P. Thus, depending on the primary spectrum, these secondaries could contribute up to two percent to the current at P.

To summarize, it will be noted that secondaries from P diminish, those from B, G_1 and G_2 increase, the total current at P, in an amount possibly amounting to several percent. If this percentage were independent of retarding voltage the secondaries would have no effect on the observed spectra. A more detailed estimate gives, for the primary spectrum of sulfur 35, relative errors of less than one percent in the observable part of the differential or integral spectra.

Positive Ion Current

When monoenergetic 6 kilovolt electrons are turned back just before reaching G_2, one observes at the collector 5×10^{-6} positive ions per primary electron at the standard operating pressure of 3×10^{-6} mm Hg. From data on mean free path of electrons in nitrogen[11, 12] at good vacuum, a value of 4×10^{-6} positive ions per primary electron is to be expected. The work of Filosofo and Rostagni[13] and Trump and Van de Graaf[14] seems to indicate that in comparison to ionization of residual gas at 10^{-6} mm pressure and a few cm electron path length (but not at 10^{-5} mm), positive ion liberation from clean steel electrodes is certainly negligible at 6 kilovolts and probably negligible up to 200 kilovolts. All told, these considerations indicate that positive ion current caused by action of primary electrons will be completely negligible for low energy beta-spectra.

Strong Field Emission

Electrons emitted from G_2 under the influence of the strong field in the G_1G_2 region will travel to G_1; but at G_1 some of these strong field electrons can be scattered back to G_2 with practically no loss of energy and reach P. Such an effect should be observable in the absence of source S. When this spectrograph was originally constructed with a one-inch G_1G_2 spacing, an electron current to P of 10^{-15} amp. was observed with G_1 13 kilovolts positive with respect to G_2; shrinking G_1 to make the G_1G_2 spacing two inches raised this figure to about 26 kilovolts. At a later stage the onset voltage for this current fell below 20 kilovolts. Grid G_2 (12-inch diameter) had been fabricated from 3/4-inch strips of fine tungsten mesh and had many minute whiskers; spotting these whiskers with very small amounts of polystyrene coil dope raised the onset voltage to about 26 kilovolts again. Strong field emission thus sets the useful upper limit on voltage for this spectrograph.

IV. ACCESSORY EQUIPMENT

Current Measurement

The current collected at P is measured by a split FP54 electrometer using a 10^{11} ohm grid resistor and the manufacturer's balanced circuit. The FP54 output was found to be non-linear in input grid voltage to a degree negligible for the S^{35} measurement. With a sensitive ten-second galvanometer, the sensitivity was 1.6×10^{-16} amp. per mm, with r.m.s. fluctuations of the order of one mm. However, as will be noted shortly, voltage fluctuations are introduced to the input grid of the FP54 by coupling to the G_1 voltage fluctuations via a small PG_1 capacity; this effect introduced equivalent current fluctuations some five times larger than those noted above. The P-to-ground capacity of 200 mmf gives the FP54 input circuit a 20-second time constant but helps to filter out the fluctuations coming through from G_1.

High Voltage Supply

The d.c. retarding voltage which is applied to G_1 and enclosed electrodes was supplied by a regulated r-f supply variable between 2.5 and 30 kilovolts and designed by R. H. Dicke.

The basic element in the regulation is a 300-megohm bleeder resistance which runs from high voltage to the negative terminal of a 180-volt bank of B-batteries, the other side of which is grounded. Thus, for any given power supply output voltage some point on the bleeder is at ground potential. A variable tap on the bleeder goes to the input grid of a d.c. amplifier which in turn controls the output of the voltage supply in such a way as to hold the amplifier input grid at ground and the output voltage at a constant value.

A change of the 60 cycle a.c. input voltage from 100 to 120 volts results in less than 20 volts change in output voltage. The r-f modulation on the output voltage amounts to 1/2 volt at 30 kilovolts; the 60-cycle ripple is about two volts. With the relative output voltage being read on an 8-second galvanometer (as described below) the fluctuations in output voltage in one minute were less than ±5 volts at 30 kilovolts.

As affecting knowledge of the voltage at which one is reading collector current at any given time, the variations just described are trivial; but really important is the fact that voltage fluctuations on G_1 appear as an equivalent current fluctuation in the FP54 output. A shielding grid which runs from G_2 to the wall of the vacuum chamber considerably reduces the PG_1 coupling; nevertheless in the sulfur 35 measurements the accuracy of current measurement was set by the fluctuations in the G_1 voltage.

Voltage Measurement

The retarding voltage is measured using a Sprague 500 megohm Meg-O-Max resistor as a meter multiplier in series with a 10K decade box, the voltage across which is measured with a type K potentiometer.

Calibration of the 500 megohm resistor, and of the intermediate standards necessary for its calibration in terms of a tenth-percent megohm standard, was carried out with a series of Wheatstone bridges. The null indicator was in each case a d.c. amplifier of 10-megohm input impedance, the high impedance providing satisfactory tenth-percent bridge sensitivity.

Since the meter multiplier resistance was observed to vary somewhat over the period of several months during which data were taken with it, the resistance is quoted only as 540.6 megohms, ±1 percent.

The value of approximately 500 megohms, as set by the current capacity of the voltage supply, necessitated a carbon resistor with a correspondingly large negative temperature coefficient; this has the effect that at zero applied voltage, after reaching thermal equilibrium in still air at an applied voltage V kilovolts, the particular resistor used here has a resistance found to be given by

$$R=R_0(1-6.5\times10^{-6}V^2).$$

After any change in voltage, the new resistance is approached exponentially with a time constant of 0.7 hour; observation of the apparent rate of drift of voltage due to resistance drift allows a correction to be made, since independent measurements show that the time rate of drift of output voltage of the voltage supply is negligible by comparison.

The Meg-O-Max resistor also has an instantaneous negative voltage coefficient; the manufacturer's value for this coefficient yields the relation

$$R=R_0(1-3\times10^{-4}V)$$

for the instantaneous effect. (V is in kilovolts.) This correction is small compared to the "thermal" effect.

V. THIN SOURCE TECHNIQUES AND DATA

Backscattering in the Source

Since the present spectrograph is concerned primarily with the low energy portions of spectra, the source phenomena which limit low energy beta-spectroscopy become of more than usual importance.

Among such source phenomena are absorption and energy loss in the finite source thickness, and backscattering from the source and source backing; the former occurs for electrons which are emitted in the direction of the detector. Since the initial diminution in the intensity of an electron beam in passing through a thin foil is almost entirely due to backscattering,[15] it is apparent that for thin films, absorption and backscattering are practically equivalent phenomena which will set in below the same point in the spectrum, backscattering being predominant when the backing is thicker than the active source.

The backscattering ratio (scattered electrons per primary) increases with thickness of the scattering film until at some critical thickness t_0 it reaches an asymptotic value called the "backscattering constant" S. The value of S is proportional to Z and has little energy dependence. The critical thickness t_0 on the other hand, is always of the same order of magnitude as the thickness at which electrons passing through the film emerge completely diffusely (i.e. probable scattering angle approximately 1/2 radian);[15] and this fact, together with the relation for the probable scattering angle,[15] indicates the connection of t to the electron energy V_c by the approximate relation

$$V_c=800[(Z^2/A)t_0]^{\frac{1}{2}}. \tag{3}$$

Here V_c is in kilovolts, Z and A are atomic number and weight of the scatterer, and t_0 is thickness in g/cm^2; this relation holds true below several hundred kilovolts. Conversely, for a film of thickness t_0 the energy V_c given by Eq. (3) characterizes a transition region for backscattering; in this region the backscattering is strongly energy-dependent and at voltages above this region there is little backscattering.

These considerations furnish no guarantee that the critical backscattering voltage of Eq. (3) is the same as the voltage at which backscattering gives rise to deviations from a straight line in the Kurie plot of a beta-spectrum. But they do suggest the comparison which is shown in Fig. 3 and which refers to all data through July 1949 on negatron activities for which good information on source thickness is available.[16] The observed critical voltage for Kurie plot deviations, V_K, is shown as a function of thickness t, or rather as a function of the weighted average value of the parameter Z^2t/A for source plus backing. The letter which is encircled for each point corresponds to the corresponding subreferences in reference 16. Points with an arrow represent upper limits in that they correspond to spectra in which the initial deviations were apparently caused by counter-window rather than backscattering effects. The solid line in the figure represents the relation

$$V_K = 1700[(Z^2/A)t]^{\frac{1}{2}} \text{ kilovolts,} \qquad (4)$$

which therefore seems to provide a good empirical relation for beta-spectra and which is closely related to the equation for critical backscattering thickness deduced above.

Source Charging

The thin-film sources of low-energy beta spectroscopy become charged up as beta-particles leave them; spectrum distortion results.[17] In the present case the source is mounted on a film 1½ inches in diameter, making unfeasible some of the stratagems which work on a slit-shaped foil. The procedure used for sulfur 35 consisted of mounting one-half inch behind the source a 0.001-inch tungsten filament. When heated this filament provides a copious source of thermal electrons which will be attracted to and neutralize any charged part of the film. The filament also boils off positive ions, which, once they pass G_1, are accelerated to the collector. To avoid this positive ion background the filament was flashed and then turned off before each reading of collector current, the subsequent reading being given a small correction by extrapolating back to the moment of flashing. The charging up of the source was definitely observable over a period of a few minutes and corresponded to the rate to be expected from a source of the known activity (0.15 millicurie S^{35}) and a few micromicrofarads capacity.

Source Backing Preparation

Since the present spectrograph is not limited by counter-window thickness, and since the comparisons in Fig. 3 indicate that a fair prediction of the effects of a very thin source backing can be made, it is important both to have a source backing of minimum thickness and to know what this thickness is.

With slight modification of apparatus developed for undergraduate physical optics, it was found possible to measure reflecting power, and hence thickness, of thin films at normal incidence. A check was made of the minimum thickness obtainable by the usual technique of picking up double films from water, using solutions of zapon in zapon thinner and of Merck flexible collodion in amyl acetate. To a first approximation, the reflecting power R of a film of thickness d and index of refraction n, for monochromatic light of wave-length λ, should be given by

$$R = 4(n-1/n+1)^2 \sin^2(2\pi dn/\lambda).$$

Measurements on collodion and zapon films gave an approximately sine-squared dependence of R on concentration of the solution used to form the film. From the maximum value of R one knows n and hence, for every other value of R, the thickness d. The respective indices of refraction of zapon and collodion film were found to be 1.57 and 1.47; the film thickness varied approximately linearly with concentration of solution. For collodion the film thickness ranged from 3 to 16 $\times 10^{-6}$ cm for solutions 20 to 80 percent by volume; corresponding figures for zapon are 6 to 51×10^{-6} cm for 10 to 60 percent solutions. In each case the lowest value represents the minimum usable thickness for a 1½ inch diameter film which has to support 0.2 cc of water for an hour or so during the process of active source deposition. The thinnest collodion films seemed to gain in strength during the course of drying out for a day or two.

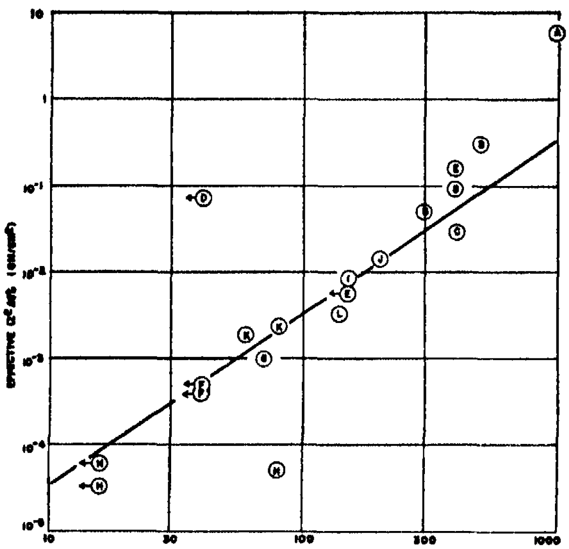

FIG. 3. Relation between source and backing thickness and critical voltage below which deviations from straight line Kurie plot occur, for a number of spectra as indicated by the corresponding letters in reference 15.

Thicknesses measured by this method checked well with values obtained by stacking up a number of films and weighing the lot.

The source backing finally used in the sulfur 35 measurements was a 3×10^{-6} cm collodion film.

ACKNOWLEDGMENTS

We are deeply indebted to Professor R. H. Dicke for the design of and advice concerning the r-f power supply described herein. One of the authors (L.G.) was the recipient of a Charles A. Coffin fellowship (1947–1948) and an AEC predoctoral fellowship (1948–1949) during the course of this work. This research has been supported in part by the joint program of the ONR and AEC.

A Note on the Geometry of Geiger Counter Telescopes

HOMER E. NEWELL, JR. AND ELEANOR C. PRESSLY
Naval Research Laboratory Washington, D. C.

(Received August 8, 1950)

The contribution of a portion of the solid angle of a two-counter telescope to the total coincidence rate is studied for both isotropic and cosine squared law radiation fields. Formulas and graphs are presented for estimating the percentage of counts due to radiation from directions near the telescope axis. The average path length traversed by particles passing through the telescope is touched upon briefly.

I. INTRODUCTION

THE geometry of a two-counter telescope was discussed in two earlier papers.[*] The coincidence rate was expressed in the form

$$N_2 = GI,$$

where G depends both upon the geometry of the telescope and upon the character of the surrounding radiation. When the radiation is isotropic, I is the unidirectional intensity in particles per unit area-unit solid angle-unit time. If the radiation intensity depends upon zenith angle ζ in accordance with a cosine squared law, then $I\cos^2\zeta$ is the intensity factor. Subject to simplifying conditions explicitly set forth in the second paper, formulas were obtained for calculating G once the effective length, diameter, and separation of the counters are known.

A brief consideration of the underlying geometry shows that the directions in the neighborhood of the telescope axis are the most effective in producing coincidences in a two-counter telescope. To make this not so, radiation from directions about the telescope axis would have to be of markedly lower intensity than that from other directions. The present paper provides formulas for estimating the relative effectiveness in producing counts of different portions of the solid angle viewed by the telescope. Some illustrative graphs are given in connection with the discussion.

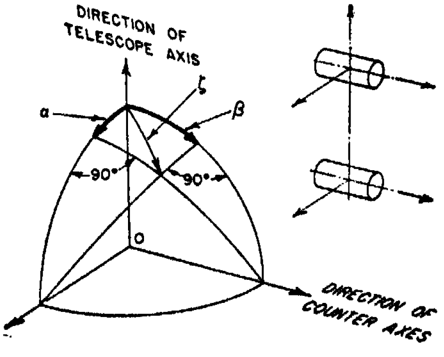

FIG. 1.

II. REVIEW

A direction in space can be specified uniquely by an ordered pair of parameters $[\alpha, \beta]$. Let $\sigma(\alpha, \beta)$ be the plane area normal to the direction $[\alpha, \beta]$ which a ray travelling parallel to $[\alpha, \beta]$ must cross in order to traverse both counters of the telescope. By Σ denote the solid angle over which $\sigma(\alpha, \beta)$ does not vanish. Then the coincidence rate of the telescope is given by

$$N_2 = \int_\Sigma\int I(\alpha, \beta)\sigma(\alpha, \beta)d\Sigma. \tag{2.1}$$

If α and β are given the meanings assigned to them in the earlier papers, and illustrated in Fig. 1, the total range of integration with respect to α and β is from $-\beta_0(\alpha)$ to $\beta_0(\alpha)$ for β, and from $-\alpha_0$ to α_0 for α, where

$$\beta_0 = \operatorname{arcctn}\{(\cos\alpha/\Delta)[\cos\alpha - (\delta^2 - \sin^2\alpha)^{\frac{1}{2}}]\}, \tag{2.2}$$

and

$$\alpha_0 = \arcsin\delta. \tag{2.3}$$

Using a, d, and l to denote, respectively, the separation of the centers, the diameter, and the length of the counters, δ denotes the ratio d/a, and Δ the ratio l/a. When $I(\alpha, \beta)$ is symmetric about the telescope axis the integration may be confined to a single quadrant of the (α, β)-plane. In such a case the region of integration would be the heavily outlined area of Fig. 2.

An expression for $\sigma(\alpha, \beta)$, valid for $-\beta_1(\alpha) \leq \beta \leq \beta_1(\alpha)$, $-\alpha_0 \leq \alpha \leq \alpha_0$, where

$$\beta_1(\alpha) = \operatorname{arcctn}\{(\cos\alpha/\Delta)[\cos\alpha - (\delta\sin\alpha - \sin^2\alpha)^{\frac{1}{2}}]\}, \tag{2.4}$$

was given in Eq. (5.2) of the first paper referred to above. Using the expression given for $\sigma(\alpha, \beta)$ and carrying out the integration over the area under the curve $\beta = \beta_1(\alpha)$ in Fig. 2, a lower bound N_{2m} to the total counting rate N_2 can be calculated.

---

[*] H. E. Newell, Jr., Rev. Sci. Inst. 19, 384 (1948); and H. E. Newell, Jr. and E. C. Pressly, Rev. Sci. Inst. 20, 568 (1949).

For fixed α, $\sigma(\alpha, \beta)$ decreases monotonically to zero as β increases from $\beta_1(\alpha)$ to $\beta_0(\alpha)$. Thus if integration of (2.1) be carried out over the entire area under $\beta=\beta_0(\alpha)$, but with $\sigma(\alpha, \beta)$ replaced by $\sigma(\alpha, \beta_1(\alpha))$ for all points lying between $\beta=\beta_1(\alpha)$ and $\beta=\beta_0(\alpha)$, the result will be an upper bound N_{2M} to N_2.

Both N_{2m} and N_{2M} serve as good approximations to N_2 in most practical cases, since the values of $\sigma(\alpha, \beta)$ at points between the curves $\beta=\beta_1(\alpha)$ and $\beta=\beta_0(\alpha)$ are quite small relative to the values associated with directions in the neighborhood of the telescope axis. The closeness with which N_{2m} and N_{2M} approximate to N_2 can be estimated by reference to Figs. 3 and 5 of the second paper.

III. RELATIVE CONTRIBUTION TO THE TOTAL COINCIDENCE RATE OF RADIATION FROM PORTIONS OF THE SOLID ANGLE VIEWED BY THE TELESCOPE

A. Formulas

The number n_2 of counts per second contributed to the total coincidence rate by a portion of the solid angle viewed by a two-counter telescope may be calculated by carrying out the integration of (2.1) over the shaded area of Fig. 2. Considering radiation from a single hemisphere only:

$$n_2(\alpha, \beta)=4\int_0^\alpha\int_0^\beta I(\alpha, \beta)\sigma(\alpha, \beta)d\Sigma. \qquad (3.1)$$

The formula is valid for all α, β in the ranges $0\leq\alpha\leq\alpha_0$, $0\leq\beta\leq\beta_1(0)$. Within these ranges the expression (5.2) of the first paper may be used for $\sigma(\alpha, \beta)$.

The counting rate $n_2(\alpha, \beta)$ forms a certain fraction of the total coincidence rate N_2 of the telescope, which fraction may be expressed in percentage form as

$$P(\alpha, \beta)=100[n_2(\alpha, \beta)/N_2]. \qquad (3.2)$$

Either $100\, n_2/N_{2m}$ or $100\, n_2/N_{2M}$ can be used as an approximation to P. The absolute error in using the latter satisfies the inequality

$$\begin{aligned} P-100\, n_2/N_{2M}&<100\, n_2(1/N_{2m}-1/N_{2M})\\ &<(n_2/N_{2M})E, \quad E=100(N_{2M}-N_{2m})/N_{2m}. \end{aligned}$$

The quantity E is precisely that plotted in Figs. 3 and 5 of the second paper. Thus the error in using $100\, n_2/N_{2M}$ for P is in the negative direction and is less than

$$100\{[(n_2/N_{2M})E]/[100(n_2/N_{2M})]\}=E$$

percent of P. The error can accordingly be estimated by reference to the graphs of E in the previous paper.

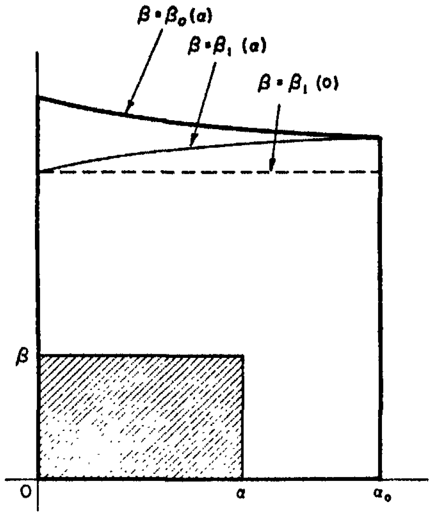

FIG. 2.

In the isotropic case the formula for n_2 is

$$n_2(\alpha, \beta)=4I\int_0^\alpha\int_0^\beta \sigma(\alpha, \beta)d\Sigma.$$

Using the relation

$$d\Sigma=\frac{\cos\alpha\cos\beta}{[1-\sin^2\alpha\sin^2\beta]^{\frac{1}{2}}}d\beta d\alpha,$$

this becomes:

Isotropic Case

$$\begin{aligned} n_2(\alpha, \beta)=2a^2I\int_0^\alpha\Big\{&\Delta(\delta-\sin\alpha)\arctan(\cos\alpha\tan\beta)\\ &+[(\Delta\operatorname{ctn}\beta-\cos^2\alpha)(\delta-\sin\alpha)+B\cos\alpha]\\ &\times\frac{\cos\alpha\sin^2\beta}{(1-\sin^2\alpha\sin^2\beta)}\Big\}d\alpha, \end{aligned} \qquad (3.3)$$

where

$$\begin{aligned} B=\frac{1}{4}\Big[&\delta^2\arccos\left(\frac{2\sin\alpha-\delta}{\delta}\right)\\ &+2(\delta-2\sin\alpha)(\delta\sin\alpha-\sin^2\alpha)^{\frac{1}{2}}\Big]. \end{aligned} \qquad (3.4)$$

When the radiation intensity factor is $I\cos^2\zeta$, the angle ζ being measured relative to the telescope axis,

$$n_2(\alpha, \beta)=4I\int_0^\alpha\int_0^\beta\cos^2\zeta(\alpha, \beta)\sigma(\alpha, \beta)d\Sigma,$$

where

$$\cos^2\zeta=\frac{\cos^2\alpha\cos^2\beta}{1-\sin^2\alpha\sin^2\beta}.$$

TABLE I. $P(\alpha, \beta)$ (Eq. (3.2)) for $\alpha/\alpha_0=\beta/\beta_0$.

	$\alpha\beta/\alpha_0\beta_0$	Isotropic case			Cosine squared law case		
d/a	l/d	0.2	0.4	0.6	0.2	0.4	0.6

	15	60	85	96	79	96	98
	25	60	85	95	78	95	96

Upon integration this yields:

Cosine-Squared Law Case

$$n_2(\alpha,\beta)=a^2I\int_0^\alpha\Bigg\{\Delta(\delta-\sin\alpha)\cos^3\alpha\times\left[\frac{\sin\beta\cos^3\beta}{(1-\sin^2\alpha\sin^2\beta)^2}+\frac{3\sin\beta\cos\beta}{2(1-\sin^2\alpha\sin^2\beta)}+\frac{3}{2\cos\alpha}\arctan(\tan\beta\cos\alpha)\right]+[B\cos^2\alpha-(\delta-\sin\alpha)\cos^3\alpha]\times\left[1-\frac{\cos^4\beta}{(1-\sin^2\alpha\sin^2\beta)^2}\right]\Bigg\}d\alpha. \quad (3.5)$$

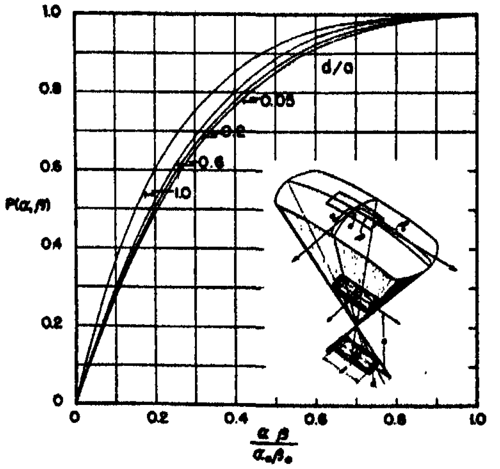

FIG. 3. Contribution of part of counter telescope's solid angle to total counting rate. Isotropic case, $n_2(\alpha, \beta)$-counting rate due to radiation from all directions (α', β') where $-\alpha\leq\alpha'\leq\alpha$, $-\beta\leq\beta'\leq\beta$, with the direction (0, 0) being taken along the telescope axis, and with $\alpha/\alpha_0=\beta/\beta_0$. N_2 = total counting rate of the telescope. $P(\alpha, \beta)=[100n_2(\alpha, \beta)]/N_2$.

In computing $P(\alpha, \beta)$ one must, of course, use the isotropic case value of N_{2M} in conjunction with (3.3), and the cosine-squared law value with (3.5).

B. Graphs

Table I gives $P(\alpha, \beta)$ for various values of d/a, l/d, and $\alpha\beta/(\alpha_0\beta_0)$, under the assumption that $\alpha/\alpha_0=\beta/\beta_0$. The approximation $(100n_2)/N_{2M}$ was used in calculating P. With $\alpha\beta/(\alpha_0\beta_0)$ and d/a fixed, P shows little variation with l/d. It seems reasonable, therefore, to average out the parameter l/d by taking, for each pair of values of $\alpha\beta/(\alpha_0\beta_0)$ and d/a, the unweighted arithmetic mean of the corresponding values of $P(\alpha, \beta)$ for l/d equal to 3, 5, 15, and 25. These average values plotted in Figs. 3 and 4 show the variation of $P(\alpha, \beta)$ relative to $\alpha\beta/(\alpha_0\beta_0)$ for four different values of d/a.

From the graphs one can see that radiation from the directions corresponding to the shaded area of Fig. 2 accounts for about 50 percent of the total coincidence rate when $\alpha=0.4\alpha_0$ and $\beta=0.4\beta_0(0)$.

The parameter $\alpha\beta/\alpha_0\beta_0$ is easily visualized and readily determined for any case in question, and for these reasons was used instead of the corresponding ratio of the actual solid angles involved. In the event that the solid angles are of interest they can be determined with some additional effort. That corresponding to the shaded area of Fig. 2 is given by

$$\Sigma=4\int_0^\alpha\int_0^\beta\frac{\cos\alpha\cos\beta}{[1-\sin^2\alpha\sin^2\beta]^{\frac{3}{2}}}d\beta d\alpha$$

$$=4\arcsin(\sin\alpha\sin\beta). \quad (3.6)$$

The total solid angle viewed by the telescope can be calculated from

$$\Sigma_T=4\int_0^{\alpha_0}\int_0^{\beta_0(\alpha)}\frac{\cos\alpha\cos\beta}{[1-\sin^2\alpha\sin^2\beta]^{\frac{3}{2}}}d\beta d\alpha, \quad (3.7)$$

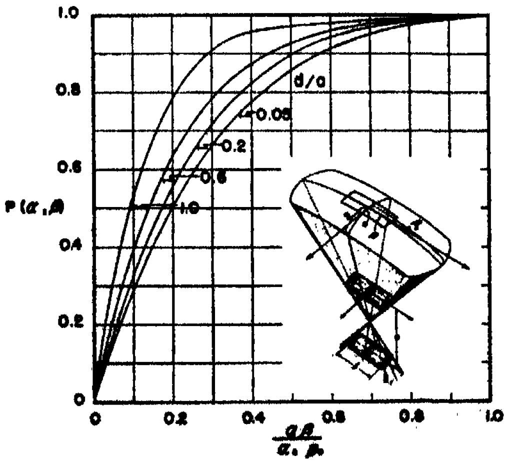

FIG. 4. Cosine-squared law case. See caption for Fig. 3 for definition of terms.

where $\beta_0(\alpha)$ is given by (2.2). When $\alpha = 0.4\alpha_0$ and $\beta = 0.4\beta_0(0)$, the ratio Σ/Σ_T is in the neighborhood of 0.2, so that 50 percent of the total counting rate is due to radiation from roughly 20 percent of the total solid angle of the telescope. This illustrates quantitatively the fact stated earlier that most of the radiation counted by a telescope comes from directions near the telescope axis.

In practice the ratio l/d for the counters of a telescope is often fairly large. In such a case, except when the counters are close together, the angle α_0 may be considerably smaller than $\beta_0(0)$. Whereas the range of angles in the β-direction may be so large that its effect upon interpretation of data must be considered, at the same time the angular spread in the α-direction may be small enough to be negligible. When α_0 isn't too large, the variation of $P(\alpha_0, \beta)$ with β is of especial interest. The variation of $P(\alpha_0, \beta)$ with d/a, l/d, and β/β_0 is shown in Table II. Once again $P(\alpha_0, \beta)$ varies but little with l/d when the other parameters are fixed, and it is thought worth while to average out l/d before graphing $P(\alpha_0, \beta)$. The average values are plotted in Figs. 5 and 6.

The graphs of Figs. 3 and 5 covering the case of isotropic radiation provide in essence a means of judging how effective a telescope is as a collimator. This is of especial interest when the directional properties of a radiation field are under study.

IV. VARIATION OF PATH LENGTH WITH DIRECTION

When the solid angle viewed by a telescope is large, the variation in path length through the telescope may be appreciable. Suppose, for example, that an absorber of thickness t is located between the counters of the telescope. As was shown in the discussion of the preceding sections, most of the particles registering counts in the telescope approach from directions near that of the telescope axis. For such particles the path length traversed within the absorber is close to t. On the other hand some of the particles causing coincidence counts penetrate the absorber at large angles to the telescope axis. For these the path lengths through the absorber are considerably greater than t. When the average path length L through the absorber is significantly different from t, it may be important to know L.

The path length through the absorber for a particle from the direction $[\alpha, \beta]$ is $t/\cos\zeta(\alpha, \beta)$, where $\zeta(\alpha, \beta)$ is the angle made by the ray with the telescope axis. Hence the average path length L is given by

$$L = \frac{t}{N_2} \int\int_{\Sigma} \frac{I(\alpha, \beta)\sigma(\alpha, \beta)}{\cos\zeta(\alpha, \beta)} d\Sigma, \tag{4.1}$$

where N_2 is the total coincidence rate, and Σ the total

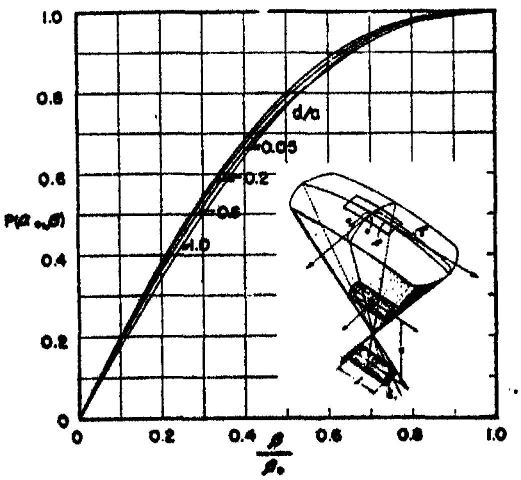

FIG. 5. Isotropic case. See caption for Fig. 3 for definition of terms.

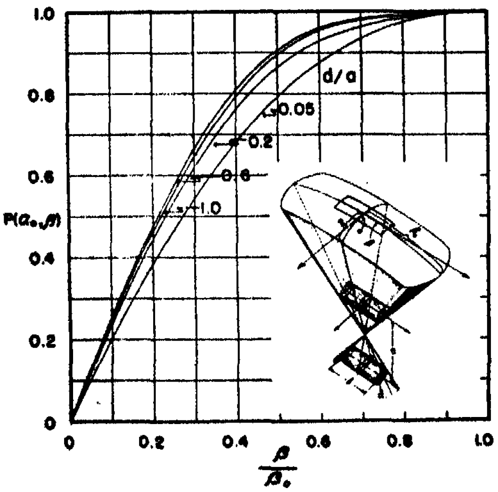

FIG. 6. Cosine-squared law case. See caption for Fig. 3. for definition of terms.

solid angle, of the telescope. Using

$$\cos\zeta(\alpha,\beta)=\frac{\cos\alpha\cos\beta}{[1-\sin^2\alpha\sin^2\beta]^{\frac{1}{2}}},$$

and the expression given previously for $\sigma(\alpha,\beta)$, one gets upon integration:

Isotropic Case

$$L\geq L_m=\frac{4tI}{N_2}\int_0^{\alpha_0}\int_0^{\beta_1(\alpha)}\frac{\sigma(\alpha,\beta)}{\cos\zeta(\alpha,\beta)}d\Sigma=\frac{4a^2tI}{N_2}\int_0^{\alpha_0}\{[(\delta-\sin\alpha)(\Delta+\operatorname{ctn}\beta_1)-B\sec\alpha\operatorname{ctn}\beta_1]$$
$$\times[\operatorname{ctn}^2\beta_1+\cos^2\alpha]^{-\frac{1}{2}}+[B\sec\alpha-(\delta-\sin\alpha)]\}d\alpha;\quad(4.2\text{a})$$

and

$$L\leq L_M=L_m+\frac{4tI}{N_2}\int_0^{\alpha_0}\int_{\beta_1(\alpha)}^{\beta_0(\alpha)}\frac{\sigma(\alpha,\beta_1(\alpha))}{\cos\zeta(\alpha,\beta)}d\Sigma=L_m+\frac{4a^2tI}{N_2}\int_0^{\alpha_0}[(\delta-\sin\alpha)(\Delta\sec\alpha\operatorname{ctn}\beta_1-\cos\alpha)+B]$$
$$\times\arctan\left[\cos\alpha\left(\frac{\operatorname{ctn}\beta_1-\operatorname{ctn}\beta_0}{\operatorname{ctn}\beta_1\operatorname{ctn}\beta_0+\cos^2\alpha}\right)\right]\times(\operatorname{ctn}^2\beta_1+\cos^2\alpha)^{-\frac{1}{2}}d\alpha,\quad(4.2\text{b})$$

for the isotropic case. Expressions for β_1, β_0, and B appear in (2.4), (2.2), and (3.3).

For the cosine-squared law case:

Cosine-Squared Law Case

$$L\geq L_m=\frac{4tI}{N_2}\int_0^{\alpha_0}\int_0^{\beta_1(\alpha)}\cos\zeta(\alpha,\beta)\sigma(\alpha,\beta)d\Sigma=\frac{4a^2tI}{3N_2}\int_0^{\alpha_0}\left\{[B\cos\alpha-(\delta-\sin\alpha)\cos^2\alpha]+\frac{3\Delta\cos^2\alpha(\delta-\sin\alpha)}{(\operatorname{ctn}^2\beta_1+\cos^2\alpha)^{\frac{1}{2}}}\right.$$
$$\left.+\frac{[(\delta-\sin\alpha)\cos^2\alpha-B\cos\alpha]\operatorname{ctn}^3\beta_1-\Delta\cos^4\alpha(\delta-\sin\alpha)}{(\operatorname{ctn}^2\beta_1+\cos^2\alpha)^{\frac{3}{2}}}\right\}d\alpha;\quad(4.3\text{a})$$

and

$$L\leq L_M=L_m+\frac{4tI}{N_2}\int_0\int_{\beta_1(\alpha)}^{\beta_0(\alpha)}\cos\zeta(\alpha,\beta)\sigma(\alpha,\beta_1(\alpha))d\Sigma=L_m+\frac{2a^2tI}{N_2}\int_0^{\alpha_0}\{(\delta-\sin\alpha)(\Delta\sec\alpha\operatorname{ctn}\beta_1-\cos\alpha)+B\}$$
$$\times\left\{\arctan\left[\cos\alpha\left(\frac{\operatorname{ctn}\beta_1-\operatorname{ctn}\beta_0}{\operatorname{ctn}\beta_1\operatorname{ctn}\beta_0+\cos^2\alpha}\right)\right]+\frac{\cos\alpha\operatorname{ctn}\beta_0}{\operatorname{ctn}^2\beta_0+\cos^2\alpha}-\frac{\cos\alpha\operatorname{ctn}\beta_1}{\operatorname{ctn}^2\beta_1+\cos^2\alpha}\right\}(\operatorname{ctn}^2\beta_1+\cos^2\alpha)^{-\frac{1}{2}}\cos^2\alpha d\alpha.\quad(4.3\text{b})$$

Erratum: The Scintillation Efficiency of Anthracene for Low Energy Electrons

[Rev. Sci. Inst. 21, 784 (1950)]

W. J. RAMLER AND M. S. FREEDMAN
Argonne National Laboratory, Chicago, Illinois

The following was omitted from the original article:

Note added in proof: To test the applicability of the efficiency correction to beta-spectra, the spectrum of Pm^{147} was measured using samples ~10 $\mu\mathrm{g/cm}^2$ thickness. Langer[18] has shown the Kurie curve to be linear for such samples down to ~8 kev. Our Kurie curve deviated below linearity below 50 kev, such that the application of a correction factor linear with energy from 50 to 20 kev, amounting to 2.0 at 20 kev in addition to the correction factor of Fig. 4 below 20 kev, gave a Kurie curve straight to ~10 kev. Thus the normalization of Fig. 4 to 100 percent at 20 kev is incorrect; the curve has a small positive slope from 50 percent at 20 kev to 100 percent at 50 kev. Such a slope is consistent with the error in the experimental points above 10 kev.

(Received June 26, 1950)

The method of construction and operating conditions are given for a respirometer suitable for determining steady-state rates of oxygen uptake by peripheral nerve. The polarographic method is used to measure the change in oxygen concentration occurring when a solution of known oxygen concentration flows at a constant, predetermined rate over a tissue sample which removes oxygen from the stream. From a knowledge of the concentration change and volume-flow rate the rate of oxygen uptake by the tissue is readily determined. Electrodes for stimulating the nerve sample and for recording the action potential are provided. By virtue of the flow system the respirometer maintains constant environmental conditions. The system is linear with respect to changes in the steady-state rate of oxygen consumption, and the sensitivity is such that, for a 10-mg sample of nerve, changes in the rate of oxygen uptake of 0.1 micromoles/g hr., (2 cu. mm/g hr.) are readily detected.

THE purpose of this paper is to present in detail the theory, the method of construction, and the operational characteristics of a flow-respirometer for the direct measurement of the steady-state rate of oxygen uptake by peripheral nerve. The present instrument is essentially the same as the earlier model mentioned by Bronk *et al.*,[1] and later described in an abstract by Carlson, Brink, and Bronk.[2] Extensive use of the instrument over the past few years has led to modifications in construction and operating technique, which in the opinion of the authors make the present model the instrument of choice for studying the steady-state rate of oxygen uptake in nerve.

Basically, the flow respirometer is a device which allows one to measure the change in oxygen concentration occurring when an oxygenated solution flows at a constant, predetermined rate over an oxygen-consuming tissue sample. From a knowledge of the concentration change and the rate of volume flow it is a simple matter to compute the rate of oxygen uptake by the tissue. The critical problem in the construction of such a respirometer is the development of a device for detecting the concentration of oxygen in a solution of electrolytes.

Brink and Davies[3,4] have described a platinum microelectrode, referred to as the oxygen cathode, which can be used as the active electrode in a polarograph[5] designed to measure oxygen concentration. The method is based on the fact that under certain specifiable conditions the rate of electrolytic reduction of oxygen at the surface of a platinum electrode immersed in a solution of electrolytes is directly proportional to the concentration of dissolved oxygen, the current in the external circuit being used as a measure of the rate of electrolytic reduction. As far as the present discussion is concerned, the important features of such a technique are its high sensitivity to dissolved oxygen concentration and its small physical size. These two features make possible the construction of the respirometer described here, since none of the existing manometric or volumetric techniques are readily adaptable for use in a flow system.

The results of previous studies have suggested to us the following specifications for a respirometer intended to measure the steady-state rates of oxygen uptake of nerve.

1. The respirometer should maintain a constant chemical and thermal environment consistent with the maintenance of a steady-state of metabolism. This requires a constant source of oxygen, and other necessary substrates, together with a sink for heat, carbon dioxide, and any other diffusable material produced by the metabolic processes.
2. The system should be capable of detecting changes in the rate of oxygen uptake of about 2.0 cu. mm/g hr. for a 5 mg to 10 mg sample of nerve tissue, and at the same time give a measure of the total amount of oxygen removed from the stream.

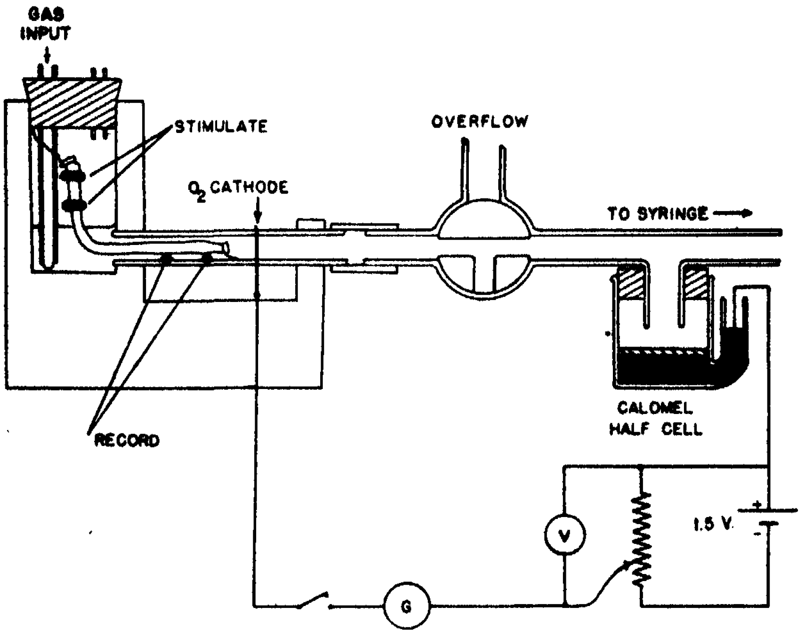

FIG. 1. Schematic diagram of flow respirometer.

3. The oxygen detecting system should be linear over the operating range with respect to the steady-state rate of oxygen uptake and the total amount of oxygen removed from the stream.

4. Adequate control experiments should be possible. For example, a tissue sample on which the effects of a metabolic inhibitor are being studied should be used as its own control.

Davies[4] has described a static respirometer in which an oxygen cathode is used to detect the change in oxygen concentration in a fixed volume of solution enclosing the respiring nerve tissue. The slope of the oxygen concentration-time curve obtained from this type of respirometer is a measure of the rate of oxygen uptake by the nerve. Subsequent work with these static respirometers has led to the following conclusions regarding their undesirable properties:

1. In the static respirometer the oxygen concentration of the solution is measured as a function of time, whereas what is really wanted is a device which measures directly the rate of removal of oxygen.
2. The steady uptake of oxygen by the nerve sample reduces the oxygen concentration in the fixed volume of solution to zero in about an hour, thereby putting a limit on the allowable time for continuous observation.
3. The oxygen cathode in the static respirometer is close to and in some cases actually touching the tissue. While this situation is satisfactory for some experiments, it is not conducive to a high degree of stability of the calibration, and introduces the possibility of the electrode current influencing the metabolic and functional behavior of the nerve.
4. In a static respirometer there exists the possibility that changes due to the accumulation of metabolic products could prevent the establishment of a steady state of metabolism.
5. The static respirometer does not permit an accurate determination of the absolute value of the rate of oxygen uptake; it can be used only to measure relative rates of oxygen uptake owing to the difficulty of determining the amount of oxygen dissolved in the nerve sample itself.

All of these considerations suggested a flow respirometer as a possible improvement.

GENERAL DESCRIPTION OF RESPIROMETER

Figure 1 is a schematic diagram of a flow respromiter. There is a reservoir containing suitable perfusion solution,‡ equilibrated by constant bubbling with a gas of known oxygen concentration. Above the level of the solution mounted in the wall of the reservoir are the platinum electrodes across which the stimulating voltage is applied to the nerve. A heavy-walled glass capillary of suitable diameter enters the reservoir. Tubes having an inside diameter of 1.4 mm are satisfactory for studies of frog and crab nerve. Sealed in the capillary wall and exposed to the lumen are two 0.003-in. platinum wire electrodes for recording the electrical activity of the nerve. Beyond the second of these is the oxygen cathode.

---

‡ The results presented in this paper were obtained with a perfusion fluid for frog's nerve of the following composition:

$CaCl_2$	1.81 millimoles/liter
NaCl	115.0 millimoles/liter
KCl	2.10 millimoles/liter
$NaHCO_3$	1.98 millimoles/liter

Equilibrate with two percent CO_2 gas giving a pH of 7.0 at 20°C.

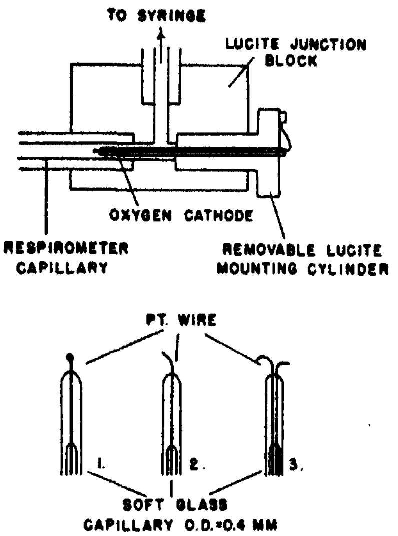

FIG. 2. Detail of oxygen cathode construction and mounting.

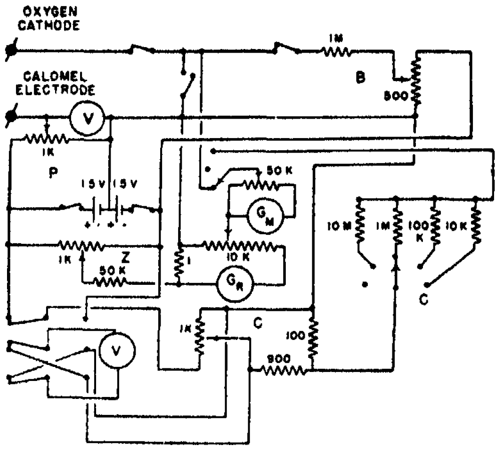

FIG. 3. Circuit diagram of polarizing circuit and auxiliary circuits. P, polarizing circuit for oxygen cathode. Z, galvanometer zero adjustment circuit. B, "bucking" circuit (see text). C, circuit for providing calibrating currents.

Two types of oxygen cathode have been used successfully, consisting of either a 0.002-in. platinum wire sealed across the lumen of the capillary (Fig. 1) or a short length of platinum wire supported on the end of a longitudinal glass rod located in the center of the stream (Fig. 2). The chief advantage of the second type of oxygen cathode is that it allows easy replacement at any time.

Following the chamber are: a three-way stopcock for refilling and cleaning purposes, and a calomel electrode. A simplified polarizing circuit is also shown in Fig. 1.

Beyond the calomel electrode a syringe draws solution from the reservoir through the capillary at a constant volume flow rate. It is obvious that such an arrangement can detect only changes in the rate of oxygen uptake associated with the portions of nerve in the capillary, since the section of nerve in the reservoir is in a region of constant oxygen concentration. In use, only the respirometer proper is placed in a temperature bath regulated to 0.1°C, while the stopcock, calomel electrode, and syringe remain outside at room temperature.

In actual operation, the oxygen cathode circuit is closed 12 seconds out of every minute. Intermittent operation of the electrode reduces the rate of drift of sensitivity. A Leeds and Northrup type *R* galvanometer is used in conjunction with motor-driven camera for recording the oxygen cathode currents. In addition, this current is monitored on a Rubicon table galvanometer placed in series with the Leeds and Northrup instrument.

Figure 3 is a circuit diagram of the polarizing and auxiliary circuits for providing calibrating currents, zero-control currents, and "bucking" currents. The polarizing circuit provides a controllable voltage for the oxygen cathode circuit, as well as a galvanometer and shunt for measuring the current in the circuit. Changes in the mechanical zero of the galvanometer are compensated by a small current from the zero-control circuit. Currents of known amounts for calibration purposes are provided by the calibrating circuit.

The "bucking" circuit shown in Fig. 3 allows one to oppose part of the oxygen cathode current flowing through the galvanometer shunt. In this way, the resulting current can be adjusted to give full scale deflection for the maximum galvanometer sensitivity. This procedure increases the over-all sensitivity of the instrument to changes in rates of oxygen consumption. In practice, fivefold increases have been obtained with a continuously operated oxygen cathode and the Leeds and Northrup galvanometer. The large initial current associated with closing the oxygen cathode circuit made it impossible to use this technique for intermittent electrode operation. In the future it is hoped that by using an electronic current-sensitive device, full use can be made of the "bucking" technique for increasing the useful over-all sensitivity to the limit set by current fluctuations due to variations in the volume flow rate.

THEORY OF FLOW RESPIRATOR

Before launching into any detailed theoretical analysis of the flow respirometer, it is worth while to state the important results obtained from such an analysis. These are the expression relating galvanometer deflection and volume flow rate to the steady-state rate of oxygen

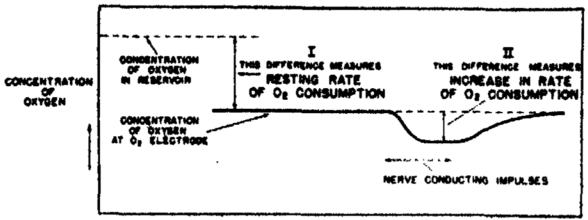

FIG. 4. Simplified record of a typical experiment.

uptake by the nerve in the capillary, and the operational conditions necessary for this expression to hold. Unless these conditions are met, it is not certain that the rate of oxygen uptake computed from the derived expression will be correct.

Figure 4 is a simplified record of a typical experiment. The ordinate is directly proportional to the oxygen concentration at the cathode, time is measured along the axis of abscissas. The difference between the oxygen concentration measured with the capillary empty and then with a resting nerve present is a measure of the resting rate of oxygen uptake by the nerve. Similarly, the difference between the oxygen concentration measured with a resting nerve in the capillary and then with a nerve conducting impulses is a measure of the increase in the rate of oxygen uptake. If the proper conditions are met, it can be shown also that the area between the broken line and the solid curve of II, Fig. 4 is a measure of the total amount of oxygen removed from the stream as a result of the nerve's activity.

The equation used to determine the rate of oxygen uptake of the nerve sample from the measured electrolysis current and the constants of the system is:

$$Q = V\cdot C_0(1 - i_1/i_0).$$

Q is the steady-state rate of oxygen uptake in micromoles/hour. V is the volume flow rate of solution through the capillary in liters/hour. C_0 is the concentration of oxygen in the reservoir in micromoles/liter. i_0 is the current in the oxygen cathode circuit when no nerve is present in the capillary and the oxygen concentration in the stream is C_0. i_1 is the current in the oxygen cathode circuit when a nerve with a rate of oxygen uptake equal to Q is present in the capillary and the oxygen concentration in the reservoir is C_0.

The first of the necessary operational conditions to be met is the constancy of C_0. In practice this is achieved by constantly bubbling a gas of known oxygen concentration through the solution in the reservoir.

It is also necessary that V be maintained at a constant known value. The syringe drive used in the present work consisted of a precision screw coupled to a 1-ml B-D Yale Tuberculin syringe. The screw was driven through a reduction gear by a Holzer-Cabot 75 in.-oz., 1 r.p.m. synchronous motor. This drive produced a volume flow rate of 2.16×10^{-4} liters/hour, constant to within one percent. A constancy of one percent is adequate for rates of oxygen uptake greater than 2.0 cm/g hr.; for rates smaller than this value a more uniform syringe drive is needed.

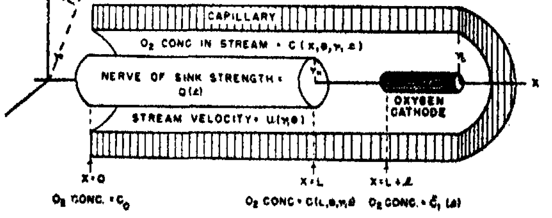

FIG. 5. Schematic diagram of respirometer capillary showing orientation of nerve and oxygen cathode with respect to the cylindrical coordinate system.

Finally, and of utmost importance in assuring proper operation of the respirometer, is the location of the oxygen cathode; it is essential that it be located at a point in the capillary where the oxygen concentration is constant across the area of the stream. This can be achieved by placing the oxygen cathode sufficiently far downstream from the end of the nerve to allow all concentration gradients existing across the stream as it leaves the end of the nerve to equilibrate. The results of the following discussion show that the oxygen cathode should be located downstream from the end of the nerve by a distance l in cm greater than $12r_c^2D/[V-(V^2+145r_c^2D^2)^{\frac{1}{2}}]$. V is the volume flow rate in ccm/sec. and D the diffusion coefficient of oxygen in water at the operating temperature in units of cm²/sec. and r_c the radius of the capillary. At this distance from the nerve the oxygen concentration across the area of the capillary will be constant to within two percent of its average value.

Although it is not necessary for the proper operation of the respirometer itself, mention should be made of the necessity for choosing the volume flow rate and initial oxygen concentration high enough to insure that no part of the nerve becomes anoxic. For a ten-milligram sample of frog sciatic nerve a volume flow rate of 2.16×10^{-4} liters/hour and an initial oxygen concentration of 265 micromoles/liter (20 percent oxygen in the equilibrating gas) was sufficient to prevent any part of the nerve from becoming anoxic even under the most extreme conditions. Anyone contemplating using this type of respirometer for studies on other tissues should first examine the extent to which the rate of oxygen uptake is dependent on oxygen concentration and choose the volume flow rate and initial oxygen concentration accordingly.

In discussing the theory of the flow respirometer it is convenient to orient the nerve and capillary with respect to a cylindrical coordinate system as shown in Fig. 5, and to introduce the following symbols and definitions:

x, r, θ = coordinates of a point in the capillary stream defined by the coordinate system shown in Fig. 5.
t = time in hours.
$C(x, r, \theta, t)$ = oxygen concentration in micromoles/liter as a function of x, r, θ, and t.
$u(r, \theta)$ = stream velocity as a function of r and θ in cm/hour.
$Q(t)$ = rate at which entire nerve sample removes oxygen from the stream in micromoles/hour as a function of time.
L = length of nerve in capillary in cm.
r_n = radius of nerve in cm.
r_c = radius of capillary in cm.
C_0 = oxygen concentration in the reservoir, $x=0$, a constant, in micromoles/liter.
$C_1(t)$ = oxygen concentration at the oxygen cathode, $x=L$, as a function of time in micromoles/liter.
V = volume flow rate through the capillary in liters/hour.

i_0 = current in microamperes in oxygen cathode circuit due to a flowing solution of oxygen concentration C_0 and volume flow rate V.

$i_1(t)$ = current in microamperes in oxygen cathode circuit due to a flowing solution of concentration $C_1(t)$ and volume flow rate V.

K = sensitivity of the oxygen cathode in (micromoles/liter) per microampere.

D = diffusion coefficient of oxygen in water at the temperature of operation, in cm²/sec.

The total amount of oxygen contained in the portion of the stream surrounding the nerve of length L at the time t is given by the integral of the oxygen concentration function over the volume. This quantity is equal to the average concentration over the volume, $\bar{C}_v(t)$, at the time t multiplied by the volume. That is:

$$\int_0^L dx \int_0^{2\pi} d\theta \int_{r_n}^{r_c} C(x, \theta, r, t) r dr = \bar{C}_v(t) \pi L (r_c{}^2 - r_n{}^2),$$

where the radii of the nerve r_n and capillary r_c are assumed constant over their length. Similarly, at the time $(t+\Delta t)$ the amount of oxygen in the stream is:

$$\int_0^L dx \int_0^{2\pi} d\theta \int_{r_n}^{r_c} C(x, \theta, r, t+\Delta t) r dr = \bar{C}_v(t+\Delta t) \pi L (r_c{}^2 - r_n{}^2).$$

The change in the amount of oxygen in this volume during the time Δt is equal to the difference between the amount which enters the volume over the annular section at $x=0$ and the amount which leaves because of both the flow through the annular section at $x=L$ and the oxygen uptake of the nerve present in the capillary. This assumes, of course, that the amount which enters and leaves by diffusion and mixing in the x-direction is small compared to the amount transported by the stream. Equating these quantities we obtain:

$$\begin{aligned}[\bar{C}_v(t) - \bar{C}_v(t+\Delta t)] \pi L (r_c{}^2 - r_n{}^2) \\ = \Delta t \int_0^{2\pi} d\theta \int_{r_n}^{r_c} u(r, \theta) C(0, r, \theta, t) r dr \\ - \Delta t \int_0^{2\pi} d\theta \int_{r_n}^{r_c} u(r, \theta) C(L, r, \theta, t) r dr - Q(t) \Delta t. \quad (1)\end{aligned}$$

The two integrals on the right of (1) are the oxygen fluxes through the section at $x=0$ and $x=L$, respectively. Division of each side of (1) by Δt and passing to the limit as Δt approaches zero yields:

$$\begin{aligned}Q(t) = \int_0^{2\pi} d\theta \int_{r_n}^{r_c} u(r, \theta) C(0, r, \theta, t) r dr \\ - \int_0^{2\pi} d\theta \int_{r_n}^{r_c} u(r, \theta) C(L, r, \theta, t) r dr \\ - \pi L (r_c{}^2 - r_n{}^2) [d\bar{C}_v(t)/dt]. \quad (2)\end{aligned}$$

Equation (2) is the general expression relating the rate of oxygen uptake of the nerve, $Q(t)$, to the concentration functions $C(0, r, \theta, t)$ and $C(L, r, \theta, t)$, the stream velocity function $u(r, \theta)$, and the time rate of change of the average volume concentration function, $d\bar{C}_v(t)/dt$. By imposing certain physically realizable conditions on the concentration function it is possible to obtain a simplification of (2) which relates $Q(t)$ to measurable quantities. If the concentration function $C(0, r, \theta, t)$ is made independent of r, θ, and t and at the same time the function $C(L, r, \theta, t)$ is made independent of r and θ, then these two functions can be taken outside of their respective integrals in (2) and we obtain:

$$\begin{aligned}[C_0 - C_1(t)] \int_0^{2\pi} d\theta \int_{r_n}^{r_c} u(r, \theta) r dr \\ - \pi L (r_c{}^2 - r_n{}^2) [d\bar{C}_v(t)/dt] = Q(t), \quad (3)\end{aligned}$$

where C_0 is the constant concentration at $x=0$ and $C_1(t)$ is the uniform oxygen concentration at the oxygen cathode, a function of time only. Further simplification of (3) results when use is made of the fact that:

$$\int_0^{2\pi} d\theta \int_{r_n}^{r_c} u(r, \theta) r dr = V,$$

where V is the volume flow rate through the capillary. Equation (3) then becomes:

$$V[C_0 - C_1(t)] - \pi L (r_c{}^2 - r_n{}^2) [d\bar{C}_v(t)/dt] = Q(t). \quad (4)$$

In practice the function $C(0, r, \theta, t)$ is made constant by constantly bubbling oxygen through the solution in the reservoir, thereby stirring it and maintaining the oxygen concentration at a constant value independent of r, θ, and t at $x=0$.

The concentration at $x=L$, $C(L, r, \theta, t)$ cannot be made uniform over r and θ directly. What can be done, however, is to place the oxygen cathode far enough downstream from the end of the nerve so that concentration gradients existing in the stream as it leaves the end of the nerve have sufficient time to be dissipated by diffusion. For the time being we will assume that the oxygen cathode has been located in that portion of the capillary where the oxygen concentration is essentially constant. The details of determining the separation between the end of the nerve and the region of constant oxygen concentration are given at the end of this discussion.

Returning to Eq. (4) we are now in a position to derive the desired relationship between the steady-state rate of oxygen uptake by the nerve and the measurable quantities. If the system is in the steady state, then all of the concentrations are constant in time; therefore, $d\bar{C}_v(t)/dt = 0$, and (4) becomes:

$$V[C_0 - C_1] = Q, \quad (5)$$

where C_1 and Q refer to the steady-state values of $C_1(t)$ and $Q(t)$, respectively.

Since the current in the oxygen cathode circuit is directly proportional to the oxygen concentration, it follows that:

$$\begin{aligned} C_0 &= K\cdot i_0, \\ C_1 &= K\cdot i_1, \end{aligned} \tag{6}$$

where K is the sensitivity of the oxygen cathode. Substitution of (6) in (5) yields:

$$Q=VC_0[1-i_1/i_0]. \tag{7}$$

Equation (7) is the desired expression relating the unknown steady-state rate of oxygen uptake to the known constants of the respirometer, V, C_0, and i_0 and the measured quantity i_1.

For the transition from one steady state to another we can derive the following useful relationship between the variables of Eq. (4). Without loss of generality, it is allowable to assume that at time $t=0$ the rate of oxygen uptake by the nerve is equal to zero, and that for all subsequent times it is given by some function $Q(t)$ which approaches the constant value Q for $t=\infty$. Under this condition the boundary values of the variables become:

$$\begin{aligned} &t=0, \quad C_1(0)=C_0 \quad \text{and} \quad \bar{C}_v(0)=C_0, \\ &t=\infty, \quad C_1(\infty)=C_1 \quad \text{and} \quad \bar{C}_v(\infty)=C_v. \end{aligned}$$

Integration of (4) with respect to time from 0 to ∞ now yields:

$$V\int_0^\infty C_1(t)dt-\pi L(r_c^2-r_n^2)[C_v-C_0]=\int_0^\infty Q(t)dt. \tag{8}$$

For the particular case in which $C_v=C_0$, the final steady state, is the same as the initial steady state, we obtain:

$$V\int_0^\infty C_1(t)dt=\int_0^\infty Q(t)dt. \tag{9}$$

Since the current in the oxygen cathode circuit is proportional to the concentration $C_1(t)$, it follows that:

$$C_1(t)=K\cdot i_1(t). \tag{10}$$

Substitution of (10) in (9) yields:

$$VK\int_0^\infty i_1(t)dt=\int_0^\infty Q(t)dt. \tag{11}$$

Equation (11) is a statement of the fact that the total amount of oxygen taken up by the nerve because of a temporary change in the rate of uptake is equal to the product of the volume flow rate, sensitivity, and time integral of the current curve.

There remains the problem of determining how far beyond the nerve the oxygen cathode must be located in order to be in a region of constant oxygen concentration. The discussion that follows is not intended to be a precise treatment of this problem but rather an approximate solution sufficiently accurate for design purposes.

It is possible to determine approximately from the theory of diffusion in moving liquids the minimum distance beyond the nerve at which the oxygen concentration is essentially constant across the stream. In the steady state, diffusion in a cylindrical stream of constant mean velocity $u_2=V/\pi r_c^2$ satisfies the differential equation:[6]

$$u_2(\partial C/\partial x)=D[(\partial C^2/\partial r^2)+(1/r)(\partial C/\partial r)+\partial^2 C/\partial x^2]. \tag{12}$$

For the portion of the stream beyond the end of the nerve, $x=L$, the following boundary conditions apply:

at $x=L$, $C=C(L,r)$
at $x=\infty$, $C=C_1$ (a constant)
at $r=r_c$, $\partial C/\partial r=0$.

The boundary condition at $x=L$ is a statement of the fact that in the steady state a radial oxygen concentration distribution $C(L,r)$ exists across the stream. It should be noted that $C(L,r)$ can never be less than zero nor greater than C_0, the oxygen concentration in the reservoir. Under the most extreme conditions of oxygen uptake by nerve tissue $C_0<2C_1$. The boundary condition at $x=\infty$ is merely a statement of the absence of radial concentration gradients and the requirement that the concentration gradient vanish at the capillary wall is demanded by its impermeability to oxygen.

Application of the above boundary conditions to the solution of Eq. (12) given by Riemann-Webers yields:

$$C(x,r)=C_1+\sum_{i=1}^{\infty} B_i J_0(r\sigma_i/r_c)e^{\xi_i(x-L)}, \tag{13}$$

where $J_0(r\sigma_i/r_c)$ are the Bessel functions of order zero and:

$$\xi_i=(u_2/2D)-[(u_2^2/4D^2)+\sigma_i^2/r_c^2]^{\frac{1}{2}},$$

σ_i are the roots of $J_1(\sigma_i)=0$; $\sigma_1=3.83$, $\sigma_2=7.02$, etc. The constants B_i are determined by the boundary conditions at $x=L$ and need not be evaluated for our purposes.

Since $C(L,r)$ is bounded by the values 0 and $2C_1$, the quantity $|C(L,r)-C_1|$ has a maximum value no greater than C_1. Furthermore, since there is no device present in the stream beyond the point $x=L$ which concentrates the oxygen above its maximum value at $x=L$, it follows that the quantity $|C(x,r)-C_1|$ falls off with increasing x, for $x>L$, in a manner determined by the exponential series of (13), that is:

$$|C(x,r)-C_1|\leqq C_1\sum_{i=1}^{\infty} e^{\xi_i(x-L)}. \tag{14}$$

---

[6] Riemann-Webers, *Differential-gleichungen der Physik* (Braunschwieg, 1927), Vol. II, page 252.

The series converges rapidly in ξ_i so the first term can be used as a good approximation, therefore:

$$|C(x,r)-C_1|/C_1 \leqq \exp[\{(u_2/2D)-[(u_2^2/4D^2)+\sigma_1^2/r_c^2]^{\frac{1}{2}}\}(x-L)], \quad (15)$$

where $\sigma_1=3.83$.

The left-hand term in the inequality (15) is the maximum fractional deviation of the oxygen concentration at a point x $(x>L)$ from its constant value at $x=\infty$. If a numerical value is assigned to this quantity, it is possible to solve the above inequality for the value of $(x-L)$ at which the fractional deviation will not exceed the assigned value.

To be sure, in the actual case the stream velocity is not constant across the cross section, but varies with the radius in the characteristic parabolic manner of Poiseuille flow. The solution of the diffusion equation for such a parabolic velocity distribution is not worth while for our purposes. If instead of using the mean velocity of the stream the peak velocity is used, the value of $(x-L)$ obtained will certainly be greater than that for a Poiseuille velocity distribution. For a Poiseuille velocity distribution the peak velocity is twice the mean velocity. Using twice the mean velocity in (15) we obtain for l, when the fractional deviation is taken as 1/50, the expression:

$$l\geqq -3.9/\{(u_2/D)-[(u_2^2/D^2)+14.7/r_c^2]^{\frac{1}{2}}\} \quad (16)$$

or,

$$l\geqq 12r_c^2D/[V-(V^2+145r_c^2D^2)^{\frac{1}{2}}]. \quad (17)$$

MEASURED PROPERTIES OF THE FLOW RESPIROMETER

The particular respirometer on which the experimental studies described below were made possessed the following dimensions and constants: r_c = radius of capillary $=7\times10^{-2}$ cm. r_n = radius of nerve sample = about 5×10^{-2} cm. V = volume flow rate $=2.16\times10^{-4}$ liters/hour $=6.0\times10^{-5}$ cm³/sec. L = length of nerve sample = 2.2 cm. l = distance from nerve to oxygen cathode = 0.4 cm. D = diffusion coefficient of oxygen in water $=3\times10^{-5}$ cm²/sec. For a respirometer with these constants one obtains a value of 0.38 cm for l, using Eq. (17) derived above. Since the actual value of l was 0.40 cm, it is reasonably certain that the oxygen concentration was constant across the stream at the oxygen cathode.

Average value	971

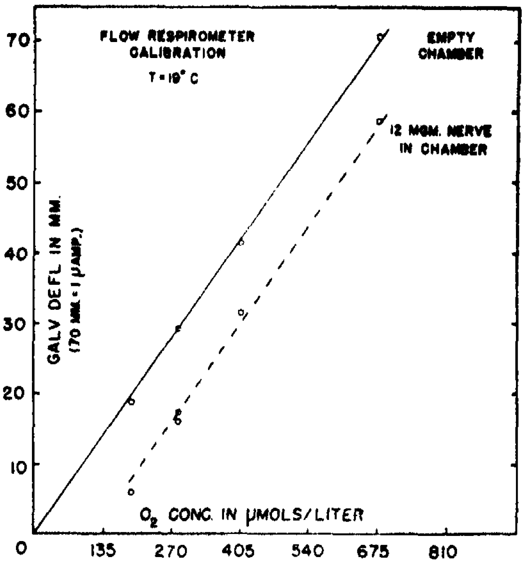

FIG. 6. Calibration curve for an oxygen cathode.

The first operational characteristic to be examined experimentally was the dependence of the oxygen cathode current on oxygen concentration. This was done both with and without a nerve present in the capillary. Figure 6 is a calibration curve showing the observed galvanometer deflection and calculated oxygen cathode current as a function of oxygen concentration. The fact that this curve is a straight line through the origin establishes the strict proportionality between oxygen cathode current and oxygen concentration. The lower curve in the figure is a calibration curve with a nerve present in the chamber. Once again a straight line is obtained with the same slope as the line for the empty chamber. This fact establishes the constancy of sensitivity with respect to the presence or absence of a nerve sample in the chamber, since the respiration of nerve is constant in this range of oxygen concentrations. The slope of both of the lines is 645 (micromoles/liter)/microampere, which is the sensitivity of this oxygen cathode.

Table I is a tabulation of the sensitivities for one of the oxygen cathodes over a two-week period. It is seen that the change in sensitivity does not exceed 10 percent during this period. If the oxygen cathode is allowed to operate continuously, there is usually an appreciable drift in sensitivity over the course of a day. This drift is greatly reduced by allowing the cathode current to flow only 12 seconds out of every minute. Intermittent operation of the oxygen cathode is easily achieved by means of a microswitch actuated by a 1 r.p.m. motor-driven cam.

In general, the calibration changes with changes in the chemical constitution of the perfusion solution. It is therefore necessary to determine the calibration curve

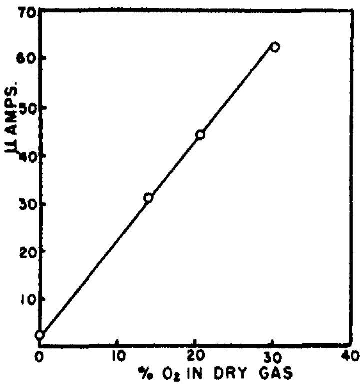

FIG. 7. Platinum sink current as a function of oxygen concentration in the entering stream.

for each new solution. Although small temperature changes (1°C) have slight effects on the calibration, it is advisable to calibrate the system at each temperature used.

While we have established the linearity of the system with respect to changes in oxygen concentration, it remains to be shown that it is linear with respect to changes in the rate of removal of oxygen by the nerve present in the chamber. To do this, a sink[§] was constructed from 2 to 3 cm of 0.001-in. platinum wire wound around a glass tube 0.7 mm in diameter and 1.9 cm long. One end of this wire was connected to a polarizing circuit and calomel electrode similar to those used in the oxygen cathode circuit. The sink was then placed in the chamber so that it occupied much the same space as would a nerve sample. With the polarizing voltage properly adjusted, such a system acts like the oxygen cathode and electrolyzes oxygen from the solution. The current through such a sink varies linearly with the concentration of oxygen in the stream (Fig. 7). Assuming that the number of electrons required to reduce an oxygen molecule at the sink electrode is independent of the oxygen concentration, we can conclude from the linear dependence of sink current on oxygen concentration that this particular sink reduces oxygen at a rate directly proportional to the oxygen concentration.

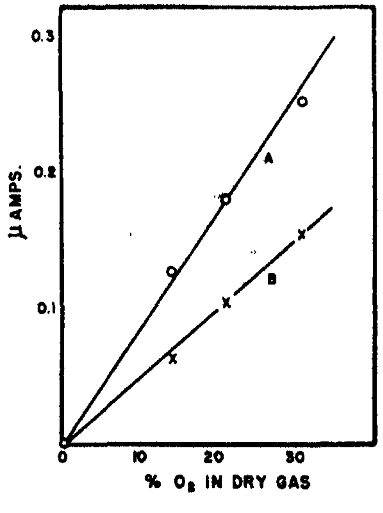

FIG. 8. Curve A, oxygen cathode current as a function of oxygen concentration in the entering stream with the platinum sink off. Curve B, oxygen cathode current as a function of oxygen concentration in the entering stream with the platinum sink on.

If the oxygen cathode current depends linearly on the strength of the sink in the capillary, a calibration made with the above described sink in operation should produce a straight line with a slope less than the calibration curve for a sink of zero strength. Figure 8 is a plot of the steady-state oxygen cathode current as a function of oxygen concentration with the sink off (curve A), and with the sink on (curve B). The sink polarizing voltage was the same for each point on curve B. The linearity of curve B proves that the current in the measuring electrode is related linearly to the rate of removal of oxygen from the flowing stream in the capillary tube.

All of the above experimental results are consistent with the existence of the necessary conditions for proper operation of the respirometer; however, none of them afford direct proof of the uniformity of oxygen concentration over the area of the stream at the oxygen cathode. If it were possible experimentally to show that the integrative relationship expressed by (11) held for the respirometer, then it would be fairly certain that the condition of uniformity of concentration had been met. Such an experiment requires a sink of accurately known strength. The sink described above is of unknown strength owing to an ambiguity in the number of electrons involved in the electrode reaction. Accordingly, it is necessary to resort to an indirect proof.

If the respirometer does satisfy the condition that the oxygen concentration at the oxygen cathode is uniform across the stream, we should expect the oxygen concentration measured at this point to be independent of the form of the oxygen cathode. To test this, the platinum wire sink was inserted in the respirometer and turned on. The oxygen concentration in the stream beyond the sink was determined first with a spherical type oxygen cathode, Fig. 2, 1. The spherical oxygen cathode was replaced with a whisker type, Fig. 2, 3, and the oxygen concentration again determined. The oxygen concentration in the first case was 195 μmoles/l., while in the second case a value of 208 μmoles/l. was obtained. The close agreement of these two values establishes the fact that measurements of oxygen concentration are independent of oxygen cathode geometry for the two types of oxygen cathodes used.

In view of the fact that the flow respirometer is primarily intended for studying steady-state rates of oxygen uptake by nerve, no detailed analysis of its transient response has been attempted. It seems certain that even if the formal expressions for the transient response were known, the computational problem of determining the actual transient behavior of a given sink from the measured response would be quite laborious.

[§] For the purposes of this discussion it is convenient to define as a sink any device which when placed in the capillary stream, can be made to remove oxygen from the stream at a constant rate. The rate of oxygen removal will be referred to as the strength of the sink.

In order to provide some criterion for deciding to what extent an observed transient is due to the response characteristics of the respirometer and to what extent it is due to the properties of the sink, a study was made of the transient response to a step change in sink strength. The platinum wire sink described above was placed in the capillary, turned on, and allowed to come to a steady state. At time $t=0$ the sink was turned off and the resultant response recorded. The open circles of Fig. 9 are the experimentally observed values for three separate experiments.

The solid line of Fig. 9 is the transient response calculated for the simplified case of a sink of constant strength per unit length in a stream of constant velocity u_1 along the length of the sink and u_2 between the sink and the oxygen cathode. It is apparent that in the steady state the average oxygen concentration falls linearly with x from the value C_0 at $x=0$ to some final value at $x=L$. If S is the sink strength per unit length, the concentration distribution is given by:

$$\begin{aligned} &C_1(x)=C_0; \quad x=0,\\ &C_1(x)=C_0-S\cdot x/V; \quad 0\leqq x\leqq L,\\ &C_1(x)=C_0-S\cdot L/V; \quad L\leqq x\leqq L+l. \end{aligned} \tag{18}$$

If at time $t=0$ the sink is turned off ($S=0$), the concentration distribution given by (18) will move to the right, past the oxygen cathode, giving rise to the transient response. By virtue of this movement the space variable x is transformed to a time variable t according to the transformation.

$$\begin{aligned} &x=L+(u_1l/u_2)-u_1t \quad \text{for} \quad 0\leqq x\leqq L,\\ &x=L+l-u_2t \quad \text{for} \quad L\leqq x\leqq L+l, \end{aligned} \tag{19}$$

where the velocities u_1 and u_2 are given by:

$$u_1=V/\pi(r_c^2-r_n^2), \quad u_2=V/\pi r_c^2.$$

Substituting the above transformation (19) for x in (18) yields the transient response:

$$\begin{aligned} &C_1(t)=C_0-S\cdot L/V \quad \text{for} \quad 0\leqq t\leqq l/u_2,\\ &C_1(t)=C_0-(S/V)[(u_1l/u_2)+L-u_1t]\\ &\qquad\qquad \text{for} \quad l/u_2\leqq t\leqq (L/u_1)+l/u_2,\\ &C_1(t)=C_0 \quad \text{for} \quad (L/u_1)+l/u_2\leqq t. \end{aligned} \tag{20}$$

The platinum-wire sink used was 1.9 cm long (L) and 3.5×10^{-2} cm in diameter (r_n); the distance between the sink and oxygen cathode (1) was 0.7 cm. Using these values together with the values for V and r_c given above in (20) the solid curve in Fig. 9 was obtained. The agreement between the experimentally and theoretically determined values for the time of initiation and the time of completion of the transient are quite good considering the many approximations made in determining the latter.

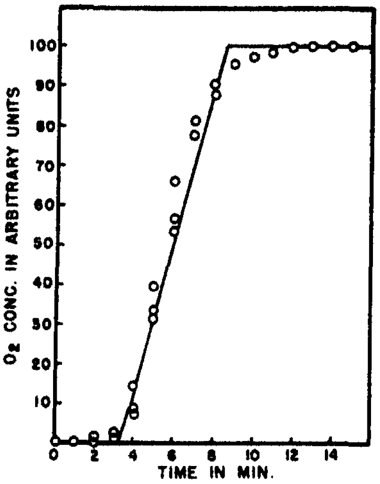

FIG. 9. Transient response of flow respirometer to a step change in sink strength. Open circles are experimentally determined points for three separate experiments. Solid line is theoretical transient response for the simplified case described in the text.

The response time of the respirometer is conveniently defined as $(L/u_1)+l/u_2$, the duration of the transient response to a step change in sink strength. Any observed transient of duration appreciably greater than $(L/u_1)+l/u_2$ is due to the transient response characteristics of the sink being studied. In the case of a nerve 2.2 cm long and 1×10^{-1} cm in diameter the value of $(L/u_1)+l/u_2$ for the respirometer described above is about 6.5 minutes.

SENSITIVITY TO ERRORS

One further aspect of the apparatus remains to be discussed, namely, the sensitivity to error. Equation (7) provides the relationship between the measured and desired quantities, that is:

$$Q=VC_0(1-i_1/i_0).$$

Q is the desired quantity. V and C_0 are constants of the system which, once determined, remain constant and do not constitute a source of error. i_1 is the measured current which can be determined to better than 1 part in 200 with no difficulty. i_0, the calibration current, cannot be determined during any one experiment without removing the nerve from the chamber. Its value can be measured before and after an experiment only. This being the case, unexpected changes in i_0 would give rise to an error in the calculated value of Q. The sensitivity of the calculated value of Q to small changes in i_0 can be ascertained as follows:

$$\partial Q/\partial i_0=V\cdot C_0 i_1/i_0^2$$
$$dQ=(\partial Q/\partial i_0)di_0.$$

Therefore:

$$dQ/Q=(\partial Q/\partial i_0)(di_0/Q).$$

Substitution yields:

$$dQ/Q = (di_0/i_0)[(i_0/i_1)-1]^{-1}.$$

The percentage error in Q is $100\times dQ/Q$ or:

$$100(dQ/Q) = 100(di_0/i_0)[(i_0/i_1)-1]^{-1}.$$

Measurements of i_0 over the course of a day's experiments show that it drifts steadily downward. For a good oxygen cathode the total change in i_0 is about 10 percent over a twelve-hour period; the mean value of i_0 would be within ±5 percent of its actual value at any time during the day. For the nerves used i_0/i_1 was never less than 3/2. Substituting this value for i_0/i_1 together with the figure of ±5 percent for the percentage change in i_0 gives ±10 percent as an upper limit for the percentage error in Q.

Studies of the way in which i_0 changes in time with no nerve in the chamber indicate that it is uniform. This being the case, one can determine from its initial and final values a correction term applicable at any time during the course of the experiment. It is likely that this corrected value is not in error by more than two or three percent, which gives ±5 percent for the error in Q. The values five percent and 10 percent are estimates of the extremes of the percent error in the value of Q determined from flow respirometer data when the calibration changes during a day's run. Under optimum conditions (no change in i_0 over the course of the experiment), the absolute error in Q is determined by the precision of measurement of V, C_0 and i_1. In work where i_0 is corrected for drift it is likely that the ±5 percent figure is applicable. More frequent calibration is necessary if greater accuracy is desired.

For the error in the increment in Q due to activity, the situation is somewhat better. Let Q_1 be the resting rate of oxygen utilization; and Q_2 the steady-state activity rate of oxygen consumption. The increment in rate of oxygen utilization is therefore:

$$[Q_2-Q_1] = VC_0(1-i_2/i_0) - VC_0(1-i_1/i_0).$$

Therefore:

$$\partial[Q_2-Q_1]/\partial i_0 = -VC_0(i_1-i_2)/i_0^2.$$

The fractional error in $[Q_2-Q_1]$ becomes:

$$d[Q_2-Q_1]/[Q_2-Q_1] = -di_0/i_0,$$

or the percentage error in the increment is equal in magnitude to the percentage change in i_0. As was previously mentioned, the percentage error in i_0 is less than five percent. In general, then, errors from two to five percent can be expected in the values for changes in Q.

SUMMARY OF METHOD

The oxygen cathode flow respirometer together with the action potential recording system described above possess the following operational characteristics:

1. Electrodes for stimulating nerves and for recording the action potential are provided which allow the establishment and monitoring of varying degrees of activity in frog sciatic nerve.
2. The respirometer provides a constant source of oxygen and constant sinks for heat, carbon dioxide, and diffusable metabolites. The pH is held constant by means of the carbon dioxide-bicarbonate buffer system, two percent carbon dioxide being supplied by the equilibrating gas.
3. Linearity with respect to changes in the steady-state rate of oxygen consumption is achieved. The total oxygen uptake during a transient change of sink strength is measured by the area under the recorded transient curve.
4. The sensitivity is such that, for a 10-mg sample of nerve, changes in the rate of oxygen consumption of 0.1 micromoles/g hr., 2 cu. mm/g hr., are readily detected.
5. Errors in absolute values and incremental values of the rates of oxygen consumption, arising from drifts in the sensitivity of the oxygen cathode, are 10 percent or less and five percent or less, respectively. These may be reduced by calibrating more than twice a day.

Laboratory and Shop Notes

Improvements in the Li^6 Technique

George R. Keepin, Jr.*
Radiation Laboratory, Department of Physics, University of California, Berkeley, California

August 15, 1950

A NUMBER of improvements have been made during the past year at the Radiation Laboratory on the Li^6 technique. The technique[1] employs measurements on alpha-particles and tritons from Li$^6(n,\alpha)$H^3 reaction in Li^6 loaded emulsions to give a precise measure of incident neutron energy without requiring collimation of the neutrons. The new developments are outlined briefly here; for those using the Li^6 technique, a detailed report including all necessary curves is available.[2]

For the Li$^6(n,\alpha)$H^3 reaction, a new Q-value of 4.78 ± 0.03 Mev has been obtained by combining recent precision Q-value determinations for the Li$^6(p,\alpha)$He^3 and H$^3(p,n)$He^3 reactions.[3,4] Neutrons from D(d,n)He^3,† H$^3(p,n)$He^3, and Li$^7(p,n)$Be^7 have been used to obtain revised range-energy relations in Ilford Li^6 loaded C-2 emulsions. Only the sum of alpha-particle and triton ranges *versus* neutron energy is required, individual calibration of R_α and R_T *vs* E_n being superfluous data for E_n determination. From this new range-energy calibration and the new Q-value, we have obtained revised curves of $R_\alpha+R_T$ *vs* E_n, parametric in both θ, the laboratory angle between the alpha and the triton, and in ϕ, the laboratory angle between the triton and the incident neutron beam (ϕ defined for collimated neutrons only).

Discrimination between the alpha-triton pairs and recoil protons has been markedly improved by use of latent image fading.[5] Artificial fading methods, though more expedient, were rejected because of the possibility of emulsion distortion. For Ilford Li^6 loaded emulsions we have found a vertical shrinkage factor of 2.9 ± 0.1 as compared with the nominal figure of 2.0 for unloaded emulsions. Our search for a fine-grained, high-contrast developer to give optimum discrimination has led to a hybrid solution which is essentially ID 19 with 12 g/liter additional KBr acting as a differential inhibitor. The Brussels group has reported that temperature of the developer is critical, the optimum for alpha-triton discrimination being 72 ± 0.5°F. Our experience has confirmed this. Figure 1 shows the alpha-triton discrimination obtainable using the new processing procedure.

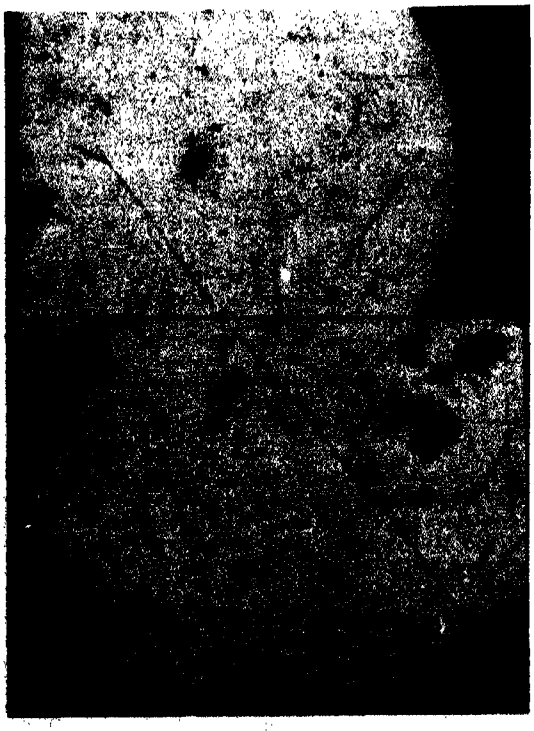

FIG. 1. Li^6 disintegration produced by D,D neutrons: $R_\alpha+R_T=124\pm1.3\mu$; $\theta=154\pm1°$; $E_n=3.8\pm.15$ Mev.

For energy measurement of non-collimated neutrons, three natural groups of track selection criteria have been established, and appropriate correction functions for each group have been developed.[2] In a given experiment, choice of the proper group depends on the energy range of the spectrum under study, the amount of data available, and the maximum energy resolution required. Under the most stringent criteria, which include $175°\leq\theta\leq180°$, resolution to better than ±70 Kev has been obtained. Though the Li^6 technique does not require neutron collimation, when good geometry is possible (ϕ known), two advantages arise: first, energy resolution is increased because E_n is a less sensitive function of $R_\alpha+R_T$ with ϕ, rather than θ, as a parameter; and, second, the θ-azimuth correction,[2] arising from measurement of projected rather than true θ angles, is eliminated. With 5° collimation, resolution to better than ±50 Kev has been obtained for $0\leq E_n\leq3$ Mev.

Exposures to neutrons produced by the Berkeley proton linear accelerator have shown the Li^6 technique to be of little value for $E_n>10$ Mev, owing mainly to the lower Li^6 cross section and to other neutron-induced reactions competing favorably at these energies. Our work has indicated an upper limit of ~5 Mev on this technique as a precision neutron spectrometer.

As a supplementary technique for use at higher energies, B^{10} impregnated plates have been developed and are now being studied. The desired B$^{10}(n,2\alpha)$H^3 reaction has a threshold near 5 Mev, giving measurable ranges of the disintegration products for $E_n>10$ Mev. The B^{10} neutron capture cross section is comparatively high in this energy range.

I am grateful to Professors E. Segrè and L. W. Alvarez for their advice and continued interest in the Li^6 program and to Mr. F. C. Gilbert for his valuable assistance.

A Slide Rule for Nuclear Emulsion Calculations

Arthur Beiser
Department of Physics, New York University, University Heights, New York 53, New York

September 5, 1950

PARTICLE identifications and energy measurements from tracks in nuclear emulsions are generally made on the basis of grain counts and track ranges in the emulsion. Multiple scattering and delta-ray determinations are, because of their less exact nature and difficulty of application, of only limited utility. Range-energy, range-grain density, and distance from end of track-grain count calibration curves are generally made for the various particles recorded in a particular emulsion from identified reference tracks and from theoretical considerations; and these curves are then used in subsequent work with the emulsion.

When the above curves are plotted on logarithmic graph paper, they will appear as virtually straight lines, with the curves for the different particles being parallel on each graph. This property may be utilized to construct a slide rule that, with very little error in

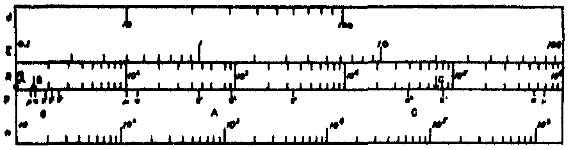

FIG. 1.

most cases, may be used to facilitate greatly work with nuclear emulsions. The scales of the slide rule are most conveniently laid out as shown in Fig. 1, being calibrated from the experimentally determined durves. The *R* (range) scale and the *E* (energy), *d* (grain density), and *n* (total grain count) scales are taken directly from the slopes of the lines on the appropriate curves. The *P* (particle) scale may then be determined by selecting a particular value of *R*, finding from the curves the value of *E*, *d*, or *n*, and setting it opposite the *R* value, with the identity of the particle appearing opposite the appropriate arrow on the *P* scale. The *A* arrow is used for *R vs E*, the *B* arrow for *R vs n*, and the *C* arrow for *R vs d*.

When the slide rule is used, the identity of the particle must first be determined. If the track ends in the emulsion, the total number of grains *n* in a distance in microns *R* from the end may be set against this value of *R*, and the identity of the particle will then be adjacent to arrow *B*. In practice this method will be accurate only if the calibration tracks had the same predevelopment history as the unknowns, and had received the same processing. However, for pre-eradicated plates from balloon and airplane flights, where all the phenomena were recorded within a comparatively short time of each other, this method is very convenient. As a check, or if the track does not end in the emulsion, the grain density *d* in grains per 100 microns at two different points in the tracks as far apart as possible should be determined. The arrow *C* may then be set against the various particles on scale *P*, and the ranges corresponding to the smaller grain density read off on *R*. The distance in microns between the two points at which the grain density was determined is then subtracted from the values for the ranges obtained as above. The arrow *C* may then be reset against *P*, and the grain densities corresponding to the new range values for the different particles determined. The one nearest to the greater measured grain density will then give the identity of the particle.

The energy of a particle ending in the emulsion may be found from the *R* and *E* scales, the arrow *A* being set opposite the particle on the *P* scale. For identified tracks not ending in the emulsion, the ranges corresponding to the smaller grain densities may be used to find the energy on the *E* scale. These energies, in all cases where both the origin and ending of the tracks are not in the emulsion, will, of course, be minimum figures.

A Geiger-Counter Mounting for Continuous Counting of Gas-Phase Radioactivity*

FRANCIS BONNER** AND ALFRED WEINSTEIN
Chemistry Department, Brookhaven National Laboratory, Upton, Long Island, New York

July 31, 1950

IN the course of a recent investigation of the carbon dioxide-carbon reaction,[1] $C^{14}O_2$ and $C^{14}O$ were pumped over charcoal by thermal syphon and the radioactivity of the gas phase was continuously monitored with an end-window Geiger tube. This tube was sealed to a vacuum system with its mica window directly over a glass chamber of about 50-ml volume. The counters used had window thicknesses of 3 to 3.5 mg/cm², thus calling for the use of relatively high activity levels of C^{14} in the system. Thinner windows could not be used because of the great mechanical stress to which they are subjected in this type of work, by flexion upon evacuation and filling of the system. Durability of counters under these severe conditions was variable; some lasted as short a time as one month, while one counter showed only slight deterioration after three months of rather hard usage.

An alternative mounting was developed and employed successfully. While it was not used extensively in the particular investigation mentioned above, the authors feel that it possesses advantages which make it worth bringing to the attention of other workers in this field. The counter, as shown in Fig. 1, is incorporated directly into the top of the male portion, or valve, of a two-way, hollow-bore stopcock. The top of the stopcock was opened and flanged so that the Geiger tube (also flanged) would fit snugly over it. A mica window of appropriate thickness was then cemented between the two flanges, the tube evacuated, filled with counting gas, and sealed. A generous nipple was left for further evacuations and fillings.

The female portion, or housing, of the stopcock is sealed directly into the vacuum system and with the stopcock assembled there are three positions available for varying needs. With the stopcock turned so that its inner portion and the vacuum system are in communication the counter may be used for continuous counting of gas flowing through the system. In the second position shown in the diagram the interior of the stopcock is by-passed altogether. This is often desirable in order to avoid wear on the mica window during pumping and filling operations which need not involve the counter and extra volume. In a third position neither pair of holes lines up with the system. This may be used for counting a static gas sample at measured pressure and volume. Intermittent sampling of a flowing gas may also be carried out without disruption of flow by quickly turning from position one to position two.

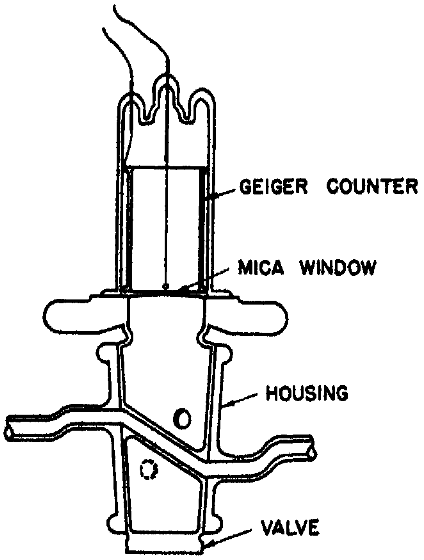

FIG. 1.

Self-absorption corrections are of utmost importance in a counting arrangement such as this, since counting response is clearly a function of gas density. The necessary corrections, carried out by measuring the variation of counting rate with pressure for a gas of fixed specific activity, are described by Bonner and Turkevich.[1]

In addition to the operational advantages already described, the counter in this arrangement can be readily removed from the system for refilling, and when the mica window gives way to flexion it can be replaced without undue difficulty.

A Reliable Pirani Vacuum Safety Circuit*

W. Franzen and J. Horton
Palmer Physical Laboratory, Princeton University
August 15, 1950

IN the operation of vacuum systems, it is frequently desirable to control the operation of valves and similar components automatically, in accordance with the pressure in the system. Requirements on a control circuit of this type are reliability, long life, freedom from "chatter," and an operating differential which is as small as possible. In addition, one would require the circuit to fail "safe" in case of a component or power failure. The circuit to be described, which was developed for use with the vacuum system of the Princeton cyclotron, is believed to fulfill these requirements, and, in view of its simplicity, may be of general interest.

The vacuum measuring device is a Sylvania Type R1111 Pirani tube which forms one arm of the bridge shown in Fig. 1.

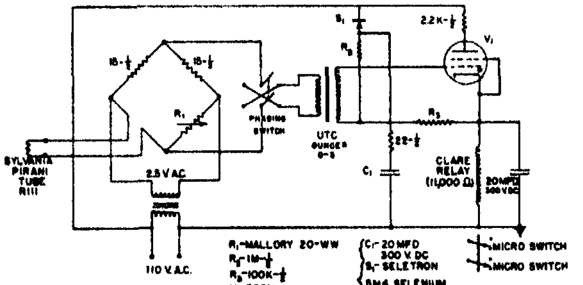

Fig. 1.

The "cold" resistance of this tube is 6.6 ohms; this increases to approximately 16 ohms when the tube is evacuated and a 100 m.a. heating current is applied. The setting of the potentiometer R_1 therefore controls the balance point of the bridge. On one side of balance, the 60-cycle a.c. signal appearing on the grid of the miniature thyratron V_1 is out of phase with the voltage applied to the plate of the tube, and the thyratron cannot fire. On the other side of balance, the two signals are in phase, and the tube will fire during each positive half-cycle provided the positive signal applied to the grid is large enough to overcome its negative d.c. bias. This bias is derived from a network consisting of the half-wave selenium rectifier S_1, the condenser C_1 and the voltage dividing resistors R_2 and R_3.

It was convenient to use a Clare d.c. relay (Navy type CRY-29161) in the cathode circuit of V_1. This relay closes on a current of 4.5 m.a. and opens when this current drops to 2.5 m.a. The switching action of the relay is performed by two micro-switches which are actuated by the moving arm of the relay. Thus the relay has a fairly large differential and a sudden action; these features result in freedom from "chatter." Nevertheless, the differential of the entire circuit is small.

Typical operating conditions in a test of the circuit allowed the relay to close at a pressure of 75 microns Hg and to open at 100 microns Hg. The life of V_1 can be prolonged by incorporating a time delay into the plate circuit of V_1 which delays the application of plate voltage relative to the application of filament heating power.

Ejection of the Electron Beam from a Betatron*

S. L. Fawcett,† and E. C. Crittenden, Jr.
Case Institute of Technology, Cleveland, Ohio
June 23, 1950

A MODIFICATION of a scheme proposed by Crittenden and Parkins[1] for ejecting the electron beam from a betatron has been applied to the Case biased betatron of 30 Mev maximum energy.[2] The ejected electron beam has been detected by means of the x-rays produced in the wall of a vacuum donut having no exit window.

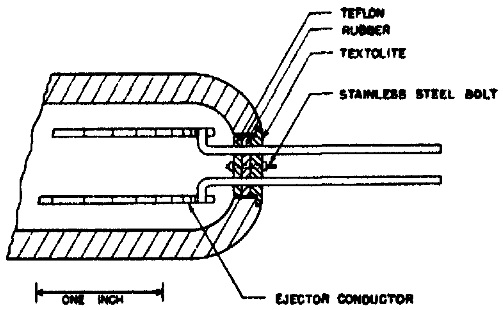

Fig. 1. Ejector conductor structure in donut.

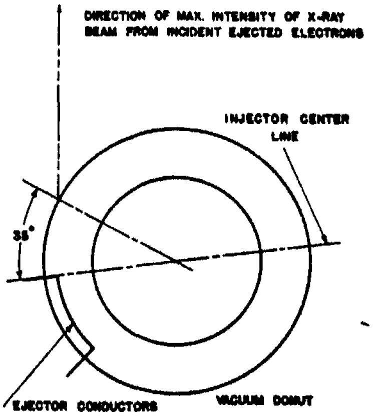
The method utilizes the perturbing magnetic field produced by a current pulse flowing in a pair of conductors, placed above and below the orbital plane, inside the donut. The conductors are segments of circles concentric with the axis of the machine, extending over an azimuth of 40° at the outer edge of the normal region of electron stability. Figure 1 shows a section through one of the two support structures which also function as electrical leads. The general location in the donut is shown in top view in Fig. 2. The two conductors are externally connected in series and carry current in the same direction. A rectangular current pulse, variable up to 500 amp., 20μsec. wide, is applied to the ejector conductors a few microseconds before the expansion coils are pulsed. The expansion pulse is a half-sine wave of about 500 amp. peak, 20μsec. long. The expansion coils consist of one turn of litz wire on both the upper and lower pole faces, at a radius just inside the normal equilibrium orbit. The resultant ejector field is shown in Fig. 3. Calculation of the orbits described by the electrons indicates the following general principle of operation. When the ejector field is added to the normal field the effect is to produce an eccentric displacement of the beam. As the electron beam is expanded the electrons eventually become unstable and are released from the magnetic field in a diverging beam which becomes converging upon passing through the focusing region *B-C*, Fig. 3. This focusing property of the region *B-C* results because electrons passing through the inside of the region spiral out faster than ones passing through the outside of the region.

Fig. 2. Azimuthal relation of direction of x-ray beam from incident ejected electrons to injector and ejector system locations.



DIRECTION OF MAX. INTENSITY OF X-RAY BEAM FROM INCIDENT EJECTED ELECTRONS
INJECTOR CENTER LINE
38°
EJECTOR CONDUCTORS
VACUUM DONUT

Detection of the ejected electron beam was accomplished through the x-rays produced by the ejected electrons incident on the donut wall. Using an RCA 931A photo-multiplier tube shielded by $\frac{1}{32}$ in. brass and photographic film shielded by $\frac{1}{16}$ in. lead as detectors, the location and direction of the maximum intensity of the x-ray beam was determined to be as shown in Fig. 2, when the variable parameters were adjusted for optimum focusing.

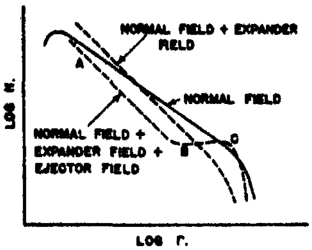


FIG. 3. Typical field shapes produced when expander and ejector fields are applied to normal betatron field.

The width of the x-ray beam was the same order of magnitude as the height, indicating a well-collimated beam. The ejection system works equally well using a conventional "outside" electron gun or an "above orbit" electron gun. The use of a conventional "outside" electron gun permits operation of the betatron as either an x-ray or electron source by switching off or on the ejection circuit. Using an outside electron gun the x-ray output due to the ejected electron beam was about equal to the x-ray output observed from the conventional target with the ejector switched off. With the ejector off the conventional target gave one Roentgen per minute at one meter as measured on a thin walled chamber. This fell to 0.5 Roentgens per minute when the ejector was operated. Difference in x-ray production efficiency between the donut wall and the conventional target makes an estimate of the ejection efficiency difficult. Observations with accelerated electron beam energies of 13 Mev, 14.6 Mev, and 15 Mev indicated no significant variations in the focusing properties of the ejector system. The possibility that the x-rays originate from incidence of electrons on some obstruction in the tube or on the ejector conductors has been ruled out by the behavior under a variety of conditions.

Since the ejector structure is non-ferromagnetic it introduces no field disturbance during injection and acceleration. In addition, operation is not limited by the magnitude of the magnetic field. Determination of more detailed properties of the ejection system awaits the completion of a donut with a window to permit emergence of the electron beam.

Design and Performance of a Joule-Kelvin Helium Liquefier

J. G. DASH, D. B. COOK,* M. W. ZEMANSKY,† AND H. A. BOORSE‡
Pupin Physics Laboratories, Columbia University,§ New York, New York

July 31, 1950

THE present paper describes a helium liquefier having a capacity of one liter per hour, using the Joule-Kelvin principle for liquefaction. Descriptions of such liquefiers have been published,[1] but the details of design have been largely omitted. In view of the increase in interest in low temperature research it is deemed worthwhile to outline the design procedure which was found to yield results in good agreement with calculation and which may be applied to the construction of almost any liquefaction system.

Design Features.—The design of an apparatus for gas liquefaction has a considerable latitude depending on the desired economy in refrigerants, the complexity of the apparatus, and the length of time required for precooling. In general, a short "starting time" is more desirable for laboratory equipment than maximum economy of operation. In the present case, a liquefier having an output of one liter per hour was chosen as a suitable size to operate in conjunction with our hydrogen liquefier which has an output rate of 3.5 liters per hour. The flow diagram chosen for the liquefier is given in Fig. 1. Exchanger D, omitted in some designs, is necessary to keep consumption of liquid hydrogen down to 5 liters for each liter of liquid helium produced.

The most important factor in determining yield efficiency is exchanger F. We may therefore use the design of this exchanger to illustrate the general procedure. Exchanger F is illustrated schematically in Fig. 2. Various tube arrangements[2] may be chosen to provide the necessary surfaces for heat transfer. If simplicity and ease of construction are guiding factors, a tube-in-tube arrangement is most convenient. Proceeding on this basis, the design may be carried out using equations given by Starr[3] according to the following sequence.

It is easily seen from a T-S diagram that the percentage liquefaction increases as the temperature T_i of the incoming gas at the hot end of the exchanger is lowered. The triple point of hydrogen (14°K) is a practical lower limit for T_i in the liquefaction of helium, if the convenience and excellent heat transfer properties of a liquid bath are to be used. For the maximum rate of liquefaction at this temperature, the proper value of the input pressure P_i must be found from the inversion curve. The coordinates of the inversion curve for helium may be approximately determined from published data,[4] values being given in Table I.

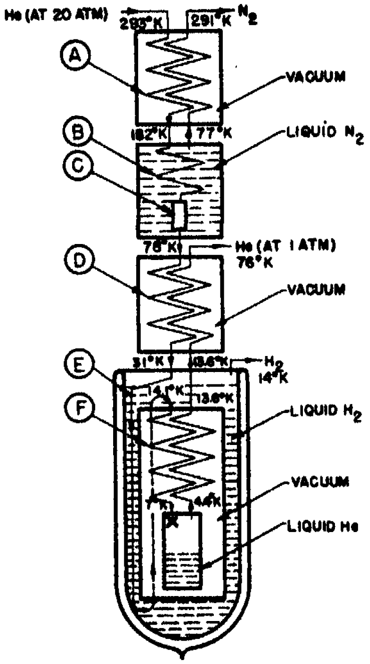

FIG. 1. Flow diagram of helium liquefier.

It is seen from Table I that the value of P_i appropriate to a value $T_i = 14$°K is 30 atmospheres. Experience at Leiden has shown[5] that a more suitable value of P is 20 atmospheres.

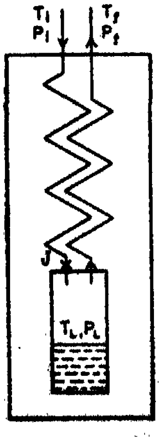

FIG. 2. Schematic diagram of heat exchanger F and liquid helium well.

TABLE I. Points on the helium inversion curve.

T°K	P (atmos.)
15	31.5
14	30
13	27.5
12	25
11	22.5
10	20

A value of P_L, the pressure at which the liquid is to be collected, is next chosen. Pressures from 1.2 to 1.5 atmospheres are usually sufficient to provide turbulent flow (Reynolds' number >2000) in the return tubes, which is necessary for efficient heat exchange. In view of the low critical pressure of helium, P_L was chosen as 1.2 atmos.; the corresponding liquid boiling temperature T_L was found from the liquid-vapor equilibrium curve to be 4.4°.

The next step was to make an arbitrary selection of the "efficiency" of exchanger F which may be expressed[3]

$$E=\frac{T_f-T_L}{T_i-T_L},$$

where T_f is the temperature of the returning low pressure gas at the hot end of the exchanger. The equation thus serves to determine the value of T_f. In the present instance E was chosen as 96 percent, and the corresponding value of T_f was found to be 13.6°.

The fraction y of the gas which will be liquified under these circumstances was then found from the well-known thermodynamic expression

$$y=\frac{h_f-h_i}{h_f-h_L},$$

where the h's are the enthalpies under the condition indicated by the subscripts. Substitution of the appropriate values shows that y is approximately 17 percent.

The heat transfer-length characteristic of the exchanger can be determined from the following relation[3]

$$UL=\frac{\dot{m}_o\bar{c}_o}{1-\dot{m}_o\bar{c}_o/\dot{m}_i\bar{c}_i}\log_e\left[\frac{1-E\dot{m}_o\bar{c}_o/\dot{m}_i\bar{c}_i}{1-E}\right],$$

where the $\dot{m}$'s refer to the flow rate of the gas in grams per second, the $\bar{c}$'s are specific heats of the gas averaged over the indicated temperature intervals, L is the length of the exchanger in cms, and U is the over-all heat transfer coefficient per unit length. The subscripts "i" and "o" refer to incoming and outgoing gas streams respectively.

To account for non-ideal conditions in the operations of exchangers, E and F and Joule-Kelvin valve, the liquefaction fraction was rounded off to 15 percent, and a liquefaction rate of 1.2 liters per hour was chosen as a basis for design. This choice of liquefaction rate and the chosen value for the liquefied fraction lead to a value of $\dot{m}_o$ equal to 0.24 g/sec. This corresponds to a value of $\dot{m}_i$ equal to 0.28 g/sec. The value of $\bar{c}_o$, obtained by averaging data from the Zelmanov diagram, was 1.43 cal./g deg. In order to calculate $\bar{c}_i$ it is necessary to find the temperature of the gas immediately before throttling. This is accomplished by determining the position of 15 percent liquid on the 1.2-atmos. isobar on the T-S diagram and following the corresponding isenthalp to the 20-atmos. isobar intersection, which occurs at 7°. With this knowledge of the correct temperature interval, the value of $\bar{c}_i$ was determined to be 1.52 cal./g deg. The product UL was then found to be 3.1 cal./sec. deg.

There remains to be determined the geometric dimensions of exchanger F, i.e., the length and diameters of the inner and outer tubes. For higher heat transfer efficiency, the inner tube is chosen for the low pressure outgoing gas stream. Convenient tube sizes are chosen and the heat transfer coefficient H per unit length is calculated for each gas stream by means of the relation[3]

$$H=0.15\bar{c}\eta^{0.25}(\dot{m}/d)^{0.75}(1+3.5d/D),$$

where η is the average viscosity in poises, d the effective diameter in cm, and D is the exchanger coiling diameter in cm. Inner and outer tube diameters were chosen as $\frac{3}{16}$ in. and $\frac{5}{16}$ in. o.d. respectively, both sizes having 0.020 in. wall thickness. To obtain favorable transverse heat transfer across the tubing walls and still minimize heat conduction along the length of the exchanger, it is necessary to use low conductivity, thin-walled tubing. Supernickel 0.020 in. wall tubing represented a good compromise and yielded a large safety factor for the high pressure gas. Computations for the coefficients gave $H_i=0.010$ cal./sec. cm deg., and $H_o=0.011$ cal./sec. cm deg. Neglecting the thermal resistance of the tube walls, we obtain the over-all coefficient

$$U=(H_i^{-1}+\mathrm{H}_o^{-1})^{-1}=0.0052\text{ cal./sec. cm deg.},$$

and by making use of the value found for UL, the value of L is found to be 590 cm. This is very close to 20 ft. which is a standard tube length and was accordingly the length used in making the exchanger.

The pressure drops in the incoming and outgoing tubes were next determined by means of the equation

$$\delta p=3.0\times10^{-4}\frac{Tm^{1.75}\eta^{0.25}L}{MPd^{4.75}}(1+3.5d/D)$$

where δp = pressure drop in lb./in.^{2}, P = average pressure in atmos., M = molecular weight, T = Kelvin temperature, and L = length of the tube in cm. Similar calculations were carried out for the other exchangers. The calculated characteristics of all exchangers are found in Table II.

TABLE II.

Characteristics	Exchanger A	B	D	E	F
o.d. of outer tube, in.	0.375	0.1875	0.3125	0.1875	0.3125

Liquefier Construction.—A copper shell enclosed the liquid hydrogen Dewar which surrounds the liquefier assembly consisting of the heat exchangers E and F, the Joule-Kelvin valve, and the liquid helium collection well. The copper shell is equipped with Lucite windows, to permit observation of the liquid hydrogen and liquid helium levels.

The exchanger F, Joule-Kelvin valve, and liquid helium well are enclosed by a high vacuum jacket consisting of a brass cylinder for the upper section and a glass lower section, attached by means of a 3 in. diameter Kovar-to-glass seal. The liquid helium well, visible within the lower section, has a capacity of 540 cm^3, and communicates to a vacuum pumping line by means of a $\frac{1}{2}$ in. diameter stainless steel tube extending through the top plate of the liquefier. This tube also permits mechanical operations on apparatus contained within the helium well.

Pressure gauges on the control board allow observations of the helium gas pressures at the entrance to heat exchanger A and the high and low pressure sides of the expansion valve. A Bourdon gauge is used to indicate the liquid hydrogen vapor pressure. The helium gas temperature immediately before expansion is measured by means of a helium gas thermometer connected to a vacuum Bourdon gauge. Liquid helium vapor pressures are read by a mercury manometer. Helium gas for liquefaction may be supplied either by high pressure supply tanks regulated to 300 lb./in.², or a compressor.

Before liquefaction, the liquefier was cooled to 77°K by admitting liquid nitrogen to the large Dewar surrounding the vacuum jacket, the vacuum space being filled with helium gas at a few cm pressure. The liquid nitrogen was then forced out into the Dewar surrounding the heat exchanger *B*, and the liquefier Dewar filled with 7 liters of liquid hydrogen. The liquid hydrogen bath was cooled to about 14° by pumping, and as the inner parts approached equilibrium, as indicated by the gas thermometer, the vacuum jacket was opened to the pumps and thermal isolation restored.

Circulation was then started through the Joule-Kelvin valve. A cooling time of about 15 minutes was required before liquefaction, at which time the gas thermometer indicated 7°K. With $m_t = 0.28$ g/sec., the liquefaction rate was 1 liter/hour.

After liquefaction was finished, the helium well was used for experimental work. To economize on the use of liquid hydrogen, the outer bath was replaced with liquid nitrogen for thermal buffering. In this condition, it was possible to cool the liquid helium to below 1.5° by pumping. The evaporation rate was sufficiently low so that experiments of over five hours' duration could be performed with about 300 cm³ of liquid helium.

A Simple Automatic Recording Microphotometer

R. M. Fisher and D. S. Miller
Research Laboratory, United States Steel Corporation of Delaware, Kearny, New Jersey

May 31, 1950

An inexpensive precision microphotometer has been constructed to measure electron diffraction patterns taken with the camera of the RCA EMU electron microscope. A novel feature of our photometer is that by means of a balanced optical and electronic system only the difference in photographic density between the lines and the plate background is recorded. Thus the large background changes on electron diffraction patterns do not cause the chart record to rise rapidly right off the paper but rather to remain flat (as in Fig. 2). Another advantage of the balanced system is that there is no need of regulation on the lamp voltage supply.*

We used the optical system and framework of an outmoded General Electric Company photometer as a starting point, although a similar arrangement could easily be constructed. In our instrument, the plate or film is mounted horizontally on a moveable stage and is illuminated from below with a projector lamp and condenser lens. A low power standard microscope objective is used with a prism to project a magnified image of part of the plate on a viewing screen mounted vertically. A 1-in. square hole in the center of the screen is covered with a sliding panel in which are cut four slits, which are 0.25, 0.5, 1, and 2 mm wide and can be varied in length up to 16 mm. By using either of two objectives, which produce magnifications of 9 or 22, effective slit widths of 12 to 220 microns are available in eight steps.

The plate stage, mounted on balls in flat ways, is connected by a split nut to the driving screw which is turned either by a hand wheel or by a synchronous motor. The screw was made by cutting 40 threads per inch on a ¾-in. diameter shaft and lapping it into the nut. About 4½ inches of thread on the screw gives sufficient plate travel, limiting switches serving to protect the screw. For use with a 12-second full-scale deflection recorder the plate is driven at 3 in. per hour by a 1 r.p.m. motor through a gear; a typical line 0.01 in. wide is passed over in 12 seconds. A faster recorder would permit a higher plate speed.

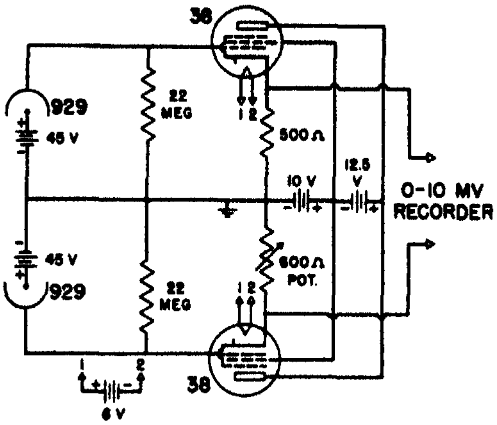

FIG. 1. Wiring diagram of amplifier circuit.

The moving plate stage, screw and motor are mounted on another stage which can be adjusted laterally to align slit and pattern and vertically to focus the image on the screen.

Two vacuum photo-tubes (Type 929) are used in the balanced cathode follower circuit shown in Fig. 1. The measuring tube mounted directly behind the viewing screen receives light passing through the slit, while the monitoring tube, mounted a few inches in front of the screen, receives scattered illumination from the projected image. Both photo-currents are amplified in the electrometer type circuit and the e.m.f. difference between the cathode resistors drives a 0–10 mv strip chart recorder. Thus, in effect, the average of the background density over several millimeters on either side of the slit is subtracted from the density right at the slit. By means of an iris diaphragm on the monitoring tube

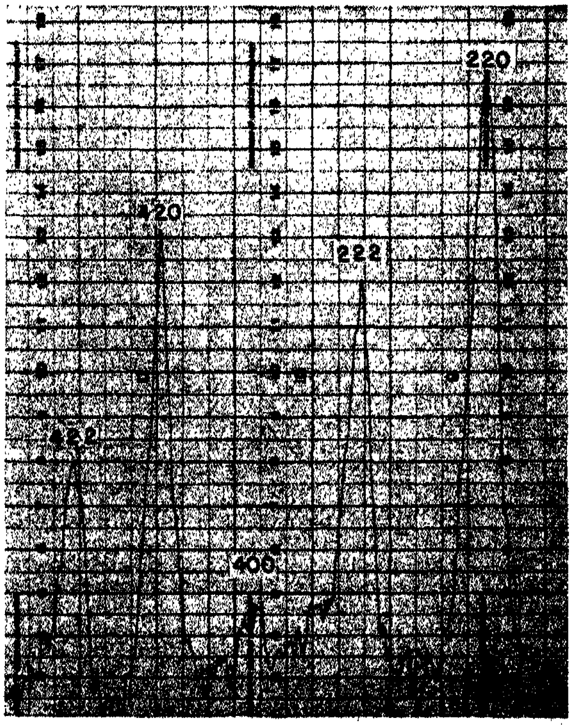

FIG. 2. Photograph of chart record.

housing and a wire-wound potentiometer as one cathode resistor, both light and circuit balance can be achieved.

After a warm-up period of about five minutes the recorder shows no objectionable drift due to resistor noise or tube grid current. The output impedance of the amplifier (1100 ohms) is not well suited to the standard recorder impedance of 400 ohms but the latter can be increased to more than a thousand ohms by removing the grid resistor of the first stage in the recorder amplifier. A still higher recorder impedance of the order of 5000 ohms can be obtained by replacing the input transformer with one of higher inductance.

Figure 2 is a typical chart record of an electron diffraction pattern of MgO taken with an effective slit width of 55 microns, a recorder impedance of 1000 ohms at a plate speed of 3 in. per hour and a chart speed of 60 in. per hour. Measurements on the complete chart give interplanar spacings within ½ percent of those calculated for the cubic structure.

Simultaneous Photography of Self-Luminous and Non-Self-Luminous Effects

JOHN S. RINEHART
Naval Ordnance Test Station, Inyokern, China Lake, California

STREAK photography[1] and microsecond multiflash[2] techniques have been used extensively to study high speed phenomena that occur during the breakup of explosive missiles, the flight of projectiles, etc. Generally only one or the other of the techniques is used. This note describes a test in which both techniques were employed simultaneously. The data desired could not have been obtained by employing either of the two techniques individually or successively.

In studies of the flights of the very high speed particles that are produced by shaped charges, the following information is needed: (*a*) the velocity of the particle, (*b*) variations in luminosity of the particle during its flight, (*c*) the duration of burning of the eroded material, (*d*) the spatial distribution of smoke left by the particle, and (*e*) the way in which the smoke trail changes with time. Data on (*a*), (*b*), and (*c*) can be obtained from normal streak photographs, since the effects are self-luminous. On the other hand, the smoke trail must be illuminated in order to be observed.

The experimental set-up that was used to photograph the self-luminous and non-self-luminous features of shaped charge particles is illustrated schematically in Fig. 1. A 35-mm continuous film General Radio camera was used. The smoke trails left by the particles were illuminated with four flash lamps that flashed at a rate of 1000 flashes per second. The duration of each flash was about one microsecond. The number of flashes was usually thirty or more.[3]

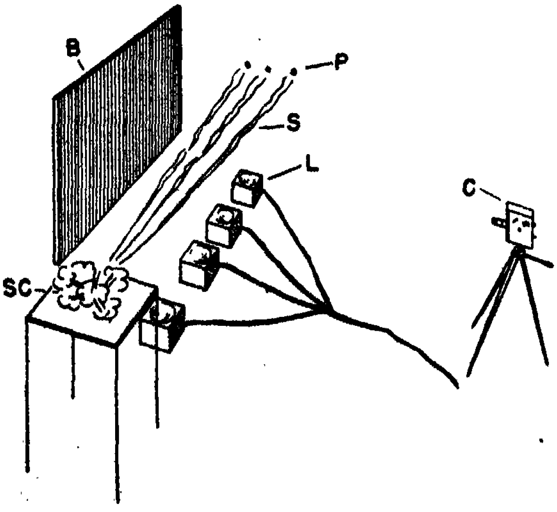

FIG. 1. Experimental set-up: SC, shaped charge; P high velocity particles; S, smoke trails left by particles; B, black screen; L, flash lamps; C, General Radio continuously moving film 35-mm camera.

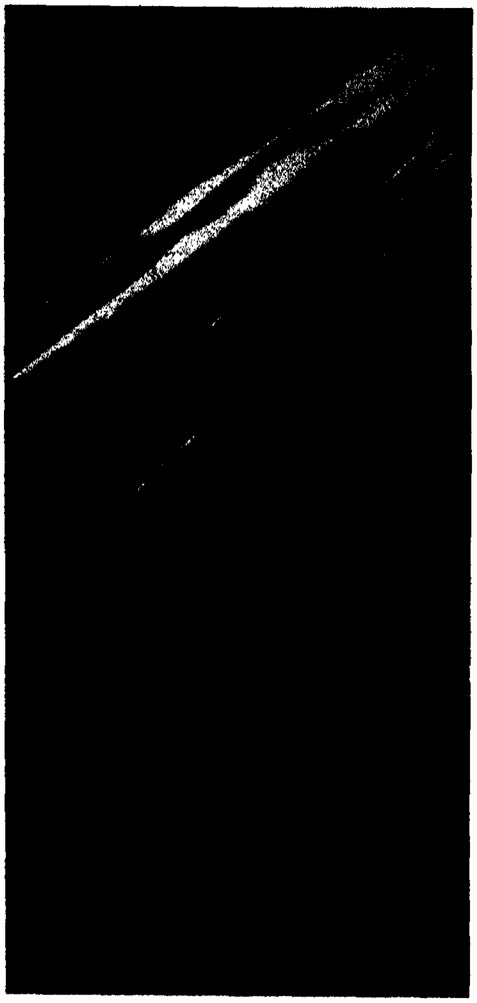

FIG. 2. Photograph of a group of high velocity particles.

The following experimental procedure is used. The camera is started, the shaped charge is fired, and flashing of the lights is begun. The final result is that both the self-luminous and non-self-luminous phenomena appear together on a single strip of film.

A typical photograph, obtained in this way, of a group of shaped charge particles is reproduced in Fig. 2. Each particle that crossed the field of view of the camera is seen as a luminous streak that runs slantwise across the film. Ten such streaks were visible on the original film. Two of the streaks are very bright. The velocity of each particle can be readily determined from film speed and camera data. The film speed in this case was about 70 ft./sec. The horizontal field of view of the camera was about 11 ft. The velocities of the two brightest particles were about 10,000 ft/sec. Variations in luminosity of the particles during flight and burning of the eroded material are also evident in the photograph.

The smoke trails left by the two brightest particles appear as horizontal lines in the photograph. The light flashed first when the uppermost particle was about two-thirds and the second particle about one-half of the way across the field of view. The second and third flashes occured at 1/1000-sec. intervals thereafter. The spatial distributions of smoke left in the wakes of the two brightest particles can be seen in the photograph. The smoke, for example, is seen to be most dense at the places along the trajectory of the particle where the particle was most luminous.

This note has been prepared primarily with the thought that the simultaneous use of streak photography and microsecond multiflash techniques can possibly be used to advantage in other investigations.

Two Beta-Gamma-Counters for Gas Samples

Rodman Jenkins
California Institute of Technology, Pasadena, California*

June 26, 1950

In connection with a study of diffusion in turbulent flow, Geiger counters of two different types were prepared for the determination of activity of a series of gas samples. In all cases the radiation originated in iodoform containing substantial quantities of iodine-131. This isotope emits several gamma-rays and a beta-ray spectrum with a maximum energy of 0.67×10^6 electron volts.[1]

The conditions of the experiment made it desirable to use Geiger tubes which recorded a large fraction of the disintegrations available. The volume of air in any given sample was restricted to a maximum of about 150 cc. Since quantitative results were an essential part of this program, it was necessary to achieve a reproducible relationship between the quantity of iodine-131 and the observed counting rate. Satisfactory plateau curves were necessary to allow a succession of analyses to be made without repetition of calibrations.

A reasonable compromise between these requirements was found in two designs, though neither was entirely satisfactory. The first design was a conventional cylindrical glass counter sealed in a concentric glass jacket. These parts were joined in the glassblowing process, and no foreign materials were introduced in the jacket chamber. Cathodes were of silver, deposited by the Rochelle salt process,[2] and gold, prepared from a commercially available solution called "Liquid Bright Gold." The anodes were prepared from 0.004-inch diameter tungsten wire, and were not heated to the glowing point. All tubes were filled with a mixture of 90 percent argon and 10 percent absolute alcohol to a total pressure of 10 cm of mercury. They were not baked out.

An experiment was performed which demonstrated the proportionality between counting rate and concentration of iodoform in the jacket. One of these counters was sealed into a vacuum system from which organic materials had been eliminated. Portions of air containing a constant fraction of radioactive iodoform were admitted to the jacket surrounding the counter at randomly varying pressures. Before entry of a given sample, the preceding one was removed by evacuation. Each time, the pressure of the air being counted was determined, and converted to pressure of the same gas at 20°C. Since some series of measurements lasted as much as 12 hours, all counting rates were corrected for the radioactive decay of the 8-day half-life iodine.

The results of these measurements are shown in Fig. 1. The number of counts taken at each point varied from 1000 to 3000, with an average of about 2200, which corresponds to a standard deviation of about 2 percent. This deviation, when obtained from the observed counting rates was found to be 2½ percent. This was considered to be a satisfactory comparison.

The second type of Geiger counter was constructed in order to record a larger fraction of the disintegrations occurring in a given sample. It consists of a ring of six commercial aluminum Geiger tubes with their cylindrical axes parallel, sealed within a close fitting stainless steel chamber. The individual counters are sealed into the chamber by means of Neoprene gaskets fitting under small flanges located near one end of each tube. Three tubes enter the chamber from each end. A follower plate which presses these flanges from the outside provides force on the gaskets.

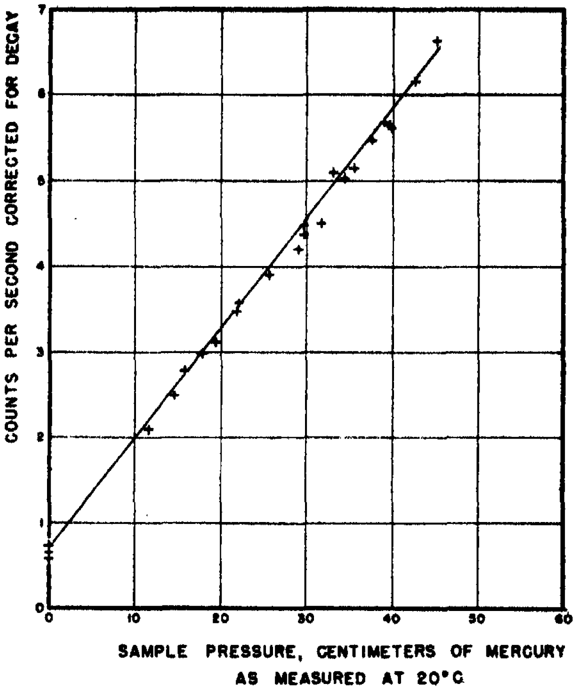

FIG. 1. Measured activity as a function of sample pressure.

The entire unit was assembled from machined parts by soft soldering. A pressure of less than one micron was easily obtained in the assembled instrument. It is estimated that with this geometrical arrangement, 35 to 40 percent of the radiation produced in a sample strikes one of the Geiger counters at an active point. The simultaneous operation of these tubes was found to give satisfactory electrical characteristics.

The writer's financial support as a National Institute of Health predoctoral research fellow during this work is gratefully acknowledged. E. W. Molloy suggested the arrangement of the Geiger tubes in the second counter described here.

An Ultrasonic Projector Design for a Wide Range of Research Applications

E. J. Fry
University of Illinois, Urbana, Illinois

July 18, 1950

In research work concerned with the ultrasonic irradiation of many types of specimens it is desirable to have a flexible projector design which offers features of adaptability to different types of systems as well as possessing the inherent ability to obtain high power output levels.

Figure 1 illustrates in cross section the essential design features of such a projector in which the crystal, vibrating in thickness mode, is held in a vertical plane. The ground plate *H* is constructed so as to be readily connectable to various irradiating chambers.

One major aspect of the design is the clamping of the crystal between two small Neoprene gaskets *A* which in the undeflected position are 0.030 in. thick. The same thickness Neoprene is used for gaskets *B*. Parts *E*, *F*, and *G* are bolted together with gasket

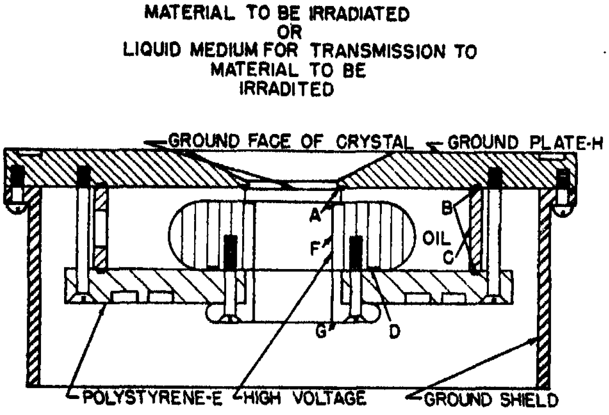

FIG. 1.

D. For assembly purposes ground plate *H* is laid in the horizontal position. Then stacked in order, on top of this plate are gasket *A*, the crystal and another gasket *A*. Gaskets *B* and ring *C* are also placed in position. Then *E*, *F*, *G* assembly is laid on top and the whole assembly is bolted together as shown. The gasket grooves in all cases are designed so that the Neoprene is not deflected too much in any tightening operation. This means that ring *C* is pulled against the ground plate and polystrene plate *E* and the gaskets *B* are not over deflected. This pulling together operation also limits the deflection of gaskets *A*.

After the assembly of the physical parts shown in the figure, the chamber surrounding the crystal edge is filled with oil for the purpose of giving a much higher voltage break down strength to the space between the two crystal faces.

Another important aspect of the design is concerned with the final electrical contacts to the crystal faces. The crystal faces are electroded to a distance from their edges equal approximately to the Neoprene gasket width. A conducting paint is then applied around the crystal faces at the gasket edges, over the gasket edges and to both the ground plate *H* and plate *F*. This produces a desirable configuration of equipotential surfaces for the electric potential.

For flexibility in changing from one crystal to another of different frequency but of the same shape in all but the thickness dimension it is only necessary to have a new length for ring *C*. Rings *C* are made beforehand for all the crystal frequencies wanted, and the limiting time for a change is then the drying time of the conducting paint which can be accelerated with warm air blasts so that only a few minutes is involved in a change of this sort.

The same design features are readily incorporated into set-ups wherein the crystal is mounted horizontally or the crystal must assume any position as in an applicator. It is also apparent that changes in crystal size of other than the thickness dimension are readily incorporated into the design. Crystals with curved shapes for focusing of the sound field can be readily handled.

Experience with eight of these projectors in which the crystals have had both horizontal and vertical mounting has been used as an indication of the general trouble free operation obtained from these design specifications.

A Float for Liquid Helium

JULIUS BABISKIN
Naval Research Laboratory, Washington, D. C.

July 31, 1950

THE density of liquid helium is much lower than that of most homogeneous solids. Therefore, a float material for liquid helium should have enclosed hollow spaces to lower its apparent density below that of liquid helium and it must be impermeable to liquid helium as well. This suggests the use of a body consisting of a continuous lattice of individual thin-walled hollow cells of low density material.

Unicellular polystyrene foam[1] was tried as a float material and has proved satisfactory for use in both liquid helium I and II. The individual cells have sufficient mechanical strength to resist collapse and the material does not crack when subjected to liquid helium temperatures. Other unicellular expanded plastics would probably also exhibit these properties.

When floating on liquid helium, it was observed that the apparent density of a ¾-in. cube of the polystyrene foam was about 0.04 g/cc. Thus it is likely that this foam will float on liquid hydrogen. The apparent density of the float is higher for shapes having a larger ratio of surface area to volume than the cube. Pieces one or two cells thick often did not float on liquid helium.

Since the unicellular polystyrene float is white, the liquid helium level in slit-silvered Dewars can be easily observed. For situations where the helium level and the white float cannot be seen, this float has sufficient buoyancy to support a thin rod of balsa wood, which can be used as the indicator. Care should be exercised in the use of balsa wood indicators, since the balsa wood shatters when warmed from liquid helium temperatures too rapidly.

[1] This material is available commercially at nominal cost. See Expanded Plastics or Styrofoam in *Modern Plastics Encyclopedia* (Plastics Catalogue Corporation, New York, 1949).

New Instruments

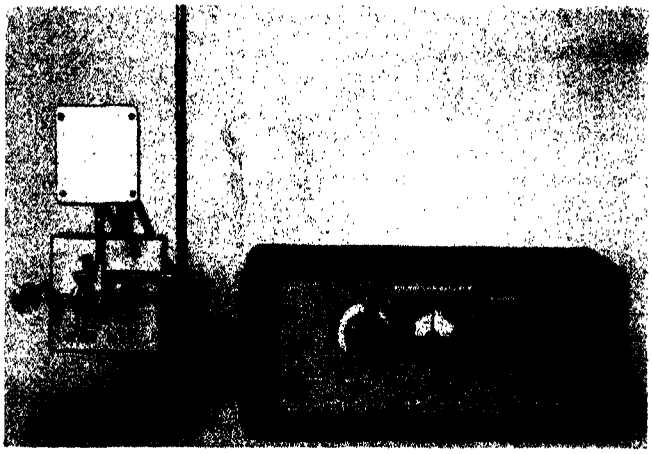
These descriptions are based on information supplied by the manufacturer and in some cases from independent sources. THE REVIEW *assumes no responsibility for their correctness.*

Micromanometer The Model 23-105 Micromanometer is a sensitive device for measuring gas pressures in the 0-150 micron range. It measures the absolute pressures of condensible as well as noncondensible gases independently of their composition. The operation is based on a pressure sensitive condenser utilizing a stainless steel diaphragm as one of the plates; the gauge forms one arm of a capacitance bridge which is balanced to a null when the pressures on each side of the diaphragm are equal and close to zero microns. In operation, the gas whose pressure is to be measured is intro-



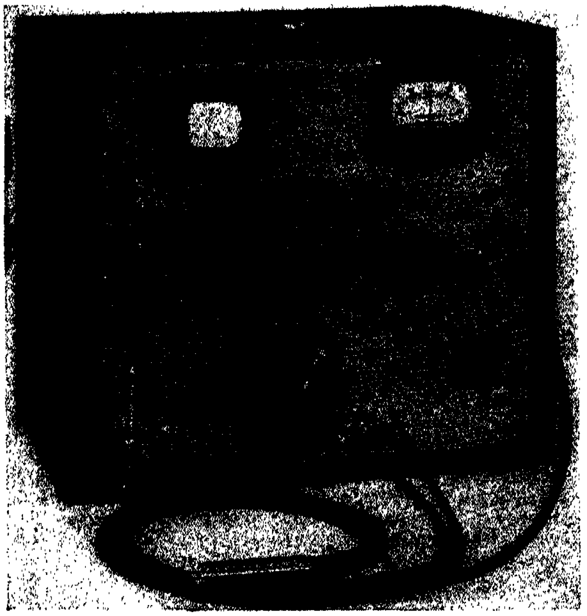
duced to one side of the diaphragm, and an electrostatic restoring force is applied by an adjustable d.c. voltage thereby rebalancing the bridge. The magnitude of the restoring voltage is read on a duodial and the reading is converted to microns of pressure by a calibration chart or simple formula.

According to the manufacturer, typical specifications of the Model 23-105 Micromanometer, when used at room temperature, are as follows: Pressure range—0.1 to 150 microns; minimum detectable pressure change—0.1 micron; reproducibility (8 hr.)—±0.3 micron, linearity—±0.2 percent; maximum overload—1 atmosphere on either side of the diaphragm; and power consumption—30 watts at 115 volts a.c.—CONSOLIDATED ENGINEERING CORPORATION, *620 N. Lake Avenue, Pasadena 4, California.*

Nuclear Fluxmeter

The Model F-6 Nuclear Fluxmeter is designed to utilize the gyromagnetic properties of the nuclei of hydrogen atoms in such a way as to reduce the measurement of magnetic field strength to a direct measurement of frequency. The instrument also provides an error signal which can be used to actuate field stabilization equipment.

The phenomenon of nuclear induction results from the interaction of nuclear spin and nuclear magnetic moment with an external magnetic field. Any species of nucleus possessing a spin also possesses a magnetic moment. Since the spin of a particular species of nucleus is always the same, and likewise the magnetic moment, any such nucleus possesses a constant gyroscopic moment similar to that of a top or gyroscope, and the magnetic poles provide a means of applying a force couple such as may be applied to a mechanical gyroscope. The result is the same in both cases: the axis precesses, swinging around in the surface of a cone. The rate of this precession, if it can be measured in relation to the applied magnetic field, will identify the species of nucleus, and conversely, if the nuclear species is known, the strength of the magnetic field may be determined. The Nuclear Fluxmeter is designed to measure this precession. Normally, the axes of the spinning nuclei point in all possible directions and under these conditions the external effects of their precession exactly cancel. In order to obtain an observable external effect, there must be a preponderance of nuclei pointing simultaneously along some particular axis, or what may be called nuclear polarization.



This can be accomplished by application of a constant magnetic field which will, after sufficient time for attaining equilibrium, produce the desired net polarization along an axis parallel to the magnetic field. An alternating magnetic field of suitable frequency produced by a small r-f coil perpendicular to the constant field will now produce a precession of the net polarization, and this effect may be detected by the induced voltage in a second coil located at right angles to the excited coil. The frequency of the induced voltage, i.e., the precession frequency, and the value of the gyromagnetic ratio of the nuclei serve to determine the absolute value of the constant field since they are linearly related to it. Ultimate precision is dependent on the absolute value of the gyromagnetic ratio of the proton, which is known to 25 parts per million. Frequency measurements can be made with much greater accuracy than this with comparative ease.

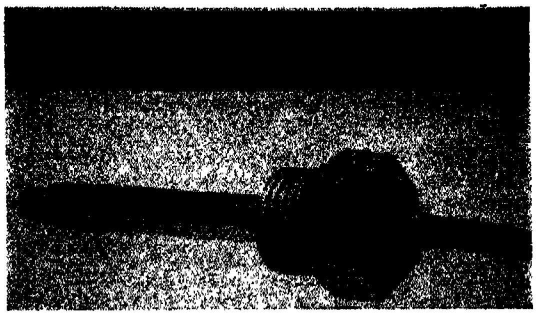
The standard model of the Nuclear Fluxmeter has a range of 9–18 kilogauss and accuracy of 0.005 percent in the presence of field inhomogeneities of less than 4 gauss per cm. Frequency measuring equipment is required covering the range from 38–77 mc. The probe containing the r-f coils is a metal cylinder ¾ inch in diameter and 4½ inches long. Additional equipment may be supplied to extend the range from 18–23 kilogauss and from 2–9 kilogauss. The error signal for control purposes is +50 volts for a ±1 gauss change in field strength. There are a multitude of methods of using the error signal from the Nuclear Fluxmeter to provide precision control of a magnetic field. It has been successfully used in connection with amplidyne current supplies, photoelectric current stabilizers and conventional current stabilizers, and conventional current stabilized power supplies. The method used depends on the magnet power requirements and the degree of control desired. Detailed suggestions of methods of field stabilization can be obtained for specific applications.

Another interchangeable r-f unit is available covering the range 0.5 to 24 kilogauss. This is accomplished by three sets of plug-in coils with frequency ranges of approximately 2 to 4, 4 to 8, and 8 to 16 megacycles; these frequency ranges, combined with the use of both deuterons and protons as samples, give the desired field range.

The price of the F-6 Nuclear Fluxmeter is $1,725.00 f.o.b. San Carlos, California, including any one r-f unit with its probe. R-f units with probes are available at $650.00 each.—VARIAN ASSOCIATES, *San Carlos, California.*

Bulb Temperature Pick-Ups

These instruments are based on the resistance thermometer principle and are suitable for the measurement of liquid, gas, and metal temperature. The resistance of the sensing element changes 6.2 ohms over the specified temperature range of the instrument. As a result the pick-up may be placed in a 300-ohm bridge to simulate strain gauge pick-ups having an output voltage of 5 millivolts per volt. Up to 155 millivolts may be obtained from the pick-up proper.



The sensing element consists of a platinum winding contained between concentric cylinders having a total wall thickness of only a few thousandths of an inch. The sensing element is located within approximately one-fourth inch of the extreme end of the structure. As a result of the unique construction, the thermometer has a thermal time constant of only 1.8 seconds in water. The pick-ups are suitable for pressurized applications and are available for use with system pressures up to 12,000 p.s.i.

The Type 19 Bulb Temperature Pick-Ups can be supplied in ranges up to 1100°C (2000°F). Units designed for ranges above 750°C (1400°F) are supplied in inconel cases.—TRANS-SONICS, INC., *Bedford Airport, Bedford, Massachusetts.*

Manufacturers' Literature

Control Motor Chart—Includes tables on physical dimensions and electrical characteristics of 25 different motors and a page of application data, such as how to connect for plate-to-plate operation, a speed-torque curve, and connections to obtain desired rotation.—TRANSICOIL CORPORATION, *1036 Broad Street Station Bldg., Philadelphia 3, Pennsylvania.*

National Bureau of Standards, Washington, D. C.

Plastic Lenses

Armorlite is a clear plastic used for spectacle lenses. Advantages claimed over the orthodox glass lens include lightness and safety features. The plastic is stated to be clearer than optical glass, to be more resistant to fogging, and to be very much harder than previous plastic lenses. It is more resistant than glass to molten spatter, flying abrasives, and the common chemicals. It has about half the weight of glass and an impact resistance greater than that of case-hardened glass. Single-vision ophthalmic lenses are available either clear or tinted, and can be coated to reduce surface reflections.—ARMORLITE LENS COMPANY, *117 East Colorado Street, Pasadena 1, California.*

Silicone Resins

No. 81132 is a flexible silicone resin for coating glass cloth and sleeving or as an adhesive for mica-glass tape. It is supplied as a 60 percent solution in toluol, and dries without a catalyst in 30 min. to 1 hr. at 250°C. Dielectric strength is 1600 to 2000 v.p.m. in a 7-mil thickness on 3-mil glass cloth.

No. 81145 is intended for bonding and impregnating motors, generators and transformers requiring class *H* insulation. It may also be applied in bonding mica and glass combinations. It is supplied as a 50 percent solution in petroleum spirits. The film dries in 10 to 15 min. at 200°C, while thick sections in coils and windings require up to 6 hr.—GENERAL ELECTRIC COMPANY, *Pittsfield, Massachusetts.*

Neoprene Mat

Neotex is a Neoprene mat built on an expanded-fiber core to provide a flexible shock-absorbing material for covering hard surfaces where glassware is to be set down. Its open mesh assists in draining. It is soft and pliable, light in weight, and is not subject to attack by gasoline, oils, acids, and alkalis commonly encountered in laboratory service. It is available in rolls measuring 27 in. in width by 50 ft. in length, and may also be bought by the yard. It can be cut to any desired shape with ordinary scissors.—SCIENTIFIC GLASS APPARATUS COMPANY, *52 Ackerman Street, Bloomfield, New Jersey.*

Filters

A new booklet *Filters and Lens Attachments* has been published by Eastman. This catalog presents comprehensive data on the purposes, available forms, and prices of all Kodak Wratten filters and other optical attachments made by the Eastman Kodak Company. More than 200 different filters are described, of which more than 100 are of interest in science and technology. This book will be available through all Kodak dealers at 50 cents per copy.—EASTMAN KODAK COMPANY, *Rochester 4, New York.*

Stainless Steel Tubing

A new stainless steel, containing 16 percent Cr, 18 percent Ni, and less than 0.08 percent C, has been made available in round and equivalent-section tubing up to 1½ in. It is characterized by its slow work hardening and permits fabrication in forms that require severe deforming, bending, or upsetting. It can be brazed or soldered after cold-working, and can be spun, coined, or extruded. It remains non-magnetic after cold-working. It is resistant to attack by nitric acid, and to some extent by sulfuric acid, but does not stand up in contact with hydrochloric or other halogen acids.—CARPENTER STEEL COMPANY, *131 Springfield Road, Union, New Jersey.*

Miniature Storage Battery

Silvercel No. A1-HR-1 is a high efficiency, low volume alkaline storage battery using silver and zinc as active materials. Less than 1 cu. in. in volume and under 1 oz. in weight, it has a discharge rate of 5 amp. for 20 min., and can be discharged at rates up to 30 amp. It is spillproof, substantially shockproof, and completely free from corrosive fumes, vapor, or spray.—YARDNEY ELECTRIC CORPORATION, *105 Chambers Street, New York 7, New York.*

Self-Adhesive Marking Tape

Labelon tape consists of an adhesive-backed carbon paper in which the carbon faces outward and is covered with transparent plastic. Markings appear on the rear face of the plastic when its outer face is marked with a pencil or stylus. Since the marking is not exposed it cannot be obliterated by rubbing. The tape can be applied to metal, plastic, and glass surfaces and can be stripped off. It is made in ½-, ¾-, and 1-inch widths in 500-inch lengths.—WILL CORPORATION, *37–41 Russel Street, Rochester 3, New York.*

Sealing Rings

Molded *Teflon* rings are available to specification in a wide range of sizes and sections for use in packing joints in equipment for handling chemicals and petroleum products. The plastic is serviceable in the temperature range from −100 to 625°F.—CONNECTICUT HARD RUBBER COMPANY, *405 East Street, New Haven 9, Connecticut.*

Mildew Preventive

An aerosol preparation of a mold killer has been developed for home use. Two types are available, one for fabrics and the other for leathers, the latter containing oils which prevent the embrittlement of leather in addition to the mildew preventive. This product, distributed by the J. W. Johnson Company of Bellwood, Illinois under the trade name of *Formula* J, is used in the form of a fine spray emitted from its container when pressure is released. It is not considered toxic to humans.—Monsanto Chemical Company, *St. Louis 4, Missouri.*

Plastic Bonding Agent

Res-n-bond, a free-flowing water-white solvent combination originally developed for bonding acrylics, has now been modified so that is is equally effective in joining polystyrene to polystyrene. It is non-flammable, contains no acid, and may be safely handled with no precautions other than adequate ventilation. No deterioration results from long storage. Plastic objects set almost instantly due to rapid penetration of the solvents and jigs are necessary only in clamping poorly fitted seams or large sections. Handling, buffing, and other finishing operations can be carried out within an hour. Small objects are cemented by brushing the liquid on one surface and then pressing this surface into position. Larger objects are joined by a "soak" method. A flat, shallow pan is lined with a felt pad kept moist with the liquid. The plastic part is allowed to rest on the moist pad for a few seconds causing the edge of the plastic to soften and absorb the liquid, after which it is pressed into position. Cemented joints in clear polystyrene or acrylics should be optically clear and free from bubbles when these procedures are properly followed. The joint is as strong as the plastic itself and cannot be separated without fracturing the surrounding area.—Schwartz Chemical Company, *326 West 70th Street, New York 23, New York.*

Vinyl Insulation

A vinyl insulating compound (*Geon 8630*), especially designed for service up to 105°C, is being used to protect iron-constantan and copper-constantan thermocouple lead wires in applications where a conventional rubber had previously been applied. This "Geon" insulation withstands oils and most chemicals at high temperatures for longer periods than rubber, is noncorrosive toward copper, does not affect painted or varnished surfaces, and exhibits good outdoor weathering characteristics. In addition to its high temperature resistance, the new insulating compound is stated to have excellent low temperature characteristics and to be suitable for sub-zero applications.—B. F. Goodrich Chemical Company, *324 Rose Building, Cleveland 15, Ohio.*

Lead-Glass Fabric

Protective gowns are available made from a spun lead glass woven into a fabric. These gowns protect the arms, shoulders and lower legs as well as the body of the operator against x-rays and beta-radiation and yet are lighter than the ordinary type of leaded rubber apron.—Bar-Ray Products, Inc., *205 25th Street, Brooklyn, New York.*

Strippers for Organic Finishes

A folder is available describing various strippers for removing synthetic coatings including lacquers, enamels, and varnishes from metals. Strippers described include fast-evaporating strippers used at room temperature, emulsion-type materials mixed with water and used either heated or at room temperature, and brush-on strippers. The folder, listing 10 standard strippers for use in a variety of applications, is available from the manufacturer.—Enthone, Inc., *442 Elm Street, New Haven, Connecticut.*

Insulating Screws

Screws are now available which are stated to be comparable in strength to conventional metal screws, but which have the additional features of electrical insulation, vibration damping and shock resistance. A thermoplastic material is extruded on a serrated metal core, and the resulting composite rod is threaded and headed in an automatic screw machine. The type of metal core and the plastic are varied to meet the requirements of particular applications. The metal core extends the full length of the screw and supplies most of the tensile and torsional strength, while the plastic threads are said to seize and form an effective lock, eliminating the need for lock washers. Length, head size, thread pitch, and color can be varied. Currently screws are being made in diameters from No. 8 to ½ inch, with cellulose acetate, cellulose acetate butyrate, polyethylene, and ethyl cellulose insulation.—Forman Insulating Screw Company, *401 Broadway, New York 13, New York.*

Non-Crazing Plastic

Sierracin-212 is a transparent, thermosetting plastic developed for applications where crazing caused by pressure, cleaning compounds or mounting cements cannot be tolerated. It is at present used in airplane windows and enclosures, and is expected to find other industrial uses. It is stated to withstand rapid changes in temperature or pressure without adverse effects and will tolerate temperatures up to 225°F, having favorable creep properties at elevated temperatures. Other formulations are available for use at temperatures up to 400°F. A laminating cement is available with which the plastic can be cemented to other plastics, wood, metal, and glass, and it is said not to craze even when cemented to metal parts. It can be cleaned with conventional cleaners, alcohol, methl-ethyl ketone or lacquer thinner.—Sierra Products Company, *1632 East Compton Boulevard, Compton, California.*

Porous Bronze

Bost-Bronz is a line of solid and cored bar stock and plates from which bushings, thrust washers, and ways may be machined. The bronze is porous, so that it absorbs and holds oil by capillary action, delivering it uniformly over the bearing surface. Solid bar stock is available in diameters from ⅜ to 4 in.; cored stock from ⅜ to 4 in. i.d., 1 to 6 in. o.d.; and plate stock from ⅛ to 1 in. in thickness. A catalog is available with further information on stock sizes, tolerances, load ratings and prices.—Boston Gear Works, *63 Hayward Street, Quincy 71, Massachusetts.*

THE REVIEW OF SCIENTIFIC INSTRUMENTS

VOLUME 21, NUMBER 12 *DECEMBER, 1950*

Beta-Ray Spectroscopes

E. Persico* and C. Geoffrion
Université Laval, Québec, Canada

(Received June 19, 1950)

This paper is a review of the various types of beta-ray spectrographs and spectrometers. The principal theoretical results as to the resolving power and luminosity attainable under various conditions are briefly related. Finally the construction and performance data of a number of instruments described in the literature are collected, and compared by means of a graphical representation.

I. INTRODUCTION

A. General Outline and History

1. *Flat Spectroscopes*

It has long been known that the β-rays emitted by a radioactive substance are a mixture of electrons of different kinetic energies. From the beginning it was realized that these electrons would be deflected in a magnetic field according to their momenta. This provided a simple method of sorting out and studying the various energies present in a given beam, since these are related to the momenta by a simple formula (4). The first experiment to this effect seems to have been made in 1910 by von Baeyer and Hahn,[1] and its principle is schematically described by the full lines of Fig. 1: S is the radioactive source (in the shape of a thin filament perpendicular to the plane of the drawing), A is a slit (*entrance slit*) limiting a narrow bundle of β-rays, and P is a photographic plate. The whole is in a vessel, evacuated to the order of 0.001 mm Hg. A uniform magnetic field, perpendicular to the plane of the drawing, bends the rays into circular paths, whose radius is proportional to the momentum. All the rays of a given momentum (two of which are shown in the figure) will be recorded on the plate as a spot L, in the shape of a rather wide

---

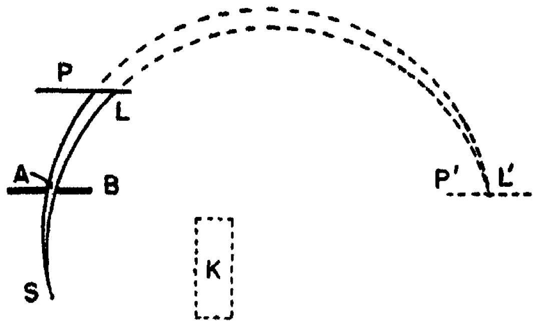

FIG. 1. Comparison of the direct deflection and the semicircular focusing spectrographs.

"line" (parallel to the slit) whose position on the plate gives a measure of the deflection and therefore of the momentum. The image formed by this (continuous or discontinuous) array of lines is called, because of its obvious optical analogy, a *β-ray spectrum*. This method of obtaining the spectrum may be compared to Newton's experiment of the analysis of a sun beam by means of a prism, which is here replaced by the magnetic field.

It is easily seen that this method cannot give a very thin line for each monokinetic radiation, because the line is necessarily wider than the slit, and the latter cannot be made very narrow without sacrificing too much of the intensity. So an enormous progress was made shortly after, when Danysz pointed out[2] that a kind of "focusing" could be obtained by making use of a very simple geometrical property of the circle (namely, that if a circle is given an infinitesimal rotation around one of its points, S, the point diametrically opposed is displaced along the tangent). So, if the two rays of Fig. 1, instead of being stopped at L, are allowed to continue their circular paths for about 180°, they meet again in L', and give rise to a very sharp line on a photographic plate P'. This is the principle of the *semicircular focusing*[3] which was immediately applied by Rutherford and Robinson[4] and, thereafter, without substantial improvements, by many others. Among other advantages on the previous one, this method gives much greater resolution for a given intensity, greater dispersion, and permits shielding the photographic plate from γ-rays from the source by means of a thick lead shield K.

This type of β-ray spectrograph, still widely employed, is described in detail in part II. Its optical analog is the prism spectrograph of Féry, in which a focusing *in the horizontal plane* is obtained by giving the prism faces a cylindrical shape. It is to be noted that no focusing is so obtained in the vertical plane: rays coming from a point of the source are vertically spread along the whole length of the spectral line (*astigmatism*). The same is true of the semicircular magnetic focusing.

The development of the Geiger-Müller counter around 1928 suggested its replacing the photographic plate in β-ray spectrographs. The apparatus so modified is called a β-ray *spectrometer*.[5] Its principle is illustrated by Fig. 2; the photographic plate of Fig. 1 is replaced by a lead diaphragm B' with a narrow slit E (*exit slit*), which allows a very small portion of the spectrum to fall on the G-M counter G. This is provided with a window W, covered with a very thin foil of metal or plastic to allow the rays to enter the counter without too much absorption. The counting rate of the counter gives the "intensity" of β-rays corresponding to the short range of momenta picked up by the slit, and therefore, if divided by this range, may be considered as a measure of the "density" of the spectrum for a given value of the momentum. The magnetic field is then slightly changed, and so another point of the spectrum falls on the slit E and its density is measured. In this way, by scanning the field in small steps and taking at each value of the field the counting rate of the G-M counter, the whole spectrum is explored and a diagram can be traced, taking as abscissa the momentum and as ordinate the "density" of the spectrum. This diagram is even more significant than a photographically registered spectrum, because in the latter the density of blackening is not always simply related to the density of β-radiation. Clearly, the optical analog of a β-ray spectrometer is a prism monochromator.

It is to be noted that the semicircular focusing on a spectral line of electrons of a given momentum in a uniform field is only approximate, and this on two accounts:

(a) For an electron leaving the source in a direction more or less inclined to the horizon,[6] the horizontal component of the momentum (which is the only one determining the deflecting force) is a little reduced: so its path, projected on the plane of the drawing, is a circle of a radius a little shorter than those shown in Fig. 1. Therefore, this ray will meet the plane of the diaphragm B' on a line a little to the left of L'. The horizontal displacement is proportional to the square of the angle of the initial momentum with the horizontal.

(b) As is made clear by Fig. 2, all the circles of a given radius passing by S do not meet the plane B' exactly at the same point: the displacements are of the order of the square of the angular aperture of the beam in the horizontal plane.

These two effects are analogous to *second-order* aberrations of the optical instruments: they both contribute to a broadening of the spectral line and therefore to a loss of resolving power (see part II). This focusing is called a *first-order* focusing because it can be said that the rays meet on the same line only if powers of the angular apertures higher than the first are neglected.

[3] This principle had been already utilized in 1908, by J. Classen, in order to determine the value of e/m for thermionic electrons: Physik. Zeits. 9, 762 (1908).

[4] E. Rutherford and H. Robinson, Phil. Mag. (6) 26, 717 (1913).

[5] The term *spectroscopes* is frequently employed to denote collectively the *spectrographs* and the *spectrometers*.

[6] For convenience of expression, we suppose that in the instruments of this type the magnetic field is vertical, as is usually the case today.

A further broadening is produced by the fact that the source is not a mathematical line but a wire or a strip of a certain finite width. Finally, in spectrometers, account must be taken of the finite width of the exit slit *E*, which also reduces the resolving power.

It is easily seen that all the conditions that would improve the resolving power (narrow beam aperture, source, and exit slit) would reduce the number of electrons reaching the detector, and therefore the "luminosity" of the instrument (see Section I B), so that a compromise must be made between these two opposite requirements. The same is true of all other types of β-ray spectroscopes, but the relation between the resolving power and the luminosity is not always the same. A good deal of theoretical work is being done at present in order to determine this relation for the different models, and some results of it will be given in parts II and III.

Coming back to the general description of the various types of β-spectroscopes, we must now mention those derived from the 180°-focusing spectrometer by replacing the uniform field by a non-uniform one (shaped field). The first spectrometer[7] of this kind was made in 1946 by K. Siegbahn and N. Svartholm:[8–10] in it the electron bundle coming from any point of the source describes an arc of $\sqrt{2}\pi = 254°33'$ in a field slightly decreasing toward the exterior of the orbit, and is focused again at a point, to a "first-order" approximation (see above). The main difference between this focusing and the semicircular one is that here two rays starting from a point of the source with different inclinations to the horizontal are concentrated at the same *point* of the image line, so that there is a focusing not only in the horizontal direction, but also in the vertical one (*double focusing*): one could say that such a magnetic field acts as a prism and as a convergent spherical lens (whereas the uniform field acts as a prism and as a *cylindrical* lens): it forms, therefore, on the plane of the exit slit a true image of each point of the source (without astigmatism). However, the chief advantage of this sort of spectrometer is another: if one considers electrons of a slightly increased momentum, one sees that they will travel in a weaker field, and therefore the radius of curvature of their paths will be increased on *two* accounts: the greater momentum and the weaker field, whereas in semicircular focusing only the first effect would be present. So the point of impact of these electrons on the exit slit will be displaced more than with semicircular focusing (in fact, twice as much), and this increases the resolving power for the same luminosity (see Sections II D).

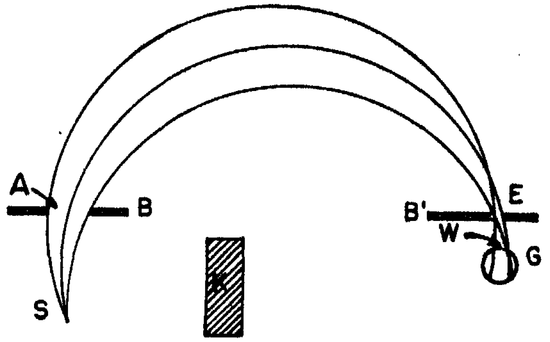

FIG. 2. The principle of the semicircular spectrometer.

Another type of shaped field has been calculated by Bock[11] and by Beiduck and Konopinski[12] so as to correct the third-order aberration due to the horizontal aperture of the beam (without correcting that due to the vertical one): one thus has "*third-order*" horizontal focusing. This permits making the beam very divergent in the horizontal plane, without too greatly impairing the resolving power (see Section II C).

In all the spectroscopes so far described, the electrons move approximately at right angle to the field in a region more or less annular-shaped. For this reason, we shall refer to all the instruments of this kind as *flat* spectroscopes.

2. *Helical Spectroscopes*

We turn now to a different family of β-ray spectroscopes which may be called *helical spectroscopes:* they are those that utilize the focusing property of an axially symmetric magnetic field for electrons coming from a source located on the axis. As is well known, this property permits the use of such a magnetic field as a convergent lens for electron rays, and is widely employed in the electron microscope and in other electron-optical devices. Figure 3a shows, in orthogonal projections, the trajectory of an electron in a uniform magnetic field (which is the simplest type of magnetic lens): the path is a cylindrical helix with the axis parallel to the direction of the field. However, the best way of representing this movement for our purpose is not by means of the orthogonal projections but by the following method, currently employed in electron optics. Imagine a rotating plane *m* always passing through the axis of symmetry *z* of the lens and through the instantaneous position of the electron (*meridional* plane): the trajectory of the electron in this plane is called its *trace* and is recorded in the drawing (Fig. 3b). Of course it does not describe completely the path in the space because it does not take into account the rotation around the axis, but since the apparatus is symmetrical around

---

[7] The shaped field can be applied in spectrometers, not in spectrographs, because only in the former is the geometry of the utilized paths the same for electrons of any momentum. These paths are like railway tracks on which, by changing the current intensity in the magnet, electrons of different momenta are conveyed in succession.

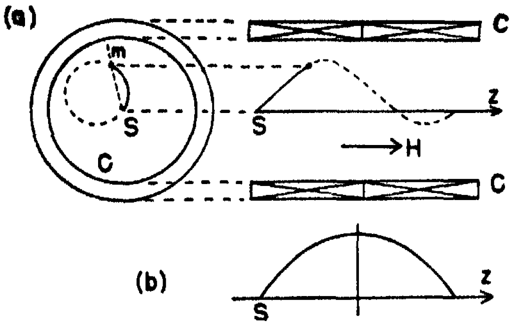

FIG. 3. (a) Two orthogonal projections of the helical path of an electron in a uniform field. (b) The "trace" of the same path in the rotating meridional plane *m*.

the latter, the trace contains just the elements relevant to the electron optics problems.

In the case of a uniform field, the trace is a sinusoid of amplitude and period double those of the orthogonal projection of the helix; in the general case of non-uniform but axially symmetrical fields the same method of representation is employed, but the trace is of course no longer a sinusoid. It is to be borne in mind that all drawings referring to helical spectrometers represent usually the traces and not the orthogonal projections of the paths.

The use of a magnetic lens for the analysis of β-rays was proposed by Kapitza in 1924[13] and realized shortly after by Tricker.[14] Its principle is the same as that of an optical experiment by Rubens and Wood, who in 1910 exploited the chromatic aberration of a quartz lens for the spectral separation of infra-red rays:[15] this principle is schematically explained by Fig. 4.

A diaphragm B, with an annular slit A, selects from the electrons of a given momentum emitted by the source S, only those whose initial directions are comprised between two cones having zz as axis and slightly different apertures. These electrons are approximately focused (full lines) on a circular hole R in the diaphragm B' and so are allowed to fall on the front window of a G-M counter of special design, G. Electrons of a different momentum (broken lines) will be focused nearer or farther and so will fall at least partially outside the hole R.

As is seen in the figure, traces of a given momentum but starting at different angles with the axis are not focused exactly at the same point, owing to the *spherical aberration*. So they will fall on a rather extended area of the plane B' and this impairs the resolving power just as does the widening of the lines in the flat spectroscopes. Therefore, substantial progress was achieved when, following Witcher,[16] the hole R was replaced by an annular slit E (Fig. 23), placed at the point (I in Fig. 4) where the bundle attains its minimum thickness before reaching the axis (*ring image*). As was pointed out by Frankel[17] and will be explained later, this improves radically the relation between resolving power and luminosity.

The magnetic lens of a helical spectrometer can be of different types:

(a) a uniform field, obtained by means of a long solenoid (*solenoid spectrometer*). The first helical spectrometer made by Tricker in 1924[14] was of this type, as was another built later (1941) by Witcher at Columbia University, where it is still in use with various alterations.[16] The chief advantages of the uniform field are the possibility of a rigorous analytical calculation of the electron paths, the easier adjustment, and the less sensitivity to external magnetic perturbations; the chief disadvantage is the necessity of considerable electric power and large dimensions if high energy β-rays are to be analyzed.

(b) a non-uniform (but axially symmetrical) field, confined to a small region between source and detector, obtained by means of a flat coil, usually without iron, similar to the conventional magnetic lenses of the electron optics. Figure 23 gives an idea of this type of instrument, which is called a "short lens spectrometer." It was built for the first time by Klemperer,[18] and later was adopted by Deutsch, Elliott, and Evans[19] and many others.

(c) a non-uniform (but axially symmetrical) field, extending throughout the paths of the electrons, and produced by several coils aligned along the same axis, with or without an iron core. Figures 24 to 26 give some examples of this type of instruments, called *"long lens spectrometers:"* the first of them was built by Siegbahn.[20]

It must be noted that, until recently, only the solenoid spectrometers had an annular exit slit: in the short and long lens instruments there was instead only a circular window on the axis (usually the entrance window of the counter). A long lens spectrometer with annular exit slit has been described in 1948 by Zunti[21] and a short lens one in 1949 by Hornyak, Lauritsen and Rasmussen[22] another one in 1950 by Verster, who has studied its theory.[23] A study for the utilization of the ring image in short lens spectrometers has been made recently by Keller, Koenigsberg and Paskin.[24] They find that in a short lens the use of an annular exit slit increases the luminosity of better than a factor of two for a given spread.

As it is seen, both flat and helical spectrometers have the same essential parts: a *magnet*, a *source*, an *entrance slit*, an *exit slit* or *window*, and a *counter*. Besides, there is usually on the axis a long lead cylinder (shaded rectangle in Fig. 4) in order to prevent gamma-rays from the source from reaching the counter, and several other baffles, variously disposed, serving not to define the electron beam but to prevent secondary and scattered beta- and gamma-rays from reaching the counter. It is to be noted, moreover, that a magnetic lens focuses at the same point positive as well as negative electrons: so, when it is necessary to discriminate between them, a further baffle is used, having a helicoidal shape as seen in Fig. 25: since the two kinds of electrons spiral in opposite directions, such a baffle lets through only one or the other of them, depending on the direction of the magnetic field. It serves also (as well as any other baffle placed on the axis) to stop the electrons that would reach the exit slit after performing more than one revolution.

3. *Calibration*

In any spectrograph or spectrometer with uniform field, an *absolute* determination of the momentum corresponding to a given line can be obtained by means of *geometrical* measurements in order to determine the radius of curvature ρ of the central path, and *magnetic* measurements to determine H (see formula 3). The latter are of course the most troublesome, and a very ingenious method of performing absolute determinations without measuring H has been devised by Siegbahn.[25] It makes use of the fact that the difference of the energies of two β-lines, originating in the conversion of the same γ-line, is simply related to the frequency of a line of the x-ray spectrum of the converter, which is known from diffraction experiments.

Another method of making absolute determination of the momentum corresponding to a β-line is based on the diffraction measurement of the wave-length of the γ-ray, whose conversion originates the said line. Many such measurements of high precision have been performed by J. W. M. DuMond and his collaborators, by means of a curved crystal gamma-ray spectrometer.[26]

With such methods the momenta of a number of "standard" β-lines (particularly of the spectrum of RaB and ThB) have been determined with an incertitude of less than 0.1 percent.

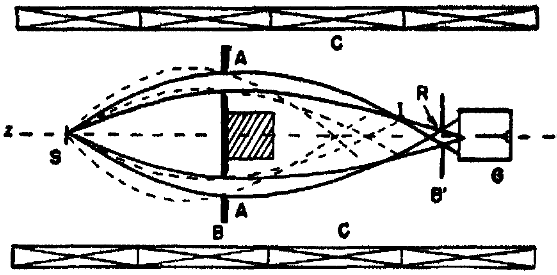

FIG. 4. The principle of helical spectrometers.

These *standard lines* are currently employed for the *relative* determination of the momentum of other lines, by means of any type of instrument. A relative determination demands, in the case of a spectrograph, only geometrical measurements, and in the case of a spectrometer only the measurement of the ratio of two successive values of the magnetic field. If the magnet has no iron core, this ratio is equal to that of the values of the exciting currents, and is easily determined: this is a great advantage of ironless spectrometers. When iron is present, the field ratio must be measured (at any point) (see Section IV E): however, if the magnet has been designed so as to keep the magnetization well under the saturation value in all sections (as is often possible, e.g. in long lens types), and if iron of low remanence has been employed, proportionality to the current can often be assumed.[27]

B. Nomenclature and Notations

The terminology in this branch of physics is far from being uniform. We summarize in this section the nomenclature and the notations adopted in this paper. Our terms are chosen, as a rule, from those used by other authors, but the choice has been guided more by considerations of perspicuity and preciseness than by current popularity. We report also, in the most important cases, some of the expressions used by different authors to denote the same thing.

Spectrograph: an instrument recording the β-ray energy spectrum on a photographic emulsion.

Spectrometer: an instrument measuring the relative number of β-particles in a short energy range, which can be gradually displaced along the spectrum.

Spectroscope: spectrograph or spectrometer.

Flat spectroscope: a spectroscope in which the central electron path lies in a plane (which will be considered as a *horizontal plane*).

Helical spectroscope: a spectroscope in which all of the paths of the particles are essentially of helicoidal shape. It is usually a spectrometer and can be a *solenoidal*, *long lens*, or *short lens* type (see Section I A).

Baffles: all the obstacles intended to prevent electrons or gamma-rays from reaching the detector directly or by scattering. Among these are the *first diaphragm* determining the *entrance slit* and the *second diaphragm*, determining the *exit slit* (in spectrometers). Both the entrance and the exit slit may have their two edges in different planes (see Fig. 16). Still other baffles act as shields against scattered radiation without contributing to the determination of the direct beam.

[27] K. Siegbahn, Phil. Mag. XXXVII, 162 (1946).

Momentum (p): the "quantity of motion" or "mechanical momentum" of an electron: $p=m_v v$, where v is the velocity and m_v the relativistic mass.[28]

In all formulas concerned with the magnetic deflection of electrons the momentum appears divided by the electron charge in e.m. units: this ratio will be denoted by p^*:

$$p^*=p/e_m.$$

Because of formula (3), this quantity is called by many authors "the $H\rho$ of the electron" even when there is no explicit reference to H and ρ (and even when $H=0$ and $\rho=\infty$). Its dimensions are those of a magnetic potential: so it will be expressed in "gilberts" (gauss-cm).

Total activity: The number of electrons emitted by a source in all directions per unit time.

Specific activity: The total activity of a source divided by its area.

Intensity: The number of electrons reaching the counter of a spectrometer per unit time (apart from scattered radiation) with a given source and a given magnetic field.

Transmission (T)*:* The intensity (see above) divided by the total activity of the source. Also: the fraction of all emitted electrons reaching the counter (except by scattering) with a given source and a given magnetic field.

Line profile: In a spectrometer, it is the diagram obtained, with a monokinetic source, by measuring the transmission (see above) with different values of the coils current j, and plotting it against the values of p^* which correspond to those of j according to the calibration law. In a spectrograph, it is the diagram having as ordinate the number of electrons falling per unit time and unit area at a point of the plate, with a monokinetic source of unit total activity, and as abscissa the value of p^* corresponding to that point of the plate according to the calibration law.

Half-maximum width: (Δp^*) The width of the line profile at half-maximum ordinate.

Spread: (η) The relative half-maximum width:

$$\eta=\Delta p^*/p^*=\Delta p/p.$$

The spread is usually expressed in percent and is called by different authors: "*irresolution*," "*spread*," "*resolving power*," "*inverse resolving power*," "*limit of resolution*," "*inverse momentum resolution*," "*half-intensity width*." Some authors call "*resolving power*" the quantity $\Delta E/E$, where E is the energy and ΔE is the half-maximum width of the line profile in the scale of energies: it is related to η by formula (5) in the following section.

Resolving power (P)*:* The inverse of the spread:

$$P=1/\eta=p^*/\Delta p^*=p/\Delta p.$$

This definition conforms to current usage in optics.

Base width ($\Delta_0 p^*$)*:* The width of the line profile at zero ordinate. Also called: "*total width.*"

Base spread (η_0)*:*

$$\eta_0=\Delta_0 p^*/p^*=\Delta_0 p/p.$$

Base resolving power (P_0)*:*

$$P_0=1/\eta_0=p^*/\Delta_0 p^*=p/\Delta_0 p.$$

Dispersion: In the plane of the photographic plate, or of the exit slit, let us call x the distance between an arbitrary origin and the line where electrons of momentum $p=e_m p^*$ from a point source are focused. Then $\gamma=dx/dp^*$ will be called "dispersion." Clearly, if the real image (or the ring image) of the source has a width Δx (due to the source width and to aberration) and if the width of the exit slit is X, the base width of the line profile will be approximately $\Delta_0 p^*=(X+\Delta x)/\gamma$.

Solid angle (Ω)*:* The solid angle filled by the initial directions of all the electrons of a monokinetic source leaving the center of the source (or, practically, any point of it) and passing through the entrance slit. It is also called "*angle of collection.*"

Gathering power (ω)*:* The fraction of all the emitted electrons of a monokinetic source passing through the entrance slit. For a source emitting isotropically it is given by

$$\omega=\Omega/(4\pi).$$

The gathering power is usually expressed in percent. In a spectrometer it is equal to the maximum intensity obtainable, with an exit slit wide open, with a source of unit total activity: so, it can be said that the gathering power measures the ability of the instrument to deal with sources of very low *total* activity.

Over-all gathering power: In a spectrometer the gathering power ω characterizes only the parts of the instrument up to the exit slit. The *over-all gathering power* with a given setting of the exit slit is measured by the value $T_{\max}$ of the transmission at the peak of the line profile. Clearly, $T_{\max}\leq\omega$.

Luminosity (L)*:* The gathering power multiplied by the source area: $L=\omega\sigma$. In a spectrometer, it is equal to the maximum intensity obtainable, with an exit slit wide open, with a source of unit specific activity (and of the given area). It measures therefore the ability of the instrument to deal with sources of very low *specific* activity. It will be expressed in cm^2.

---

[28] For the purpose of studying the theory of a β-ray spectroscope it is convenient to assume an ideal source emitting only electrons of a sharply defined momentum (*monokinetic* source): we shall always do so in the following, unless otherwise stated. Of course, a real source always emits a continuous spectrum, and even the lines of a so-called line spectrum (produced by internal or external conversion of gamma-rays) are only more or less sharp peaks in a continuous distribution of momenta. Their "natural" width (that is, apart from the broadening due to the imperfect resolving power of the instrument) is partly due to the width of the energy levels and partly (usually, for the most important part) to the fact that electrons coming from atoms deeply situated inside the source are slowed down by collisions before emerging from the source surface. This phenomenon will not be taken into account in the evaluation of the qualities of an instrument (similarly, the self-reversal or the pressure broadening of spectral lines is not introduced into the theory of optical spectroscopes). So the line profile of which we speak later is not the one that will be obtained with any real source, but only a limiting case of it.

Over-all luminosity (L^*): In a spectrometer, the luminosity characterizes only the parts of the instrument up to the exit slit. The *over-all luminosity* L^* with a given setting of the exit slit is measured by the peak transmission $T_{\max}$ multiplied by the source area:

$$L^* = T_{\max}\sigma.$$

Clearly, $L^* \leq L$.

Efficiency μ: The ratio of the luminosity L of a flat spectroscope to its useful pole piece area $\sum$ (as defined in Section II B). This dimensionless quantity helps the comparison between instruments of different types, by reducing them effectively to the same size.

C. A Few Fundamental Formulas

We recall here some formulas of relativistic mechanics that are basic in the theory of β-ray spectroscopes.

If m is the rest mass of the electron, m_v its mass at speed v and p its momentum, then

$$p = m_v v = m(1 - v^2/c^2)^{-\frac{1}{2}} v. \tag{1}$$

Since the magnetic deflection does not alter v, the relativistic change of mass does not introduce any complication in the movement of a *given* electron, provided the right value of m_v is taken at the start.

The radius of curvature ρ of the path of an electron moving at right angles to a magnetic field H is given by the well-known formula

$$H\rho = p/e_m, \tag{2}$$

where e_m is the electron charge in absolute e.m.u. ($e_m = 1.60199 \times 10^{-20}$). This formula suggests taking as a measure of momentum the quantity

$$p^* = p/e_m = H\rho \tag{3}$$

which will be expressed in gauss-cm (or "gilberts").

Let E be the kinetic energy (usually expressed in Mev). Its relation to p^* is most conveniently expressed by introducing the two universal constants

$$E_0 = mc^2 = 0.5107 \text{ Mev,}$$
$$p_0^* = mc/e_m = 8.125 \times 10^{-7} \text{ gilbert.}$$

Then the relation is

$$(E/E_0 + 1)^2 - (p^*/p_0^*)^2 = 1. \tag{4}$$

The relation between E in Mev and p^* in gilberts is tabulated, for instance, in "Miscellaneous Physical Tables" (Nat. Bur. of Stand. 1941).

The "spread" of an instrument (or its inverse, the resolving power), is most easily calculated in terms of momentum, but sometimes it is needed in terms of energy. To pass from the one to the other the following formula, obtained by differentiation of (4), is useful:

$$\eta = \frac{dp^*}{p^*} = \frac{dp}{p} = \frac{E + E_0}{E + 2E_0} \frac{dE}{E}. \tag{5}$$

The factor at the right-hand side is plotted against E and p^* in Fig. 5. It is to be noted that in the theory of magnetic spectroscopes all the relativistic corrections can be ignored as far as the spectrum is studied in terms of p (or p^*) rather than of E.

II. THEORETICAL RESULTS ON FLAT SPECTROSCOPES

A. General

For the discussion of the different types of flat spectroscopes, the cylindrical coordinates r, θ, and z are adopted, with the axes oriented in such a way that the central electron trajectory lies in the horizontal plane $z = 0$, the source in the plane $\theta = 0$ and centered at the point $r = a$, $\theta = 0$, and $z = 0$ (Fig. 6). The initial position of an electron leaving the source is determined by

$$r_0 = a + \delta r,$$
$$\theta_0 = 0,$$
$$z_0 = \delta z$$

and the components $\dot{r}_0$ and $\dot{z}_0$ of its initial velocity are approximately given by

$$\dot{r}_0/v = \varphi, \quad \dot{z}_0/v = \psi,$$

where φ and ψ are angles specifying the direction of the initial velocity.

We assume the magnetic field to be independent of θ and symmetrical with respect to the median plane $z = 0$; the vertical component H_z and the radial one H_r may be functions of z and r and H_θ is always zero. However for $z = 0$ and $r = a$, H_r is zero and H_z is such that an electron leaving the center of the source ($r_0 = a$, $\theta_0 = 0$, and $z_0 = 0$) with zero velocity components $\dot{r}_0$ and $\dot{z}_0$, will describe a circular trajectory of radius a. The necessary value of H_z,—called hereafter H_0—, is related to a and p^* by

$$H_0 = p^*/a.$$

The trajectory of the electron and its equation will depend on the initial position and momentum of the

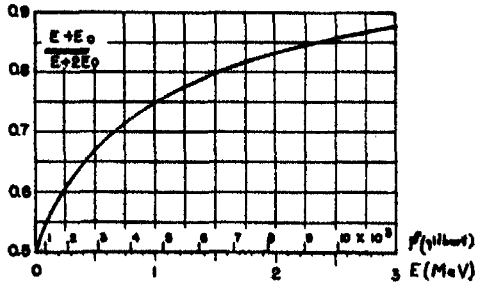

FIG. 5. The ratio between the momentum spread $\Delta p/p$ and the energy spread $\Delta E/E$ (form. 5). (E = energy in Mev; $p^* = H\rho$ = momentum divided by the electron charge in e.m.u.).

electron and also on the form of the magnetic field. It is in fact[29] the form of H_z that permits a classification of the different types of flat spectroscopes; according to this form, the kind and the degree of focusing are different. The flat spectroscopes may thus be classified in three groups:

(1) First-order single-focusing spectroscopes,
(2) Third-order single-focusing spectroscopes,
(3) First-order double-focusing spectroscopes.

In the following sections, each type will be studied; the form of the field, the equations of the trajectory, the image width, the dispersion, the resolving power, and the luminosity will be given for each, when available. The relations between the different parameters, such as source and slit dimensions and solid angle, will be investigated so as to determine the conditions of operation, —called optimum conditions—, which will result in maximum luminosity for any given radius of curvature and resolving power. Comparisons between the different types will then be possible. Attention will also be paid to the necessary size of the magnet.

B. First-Order Single-Focusing Spectroscope

1. *Focusing Properties*

This type of spectroscope is the oldest and uses a uniform magnetic field perpendicular to the central electron trajectory, i.e., in the z direction; H_z is then constant and equal to H_0 while H_r is always zero. The equations of the electron trajectory in cylindrical coordinates, as given by Shull and Dennison,[30] are approximately:

$$r=a+\left[\delta r-\frac{a}{2}(\varphi^2-\psi^2)\right]\cos\chi+\varphi(a+\delta r)\sin\chi$$
$$-\frac{1}{4a}(\delta r^2-a^2\varphi^2)\cos 2\chi-\tfrac{1}{2}\varphi\delta r\sin 2\chi$$
$$+\frac{1}{4a}(\delta r^2+a^2\varphi^2)-\frac{a\psi^2}{2}, \qquad (6)$$

$$z=\delta z+\psi a\chi, \qquad (7)$$

$$\theta=\chi-(\delta r/a)\sin\chi-\varphi(1-\cos\chi), \qquad (8)$$

where $\chi=vt/a$, and δr, δz, φ, and ψ depend on the initial conditions described before.

From these equations it is obvious that there will be no focusing in the z direction; this could be foreseen because there is no restoring force in that direction. In the r direction, on the contrary, a first-order focusing is achieved in the diametral plane through the source; the solution of Eqs. 6, 7, and 8 gives for the impact point on the $\theta=\pi$ plane:

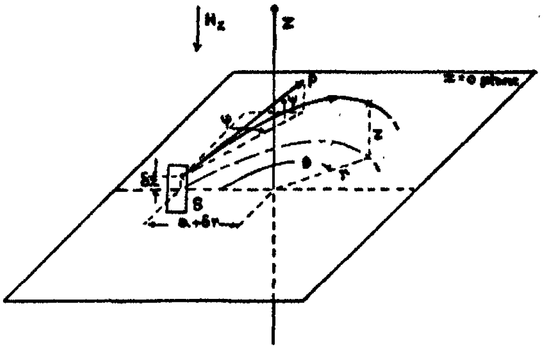

FIG. 6. Electron trajectory in a magnetic field whose main component is along the z axis of a cylindrical coordinates system (r, z, θ). The initial position of the electron on the source S is determined by $r_0=a+\delta r$, $z_0=\delta z$, and $\theta_0=0$; the dotted line is the projection of the trajectory on the $z=0$ plane.

$$r^*=a-\delta r-a(\varphi^2+\psi^2),$$
$$z^*=\delta z+\pi a\psi.$$

These two equations give the point of impact of an electron of momentum p in the plane containing the source, when it has left a source point of coordinates $r_0=a+\delta r$ and $z_0=\delta z$ in a direction making angles φ and ψ with the normal to the plane $\theta=0$. They also indicate that this type of spectroscope, semicircular with constant field, gives first-order single focusing.

2. *Image of a Finite Source*

Consider now a source of finite dimensions centered at $r=a$, $\theta=0$, and $z=0$ and extending from $a-Q/2$ to $a+Q/2$ in the r direction and from $-h/2$ to $+h/2$ in the z direction. Then, if the maximum values of φ and ψ are limited by baffles to φ_0 and ψ_0, all the electrons of the same momentum will cross the plane $\theta=\pi$ in an area whose dimensions are:

width: $Q'=Q+a(\varphi_0^2+\psi_0^2)$,
height: $h'=h+2\pi a\psi_0$.

This area may be considered as an image of the source which would be equal to it but for aberrations which are functions of φ_0 and ψ_0. The monokinetic electrons forming this image may be registered on a photographic plate or passed through an exit slit to a measuring apparatus. In the latter case, the presence of an exit slit of finite width will enlarge the line profile (for a monokinetic electron group) by the width of the latter, while in the former the line profile will be widened by the defining slit width of the microphotometer that will read the density distribution on the photographic plate. In both cases, the image is apparently increased by the width (F) of this last slit and the effective image width may be defined by

$$Q''=F+Q+a(\varphi_0^2+\psi_0^2). \qquad (9)$$

---

[29] The form of $H_z(r)$ for $(z=0)$ determines completely H, according to Maxwell's equations.
[30] F. B. Shull and D. M. Dennison, Phys. Rev. 71, 681 (1947); Phys. Rev. 72, 256 (1947).

It is this effective width Q'' that must be used in calculating the resolving power of the spectroscope.

3. *Dispersion and Resolving Power*

The dispersion γ (see Section I B) can be easily calculated: it is

$$\gamma=2\frac{dr^*}{dp}=2\frac{dr^*}{da}\frac{da}{dp}$$

and, from the preceding formulas for H_0 and r^* (neglecting second-order terms)

$$\gamma=2/H_0.$$

The base spread is, according to a preceding formula (Section I B):

$$\eta_0=\Delta_0 p/p=[F+Q+a(\varphi_0{}^2+\psi_0{}^2)]/2a. \tag{10}$$

The inverse of this formula gives the base resolving power, i.e., the resolving power for complete separation of two lines. Practically, this is not necessary because, as is well known, one may distinguish two lines even if they are partially overlapping; they are in practice said to be resolved if they are separated at half-maximum density and the resolving power of the spectroscope is usually defined with respect to this half-maximum line width. Its relation to the base resolving power depends on the shape of the profile line, which in its turn depends on the focusing properties of the apparatus, and on the relative choice of the parameters such as source and slit dimensions, and solid angle.

4. *The Spectrograph*

In a spectrograph, all the electrons of various momenta are simultaneously registered on a photographic plate while the homogeneous field is held at a constant value. The method proposed by Rutherford and Robinson[4] is still in use and may be described in the following way (Fig. 7). A rectangular source S of width Q and height h is placed in a plane parallel to the field; the divergent electron beam is limited in the plane perpendicular to the field by a slit A of width $2b$ placed in a plane parallel to the source at a distance d from it. In the same plane is located the photographic plate P on which focused monokinetic electrons form an image of width Q'. Though the photographic plate and the source do not lie in the same plane, it has been proved[31] that the image width Q' is equal as before to

$$Q'=Q+a(\varphi_0{}^2+\psi_0{}^2),$$

where φ_0 is determined by the ratio b/d and ψ_0 by $h/\pi a$ since the heights of the source and of the plate are generally made equal. The slit is larger than the source and much smaller than d; h is small enough to neglect $\psi_0{}^2$. With this design the image width Q', and consequently the spread, varies with the electron momentum. This latter value is known from the strength of the field and the radius of curvature of the path, which is given by

$$a=(1/2)[d^2+(x-Q/2)^2]^{\frac{1}{2}},$$

where d is, as before, the source-slit distance and x is the distance between the slit center and the right edge of the image or line.

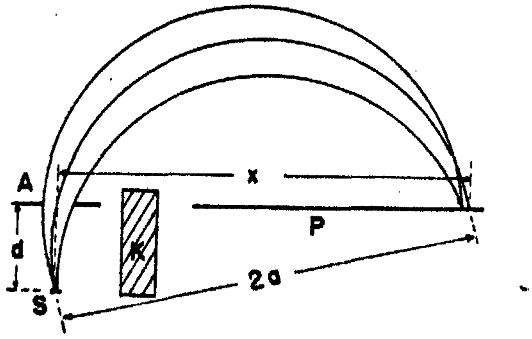

FIG. 7. Rutherford's and Robinson's design for beta-spectrograph. Electrons from the source S, going through the entrance slit A are focused on the photographic plate P; K is a lead shield.

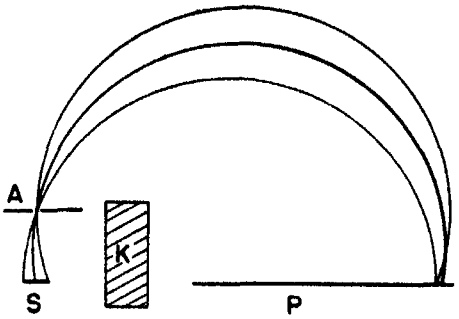

FIG. 8. Robinson's design for large source S. A and P are the entrance slit and the photographic plate and K is a lead shield.

Another design has been proposed by Robinson[32] in which the slit is very narrow and the source large (Fig. 8). This method, whose efficiency is less than that of the preceding one, is used when narrow electron sources are impractical, as for the study of secondary emission due to x-rays.

Siegbahn[26] has proposed the following design for the spectrograph (Fig. 9): the photographic plate is in the plane of the source so that the value of a is determined from a single measurement which affords greater precision. In this design also the image width, the spread and even the angle φ_0 vary with the electron momentum The method presents moreover the following disadvantage: if the spectrograph is designed for a mean radius a_m, some of the central rays whose impact points on the plate determine the value of a, may be stopped by the defining slit if their radius of curvature is much smaller or greater than a_m. This method thus limits the

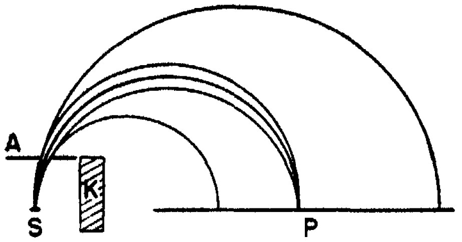

FIG. 9. Siegbahn's spectrograph design. The source S and the photographic plate P are in the same plane while the entrance slit A is in front of the source. K is a lead shield.

measurable momenta to an interval which becomes smaller as the resolving power increases.

5. *The Spectrometer*

In a spectrometer, a G-M counter is fixed at a distance $2a$ from the source and various momentum electrons are registered by varying the field (Fig. 10). The image width and the resolving power are then constant whatever may be the momentum; the base spread is given by the general formula (10) where φ_0 and ψ_0 are maximum divergence angles. The first one is determined by the width $2b$ of a diaphragm (A) placed at 90° from the source and is related to it by $\varphi_0=b/a$. The angle ψ_0 is limited by making the height h of the source, that of the diaphragm, and that of the exit slit all equal to $\pi a\psi_0$. Under these conditions, the "entrance slit" is formed by the vertical edges of the midway diaphragm and by the upper and lower edges of the exit slit; the total solid angle Ω of the beam is given by $2\varphi_0\psi_0$.

Among the advantages of the spectrometer over the spectrograph are that it requires a magnetic field over a smaller area and that the homogeneity of the field may be less perfect, since electrons of different momenta will nevertheless follow identical trajectories. The apparatus once calibrated gives the value of the momentum directly from the measurement of the field, and finally intensity measurements are more exact with a counter than with a photographic plate, even if corrections must be made for the background and for the thickness of the counter window.

6. *Optimum Conditions of Operation*

As seen before, the resolving power is a function of several parameters of which many sets of values may give the same result. However the luminosity of the apparatus, which is equal to the product of the source area by the gathering power, i.e., $L=Qh2\varphi_0\psi_0/4\pi$, depends also on the same parameters. It is evident that one should select among the possible parameter values those which for a given resolving power will achieve maximum luminosity. These conditions of operation for the semicircular spectroscope have been the subject of many papers. Wooster[33] and Li[34] first examined the advantages of various source forms, such as wires and rectangular plates, and the effects of photographic plate inclination. They also determined the resultant line profiles. From different standpoints and with different methods, Siegbahn,[26] Arnoult,[31] and more recently Owen,[35] and Fowler, Shreffler, and Cork,[36] have studied the form of the line profile as a function of various choices of parameters. In the case of spectrometers, Lawson and Tyler,[37] and Owen[35] studied similar problems and established the line profile for various operating conditions. The results contained in all of these papers are very useful to the β-ray spectroscopist. One of the most important is that for optimum conditions of operation the relative parameter choice should be $Q=a\varphi_0^2$ and $F=Q$ (for spectrometers). The angle ψ_0 which equals $h/(\pi a)$ is made small so as to make ψ_0^2 negligible in the spread formula; in practice ψ_0^2 is less than $0.1\varphi_0^2$. With these conditions, one may express the following relations:

$$\eta_0=\Delta_0 p/p=1.55\varphi_0^2 \quad \text{and} \quad L=0.05a^2\varphi_0^5,$$

and since then the line profile has a half-maximum width of 3/7 of its base width (Fig. 11), the spread is given by

$$\eta=\Delta p/p=0.665\varphi_0^2 \tag{11}$$

and the luminosity by

$$L=0.139a^2\eta^{5/2}. \tag{12}$$

In this case also, the *over-all* luminosity L^* (see Section I B) is found to be 55 percent of L, so we have finally the following relation between L^* and η:

$$L^*=0.0765a^2\eta^{5/2}. \tag{13}$$

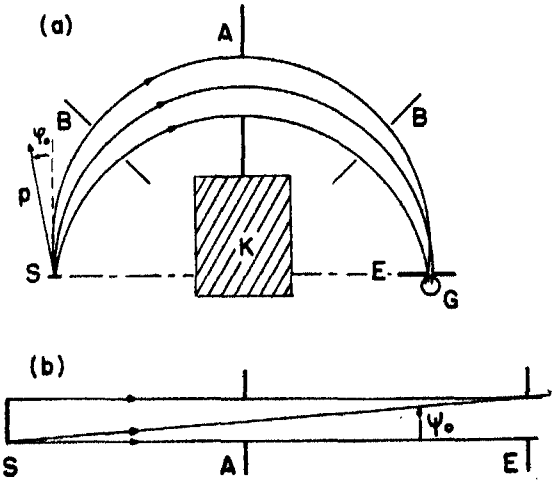

FIG. 10. First-order and third-order single-focusing spectrometers: (a) Projections on the $z=0$ plane of the central and marginal trajectories showing the maximum divergence angle φ_0, the source S, the baffles B, the entrance slit A, the exit slit E, the counter G and the lead shield K. These trajectories are all circular only with homogeneous field. (b) Development in the vertical direction of the outmost trajectories parallel to the $z=0$ plane and of the one making the maximum divergence angle ψ_0.

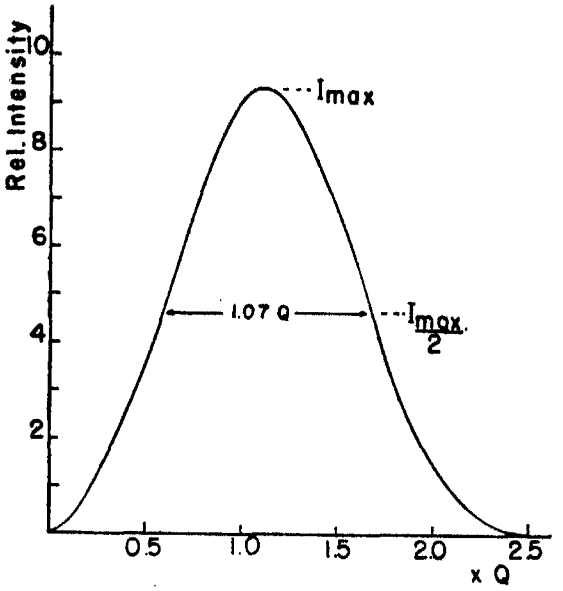

FIG. 11. Line profile for a usual type spectrometer with $Q=F=\varphi_0^2a$. Distances along the r axis are expressed in term of the source width Q.

However these are only relative optimum conditions, because the relative values of ψ_0 and h are arbitrarily fixed. A spectroscope operated under these conditions will be referred to hereafter as the "usual type."

It has been pointed out by one of us[38] that total optimum conditions could be established analytically and realized in practice. The relative choices of parameter values are then:

$$Q=2\varphi_0^2a,\quad \psi_0=2^{\frac{1}{2}}\varphi_0,\quad \text{and}\quad F=Q. \tag{14}$$

The corresponding spread and luminosity are

$$\eta=1.5\varphi_0^2\quad \text{and}\quad L=0.725a^2\eta^{5/2}. \tag{15}$$

In this case the line profile is given by Fig. 12 and the over-all luminosity L^* is 63 percent of the luminosity:

$$L^*=0.456a^2\eta^{5/2}. \tag{16}$$

A spectrometer operated under these total optimum conditions, which requires a higher source, will be called hereafter the "high source type."

Comparisons between the two types clearly show that for the same resolving power and for the same radius a, the luminosity of the high source type is greater by a factor 5.2 than that of the usual one, and that its over-all luminosity is higher by a factor 6. These advantages speak for themselves in favor of the use of total optimum conditions.

It is to be noted that these comparisons are theoretical. In practice, many designers of the usual type make ψ_0 even smaller than $\varphi_0\times10^{-\frac{1}{2}}$. Examination of some published designs of the usual type shows that the use of high source type would increase their L^* by as much as 7.5 times.

7. *The Magnet Size*

In making comparisons between various types of spectroscopes one must take into account not only the luminosity (or the over-all luminosity) at a given resolving power but also the required magnet size; the best spectroscope being the one which has the greatest ratio of luminosity (or over-all luminosity) to magnet size for a given spread. It does not seem necessary for comparison purposes to use the real magnet size; a characteristic of the magnet, such as its necessary pole piece area is quite sufficient. This area depends actually on the length of the central trajectory,[39] on the maximum beam width, and also on the maximum height of the beam since, as it is well known experimentally, the field may be considered homogeneous between parallel pole pieces in a region extending from the center to a distance from the edge equal to the air gap. Defined in that way, the necessary pole piece area is

$$\Sigma=(\text{central trajectory length})\times(\text{max. beam width}+2\text{ times beam height}).$$

This quantity gives, in our opinion, a good idea of the total size of the magnet; the height of the beam will evidently also affect the magnetomotive force required to maintain a given field in the air gap, but this is easily resolved and certainly has far less importance than the

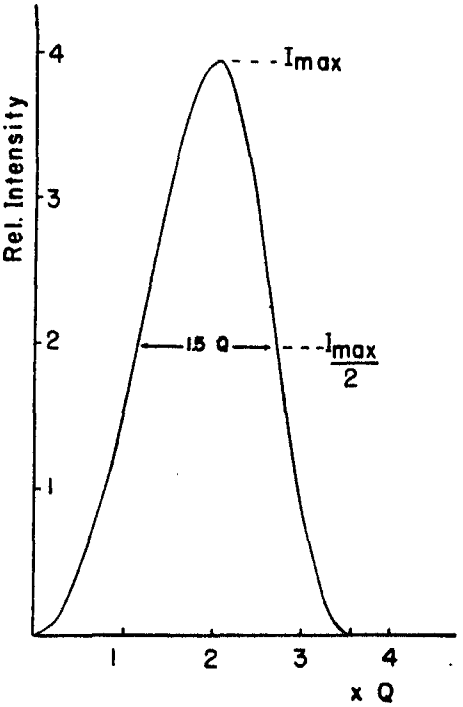

FIG. 12. Line profile for a high source type spectrometer with $Q=F=2\varphi_0^2a$ and $\psi_0=\varphi_0\sqrt{2}$. Distances along the r axis are expressed in term of the source width Q.

---

[38] C. Geoffrion, Rev. Sci. Inst. 20, 638 (1949).

[39] In the case of spectrographs, in order to make possible comparisons between them and spectrometers, we choose as the trajectory length the trajectory of mean radius between the greater and the smaller radii that the apparatus can accomodate.

pole piece area. Calculated with the preceding formula, the necessary pole piece area is for the usual type $\sum_u = 12.6a^2\varphi_0$ and for the high source type $\sum_h = 34.3a^2\varphi_0$.

The ratio of the luminosity L to the area $\sum$, which we have called the efficiency μ of the spectroscope, may be expressed by

$$\mu_u = 9.8\times 10^{-3}\eta^2 \text{ for the usual type,}$$

and

$$\mu_h = 2.59\times 10^{-2}\eta^2 \text{ for the high source type.}$$

If the ratios μ^* of L^* to $\sum$ are now calculated, the results are:

$$\mu_u{}^* = 5.4\times 10^{-3}\eta^2$$

and

$$\mu_h{}^* = 16.2\times 10^{-3}\eta^2.$$

From this study it is clear that the high source type is superior since for the same magnet size and at the same resolving power it will give a profile line with an intensity peak three times higher. From another standpoint, at the same spread and at the same intensity the usual type requires a magnet whose pole piece area is three times greater and whose total size is consequently about 5.2 times bigger than for high source type.

C. Third-Order Single-Focusing Spectroscope

1. Focusing Properties

The necessary field for this type of focusing has been studied by Bock[11] and Beiduck and Konopinski.[12] The latter derived the shape of the field so as to meet the general requirements mentioned in the beginning of this part II and also the following requirement, namely that it focuses perfectly the electrons emerging from a point source and confined in the median plane $z=0$. They found that in the median plane the H_z component of the field, which equals H since H_r is zero in that plane, should be:

$$H_z(r,0) = H_0\left[1-\frac{3}{4}\left(\frac{r-a}{a}\right)^2+\frac{7}{8}\left(\frac{r-a}{a}\right)^3 -\frac{9}{16}\left(\frac{r-a}{a}\right)^4+\frac{51}{320}\left(\frac{r-a}{a}\right)^5\cdots\right] \quad (17)$$

where H_0, r, and a have the same meanings as before.

Using for the field in the median plane the approximation $H_z(r,0)=H_0[1-(3/4)(r/a-1)^2]$ they obtain for the horizontal component $H_r \approx -(3/2)H_0 z(r-a)/a^2$, and for the vertical component $H_z \approx H_0\{1-(3/4)[(r-a)^2 - z^2]/a^2\}$.

These determine the orbit equations for an electron leaving a point source of coordinates $r_0 = a+\delta r$, $z_0=\delta z$ and $\theta=0$, with an initial velocity forming angles φ and ψ with the normal to the plane $\theta=0$.

These equations are found to be:

$$\begin{aligned}
\theta &= \chi-(\delta r/a)\sin\chi-\varphi(1-\cos\chi),\\
z &= \delta z + a\psi\chi - (3\varphi\psi a+3\delta z\delta r/2a)+(\psi\delta r-\varphi\delta z)(3\chi/2)\\
&\quad +(3\varphi\delta z/2-3\psi\delta r+3\varphi\psi\chi a/2)\sin\chi\\
&\quad +[3\varphi\psi a+3\delta r(\delta z/a+\psi\chi)/2]\cos\chi,\\
r &= a+\delta r\cos\chi+\varphi a\sin\chi+\psi^2 a\\
&\quad +5(\varphi^2 a+\delta r^2/a)/8-3(\delta z+\psi a\chi)^2/4a\\
&\quad +(3/2)(\varphi\delta r+\psi\delta z)\sin\chi\\
&\quad +(3\delta z^2/4a-\delta r^2/4a-\varphi^2 a-\psi^2 a)\cos\chi\\
&\quad +(3/8)[(\varphi^2 a-\delta r^2/a)\cos 2\chi-2\varphi\delta r\sin 2\chi].
\end{aligned}$$

From these equations it is seen that there will be no focusing in the z direction but a very good focusing in the r direction for $\theta=\pi$. The corresponding value of χ is $(\pi+2\varphi)$ and the coordinates r and z becomes for this value of θ:

$$\begin{aligned}
r^* &= a-\delta r+\delta r^2/2a-5.41\psi^2 a-1.5\delta z^2/a-4.71\psi\delta z\\
&\quad -4\varphi^2\delta r-6\varphi\psi\delta z-3\pi\varphi\psi^2 a-5\varphi^4 a
\end{aligned}$$

and

$$z^* = \delta z+\psi\pi a-3\delta z(\delta r+\pi\varphi a/2)/a-4\varphi\psi a.$$

The formulas for r^* and z^* give the point of impact of an electron of momentum p in the plane containing the source when it has left the source point of coordinates $r_0=a+\delta r$ and $z_0=\delta z$ in a direction forming angles φ and ψ with the normal to the source. They also indicate that at 180° from the source a field of such a shape gives a third-order focusing with respect to φ (for $\psi=0$ and $\delta r=0$).

2. Image of a Finite Source

In this type, the image of a finite source has the following dimensions:

$$\begin{aligned}
\text{width: } Q' &= Q+5.41\psi_0{}^2 a+1.5h^2/4a+4.71\psi_0 h+4\varphi_0{}^2 Q\\
&\quad +6\varphi_0\psi_0 h+6\pi\varphi_0\psi_0{}^2 a+5\varphi_0{}^4 a,\\
\text{height: } h' &\cong h+2\psi_0\pi a,
\end{aligned}$$

where Q and h are source dimensions, and φ_0 and ψ_0 are maximum divergence angles, fixed by baffles. This image is defined for monokinetic electrons having such a momentum that their radius of curvature in a field H_0 is a. In this case also the line profile is enlarged by the exit slit and its final width is:

$$\text{effective image width: } Q''=Q'+F.$$

3. Dispersion and Resolving Power

For this spectrometer, the dispersion is again $2/H_0$, while the base spread may be expressed (see Section I C) by:

$$\begin{aligned}
\eta_0 = \Delta_0 p/p &= (F+Q)/2a+11.86\psi_0{}^2\\
&\quad +2\varphi_0{}^2 Q/a+18.8\varphi_0\psi_0{}^2+2.5\varphi_0{}^4.
\end{aligned}$$

The relation between the spread and the base spread depends on the relative choice of parameters, and the focusing properties of the field; it should be determined for each mode of operation.

4. *The Spectrometer*

A spectrometer utilizing the previously mentioned shaped field and possessing the focusing properties described above has been built by Langer and Cook[40] and by Bruner and Scott.[41] As we have seen, the source and detector are placed 180° apart (Fig. 10); the divergence of the electron beam in the median plane is limited by a diaphragm (A) located midway on the trajectories, i.e., at $\theta=\pi/2$. Its width $2b$ is related to φ_0 by $b=a\varphi_0$ (in first approximation). On the other hand, the beam divergence in a vertical plane is fixed by the height h of the source and that of the exit slit which are made equal; ψ_0 is then given by $\psi_0=h/\pi a$. The entrance slit is thus formed partly by the midway diaphragm and partly by the exit slit and the total solid angle Ω is $2\varphi_0\psi_0$.

5. *Optimum Conditions of Operation*

The optimum conditions of operation of this recent type of spectrometer have not yet been published. An attempt to determine them in a manner identical to that used for the homogeneous field spectrometer[38] gives, to a first approximation, the following results:

$$Q=13.6a\varphi_0^4 \quad \text{and} \quad \psi_0=0.965\varphi_0^2$$

when $h=\pi a\psi_0$. Under these conditions the parameters determining both luminosity and base spread are fixed such as to produce maximum luminosity at any given base resolving power. However the value of the exit slit width F is not fixed and since the determination of its optimum choice is not easy, we fix it to be equal to Q. This choice is not completely arbitrary because in all optical spectrometers and many electron focusing devices optimum conditions of operation are reached when the exit slit is as large as the image of the source without aberrations. With this choice of the various parameters, the expressions for the base spread and for the luminosity become:

$$\eta_0=29.6\varphi_0^4$$

and

$$L=4.65\times10^{-8}\eta_0^{9/4}.$$

The relation between the base spread and the spread (at half-intensity), the form of line profile with these optimum conditions and the corresponding value of L^* as a function of L are not known theoretically. The experimental results given by Langer and Cook[40] together with their operating conditions enable us to calculate, in their case, the base width of the line profile and compare it to its half-intensity width, as taken from an experimental graph. The ratio of the spread (at half-intensity) to the base spread is then found to be $\frac{1}{6}$; this value is quite small when compared to the value 3/7 of the same ratio for the homogeneous field type. This low ratio was to be foreseen since, due to the high degree of focusing, most of the electrons are focused near the right edge of the image (Fig. 13).

If this ratio $\frac{1}{6}$, which should be approximately the same for the proposed optimum conditions, is used, the following important results are obtained:

$$\eta=4.94\varphi_0^4 \quad \text{and} \quad L=0.17\eta^{9/4}.$$

6. *The Magnet Size*

In this case also, the pole piece area can be used to characterize the magnet size; the formula established for the homogeneous field type to calculate this area may serve here since it depends also on the beam length, maximum width and height. The Langer and Cook magnet has a pole piece area which corresponds exactly with the one calculated with this formula under their operating conditions.

The value of this area $\sum$ is, for the third-order single-focusing spectrometer (under optimum conditions),

$$\sum=3\pi a^2\varphi_0.$$

The efficiency of the apparatus for a given spread is given for this type by:

$$\mu=L/\sum=2.68\times10^{-2}\eta^2.$$

Unfortunately we do not have enough information to express the ratio of the over-all luminosity to $\sum$, which is a better criterion of efficiency.

D. First-Order Double-Focusing Spectroscope

1. *Focusing Properties*

This type proposed by Svartholm and Siegbahn[9] has been also studied by Shull and Dennison[30] in a more general theory of which we shall give the most important features. In this theory, the vertical component of the field, H_z, as measured in the median plane, is taken to have the form

$$H_z(r,0)=H_0[1-\alpha(r-a)/a+\beta(r-a)^2/a^2-\cdots]$$

where H_0, a, r, and z have the same meanings as before

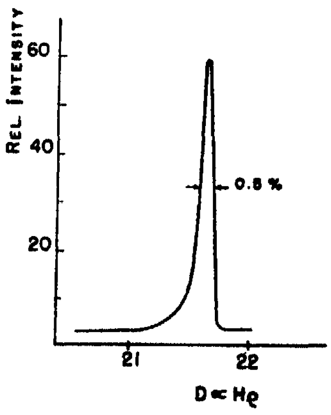

FIG. 13. Experimental line profile for the third-order single-focusing spectrometer as determined by Langer and Cook (see reference 40). The various parameters were then: $a=40$ cm, $h=2.5$ cm, $Q=F=0.4$ cm, and $\omega=0.1$ percent.

---

[40] L. M. Langer and C. S. Cook, Rev. Sci. Inst. 19, 257 (1948).

[41] J. A. Bruner and F. R. Scott, Rev. Sci. Inst. 21, 545 (1950).

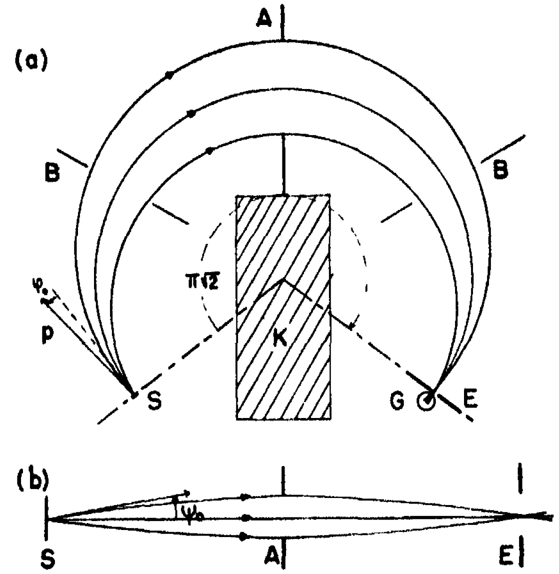

Fig. 14. Double-focusing spectrometer. (a) Projections on the $z=0$ plane of the central and marginal trajectories, showing the maximum divergence angle φ_0, the source S, the baffles B, the diaphragm A, the exit slit E, the counter G and the lead screen K. (b) Developments in the vertical direction of the central and outmost trajectories of electrons leaving a point of the source; the focusing action and the maximum divergence angle ψ_0 in the z direction are indicated.

and where α and β are arbitrary dimensionless constants. The magnetic field outside the median plane turns out to be

$$H_r(r, z)=zH_0[-\alpha/a+2\beta(r-a)/a^2]$$

and

$$H_z(r, z)=H_0[1-\alpha(r-a)/a \\ +\beta(r-a)^2/a^2-z^2(\beta-\alpha/2)/a^2]$$

where the value H_0 is such that an electron of momentum p will describe a circular path of radius a in that field. The study of electron orbits in such a field shows that there is simultaneous first-order focusing in both r and z directions for $\theta=\sqrt{2}\pi$ if the value of the parameter α is $\frac{1}{2}$. The corresponding values of the two other coordinates are

$$r^*=a-\delta r+\delta r^2(2-4\beta)/3a+\delta z^2(4\beta-3)/3a \\ +a\varphi^2(2-16\beta)/3+a\psi^2(16\beta-6)/3,$$
$$z^*=-\delta z+8\beta\delta r\delta z/3a+(32\beta-12)a\varphi\psi/3.$$

These equations, in which all terms have the same meanings as before, give the point of impact in the plane $\theta=\pi\sqrt{2}=254°33'$ of an electron which has left a point source determined by $r_0=a+\delta r$, $z_0=\delta z$ and $\theta_0=0$ with an initial velocity forming angles φ and ψ with the normal to the $\theta=0$ plane; they also indicate the double-focusing property.

2. *Image of a Finite Source*

The image of a source $(Q\times h)$ given by this type of field, if the angles are limited to φ_0 and ψ_0, has the following dimensions:[42]

width: $Q'=Q+|4\beta-3|h^2/12a$
$+|2-16\beta|a\varphi_0^2/3+|16\beta-6|a\psi_0^2/3,$
height: $h'=h+4\beta Qh/3a+4|16\beta-12|a\varphi_0\psi_0/3.$

3. *Dispersion and Resolving Power*

Svartholm and Siegbahn[9,10] have determined the dispersion of the double focusing spectrometer; they found it to be twice that of a semicircular one, i.e., $4/H_0$. The base spread formula gives in this case:

$$\eta_0=Q/4a+F/4a+|4\beta-3|h^2/48a^2 \\ +|2-16\beta|\varphi_0^2/12+|16\beta-6|\psi_0^2/12.$$

This relation indicates that η_0 will be a function of β and that for $\beta=\frac{1}{8}$ it will be independent (to the second order) of φ_0, and for $\beta=\frac{3}{8}$ of ψ_0. If one compares the base spread of this instrument with that of the homogeneous field spectrometer, it appears that the spread of the former is smaller by a factor of about two which is due to its double dispersion. On the other hand the double-focusing action increases the solid angle and consequently the luminosity by a factor of two $(L=Qh\varphi_0\psi_0/\pi)$; thus at the same resolving power this new type has a luminosity gain, over the homogeneous type, due to both its double focusing and double dispersing properties.

From experimental data of Shull,[43] the spread may be taken as half the base spread; unfortunately the ratio of L^* to the luminosity is not given.

4. *The Spectrometer*

Spectrometers of this type have been built by Svartholm and Siegbahn,[9] Shull,[43] and Kurie, Osoba, and Slack;[44] they differ by the use of different values of the field parameter β which is $\frac{3}{8}$ for Siegbahn and $\frac{1}{8}$ for Shull and Kurie. They have in common the general design (Fig. 14): the source and detector are located 254°33′ apart and the entrance slit is placed midway on the electron trajectories. The divergence angles are both determined by its dimensions; the width equals $2\sqrt{2}a\varphi_0$ and the height $2\sqrt{2}a\psi_0$.

5. *Optimum Conditions of Operation*

Shull[43] studied the line profile due to a point source when different forms of diaphragm are used and with values of β equal to $\frac{1}{4}$ and $\frac{1}{8}$. He has not however indicated any optimum relation between the different parameters. An attempt to determine such relations leads us to the following results (with the same methods as before):[38]

(1) For β equal or near $\frac{3}{8}$, the value of φ_0 is arbitrary, but for optimum conditions the following ratios must be

---

[42] It is to be noted that each term contained in the formula of the image dimensions must be positive. The absolute values of parenthesis should then be taken.

[43] F. B. Shull, Phys. Rev. 74, 917 (1948).

[44] Kurie, Osoba, and Slack, Rev. Sci. Inst. 19, 771 (1948).

realized:

$$\frac{Q}{4a}=\frac{5h^2}{48a^2}=\tfrac{2}{3}\psi_0{}^2=\tfrac{1}{3}\eta.$$

The luminosity is then

$$L=2.14a^2\varphi_0\eta^2.$$

(2) For β equal or near $\frac{3}{8}$, ψ_0 is arbitrary and the ratios are

$$\frac{Q}{4a}=\frac{1}{16}\frac{h^2}{a^2}=\tfrac{2}{3}\varphi_0{}^2=\tfrac{1}{3}\eta,$$

which gives for luminosity

$$L=2.83a^2\psi_0\eta^2.$$

(3) For β equal or near $\frac{3}{4}$, h is arbitrary and the ratios are

$$\frac{Q}{4a}=\frac{5}{3}\varphi_0{}^2=\psi_0{}^2=\tfrac{2}{3}\eta.$$

The luminosity then becomes

$$L=0.44ah\eta^2.$$

(4) For other values of β, the luminosity will be a maximum if the various parameters take the following values:

$$\psi_0=\left(\left|\frac{1-8\beta}{3-8\beta}\right|\right)^{\frac{1}{4}}\varphi_0,\quad h=\left[\left|\frac{8(1-8\beta)}{4\beta-3}\right|\right]^{\frac{1}{4}}\varphi_0,$$

$$Q=\frac{4a}{3}|1-8\beta|\varphi_0{}^2.$$

The value of the spread and of the luminosity are then

$$\eta=0.58|1-8\beta|\varphi_0{}^2$$

and

$$L=4.57a^2\eta^{5/2}[|(4\beta-3)(1-8\beta)(3-8\beta)|]^{-\frac{1}{4}}.$$

In all these four cases, the exit slit width F is chosen equal to Q, since the magnification is one, and the ratio η_0/η is taken equal to 2 as determined from Shull's[48] data on line profile (Fig. 15).

The optimum value of β is still to be determined; it is evident from the last formula (case 4) that L becomes infinite at β equal $\frac{1}{8}$, $\frac{3}{8}$, and $\frac{3}{4}$ for which the formula is not valid. It is also obvious that since the parameters h, φ_0 and ψ_0 are always finite and small, the mentioned values of β will never be optimum values. The choice of β must in this case be made with respect to some practical desiderata. For example, if one chooses a square diaphragm ($\varphi_0=\psi_0$) the optimum value of β is $\frac{1}{4}$; if he chooses the source, the diaphragm, and the exit slit to be all of the same height, then the optimum value of β is $\frac{1}{2}$. Other criteria may be used such as the ratio of L to the maximum beam cross section, which reaches its maximum value for $\beta=\frac{1}{2}$, or the ratio of L to the pole piece area (the efficiency defined for the other types) for which $\beta=\frac{3}{16}$ gives a very high value (but not a maximum). This last value, for which, furthermore, the necessary air gap is one of the smallest, is in our opinion to be chosen. The efficiency $\mu(=L/S)$ is then given by:

$$\mu=\frac{0.28\eta^2}{(|4\beta-3|)^{\frac{1}{4}}[(|8\beta-3|)^{\frac{1}{4}}+2(|1-8\beta|)^{\frac{1}{4}}]}.$$

(We have supposed that magnet pole pieces could be shaped to give any desired value of β; that may not be done so easily in practice.)

E. Comparisons between the Different Flat Types

A useful criterion for comparing the relative merits of the different flat spectroscopes is the efficiency μ as defined by the ratio of the luminosity to pole piece area for a given spread. This criterion may not be the best; the ratio (μ^*) of the over-all luminosity L^* to the same area is probably a better indication of the efficiency, but we were unfortunately unable to determine it due to the lack of theoretical data on the line profile. It is our opinion that comparisons between various μ^*'s should not differ very much from those between μ's as we define it and that this one gives to a first approximation a good idea of the usefulness of the apparatus.

In Table I are given the theoretical values of the luminosity, of the efficiency and of the gathering power as functions of the spread for the three classes of spectrometers studied. In the case of the double-focusing type, these values have been determined for β equal to $\frac{1}{2}$, $\frac{1}{4}$, and $\frac{3}{16}$ at total optimum conditions and for β equal to $\frac{1}{8}$ and $\frac{3}{8}$ with optimum conditions limited by the condition $\psi_0=\varphi_0$.

This table indicates clearly the relative merits of the various types and the advantage of the double focusing with $\beta=\frac{3}{16}$. The tabulated functions are also graphically represented in Fig. 31 together with the corresponding values for existing models.

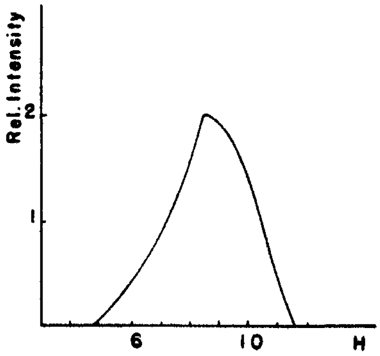

FIG. 15. Theoretical line profile for a double focusing spectrometer as determined by Shull (see reference 43). The various parameters where then: $a=170$ mm, $\beta=\frac{1}{2}$, $Q=0.3$ mm, $F=2$ mm, h (source) $=15$ mm, h' (exit slit) $=0.75$ inch, $\varphi_0=\psi_0\cong0.1$ rad. Experimental points are in close agreement with the theoretical line.

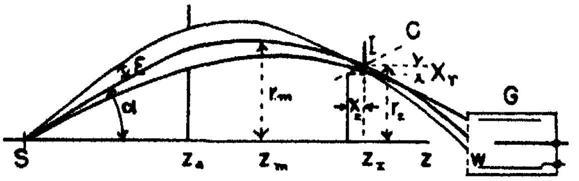

FIG. 16. *Notations employed in the theory of the helical spectrometers*: α = emission angle; ϵ = half-aperture; S = source, and origin of coordinates; z_a = abscissa of the admission slit; I = ring image; G = Geiger counter; w = front window of the counter.

F. Miscellaneous Types

The use of electrostatic fields has also been proposed for beta ray spectrometers: these apparatus, whose theory has been given by Rogers,[45] unfortunately require very high voltages, except for the low energy spectrum. For this reason they are not often used.[46]

A generalized theory of the focusing properties of magnetic spectrometers has recently been published by Judd[47] and by Rosenblum.[48] In their papers, they suggest the use of a spectrometer in which both the source and the detector are outside the field which is shaped and gives double focusing. They also study the optical properties of the system and show the possibility of increasing the resolving power without loss of intensity; it is our opinion that beta-ray spectrometers, as well as mass spectrometers, could be improved through the use of these authors results.

Other types for special use have been built such as a double spectrometer for the direct determination of the charge of the beta-particle[49] and a sextupole spectrometer for the study of the K^{40} spectrum.[50] Siegbahn and Slätis[51] have also recently built a "limegraph" for the study of the upper limit of β-spectra and of the γ-radiation.

Coincidence spectrometers which register simultaneously two monokinetic electron beams of different energy have been designed by Feather[52] and Fowler and Schreffler.[53] Their function is to determine whether or not two different radiations from a radioactive sample are in the same branch of a nuclear decay scheme.

III. THEORETICAL RESULTS ON HELICAL SPECTROMETERS

A. The Solenoid Spectrometer with Point Source

This is the spectrometer for which the theory is most advanced, because in it the "traces" of the electron paths are of a very simple shape (sinusoidal). Figure 16 shows three of them and explains the meaning of many of the symbols we shall employ in the following sections.

TABLE I.*

No.	Type of spectrometer	$L\times a^{-2}\eta^{-3/2}$	$\mu\times\eta^{-2}10^3$	$\omega\times\eta^{-1}$
1	1st-order, single-focusing, usual type	0.139	0.98	0.076
2	1st-order, single-focusing high source type	0.725	2.59	0.15
3	3rd-order, single-focusing	$0.17(\eta)^{-\frac{1}{2}}$	2.68	$0.51\eta^{-\frac{1}{2}}$
4	1st-order, double-focusing, $\beta=\frac{1}{2}$	2.67	6.29	0.31
5	1st-order, double-focusing, $\beta=\frac{1}{4}$	3.24	6.61	0.54
6	1st-order, double-focusing, $\beta=\frac{3}{16}$	3.60	7.10	0.63
7	1st-order, double-focusing, $\beta=\frac{1}{3}$ and $\psi_0=\varphi_0$	2.14	5.66	0.16
8	1st-order, double-focusing, $\beta=\frac{2}{3}$ and $\psi_0=\varphi_0$	2.78	6.70	0.16

* The figures recorded in the third and fifth columns are the values of Φ and Ψ defined in Section V.

It is convenient to consider only electrons of a given momentum $p=e_mp^*$, emitted isotropically by the point source S. If we call H the field intensity, the length

$$D=2p^*/H \tag{18}$$

(equal to the diameter of the circle that would be described by an electron emitted at right angles to the field) is the only dimensional parameter entering in the theory.[54] The trace starting at an "emission angle" α is a sinusoid of amplitude $r_m=D\sin\alpha$ and the abscissa of its (first) maximum is $z_m=(\pi/2)D\cos\alpha$.

To study a spectral line, the field H, and therefore D, must be varied in a small interval around a typical value H_0 (and D_0), which we define as that for which the central trace of the beam just grazes the outer edge of the exit slit. All the linear dimensions of the apparatus can be expressed solely in terms of D_0.

Consider now two infinitely near traces, started at "emission angles" α, $\alpha+d\alpha$: they cross each other at a point I, whose coordinates z_I, r_I are functions of α. This means that if the "aperture angle" 2ϵ were infinitely small, and a plane screen were placed at $z=z_I$, the electron beam would design on it a circle of radius r_I, which can be called a "*ring image*" of the source (some-

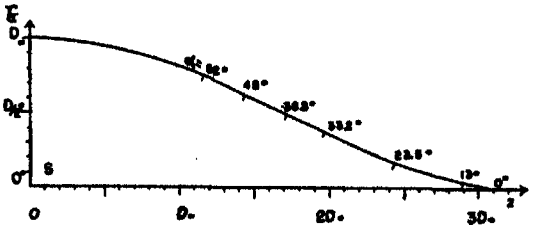

FIG. 17. The "caustic" of the uniform magnetic field.

[54] For this reason, all these problems may be studied equally well by assuming a monokinetic source and a variable field, or a source emitting a continuous uniform spectrum and a fixed field. We choose the first method.

times called a "*ring focus*"). Its position determines the location of the exit slit.

To calculate the position of the ring image, it is convenient to introduce the function $\beta(\alpha)$ defined by

$$\tan\beta = (\pi - \beta)\tan^2\alpha, \quad 0 \leq \beta \leq \pi/2. \tag{19}$$

The diagram of this function is given in Fig. 2, reference 55: it is also tabulated (with the notation $\pi - \beta = \psi_i$) in reference 56. Then one has

$$z_I = D(\pi - \beta)\cos\alpha, \quad r_I = D\sin\alpha\sin\beta. \tag{20}$$

The locus of the point I for a given D and for α varying between 0 and $\pi/2$ is analogous to the *caustic* of optical lenses: it is shown in Fig. 17.

Now suppose that H, and therefore D, is varied slightly, keeping unchanged the abscissa z_a and the radius r_a of the (infinitely narrow) entrance slit.[57] Then the point I is displaced along a (practically straight) line C. The conical surface of which C is the meridional section is the analog of the plane of the photographic plate in the flat spectrograph (in fact, on it the different lines of a heterokinetic source would be simultaneously focused). Clearly, the two edges of the exit slit must be located on this cone, and this defines the ratio X_r/X_z (*slope* of the exit slit). If the entrance slit is very near the source, where the traces are almost rectilinear, ($z_a \ll z_m$), a change in D_0 does not change the value of α: in this case, as was first pointed out by Frankel,[17] the line C is directed toward S and the edges of the slit must be placed on a cone with the vertex in the source. If the entrance slit is located farther from S (as it is usually), the slope of the exit slit may be different and even negative. In the rather frequent case that the entrance slit is placed at the point where r is maximum ($z_a = z_m$) the slope X_r/X_z is always negative and is given, as a function of α, by the lower curve of Fig. 18. By placing the entrance slit at a convenient abscissa z_a, the exit slit can be made exactly "horizontal" ($X_r = 0$), that is, the two edges of the slit can be of equal diameter, with the advantage that, by making the inner one longitudinally movable, the width of the slit can be altered without changing its slope. The necessary value of z_a/z_m is given as a function of α by the upper curve of Fig. 18.[58]

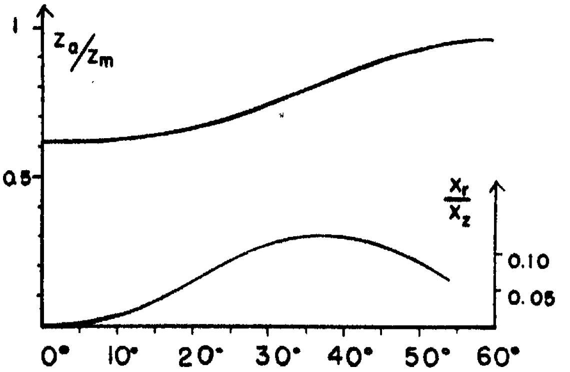

FIG. 18. *Upper curve:* abscissa z_a of the admission slit (as a fraction of the abscissa z_m of maximum r) for which the curve C of Fig. 16 is horizontal (exit slit parallel to the axis) (for a solenoid spectrometer). *Lower curve:* slope X_r/X_z of the exit slit when the admission slit is at the point of maximum r (for a solenoid spectrometer).

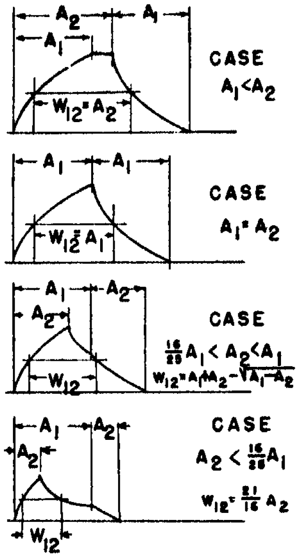

FIG. 19. Form of the line profile for a solenoid spectrometer with point source, for different widths of the exit slit A_1 = aberration width of the beam, A_2 = width of the exit slit, W_{12} = width of the line profile at half-maximum intensity. (DuMond, reference 56.)

If the aperture 2ϵ is not infinitely small, all of the traces of the beam will not pass through the same point I but will pass at a distance from I of the order of ϵ^2, (as is shown in Fig. 16): on a screen placed at z_I the beam would design a ring of a certain width, with a sharp exterior edge of radius r_I (where the electron density would be infinite). This broadening of the ring, due to the "spherical aberration," determines the width to be given to the exit slit. In fact[56] the most favorable line profile is obtained by making the exit slit as large as the aberration width, so that for $D = D_0$ the beam just grazes the two edges of the slit. In this case, the line profile has the shape shown in Fig. 19 (case $A_1 = A_2$). The same figure, taken from reference 56, shows the line profiles obtained with a larger or narrower exit slit.

The gathering power is easily calculated: it is

$$\omega = \sin\alpha\sin\epsilon \cong \epsilon\sin\alpha,$$

and the *over-all* gathering power is the same.

The half-maximum width of the line profile is proportional to ϵ^2 and is a rather complicated function of α[55]: therefore for a given α and variable ϵ the spread $\eta = \Delta p/p$ is proportional to the square of the gathering power ω:

$$\eta = \omega^2/f(\alpha),$$

---

[55] E. Persico, Rev. Sci. Inst. 20, 191 (1949).

[56] J. W. M. DuMond, Rev. Sci. Inst. 20, 160 (1949).

[57] Sometimes the two edges of the admittance slit are placed in different planes. This introduces some complications in the theory, and doubtful advantages in practice.

[58] E. Persico (to be published).

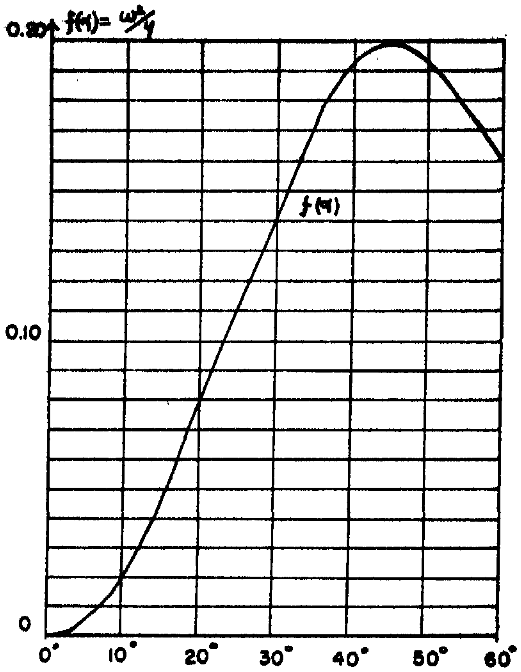

FIG. 20. The ratio $f(\alpha)=\omega^2/\eta$ as a function of the average emission angle α, for a point source solenoid spectrometer (ω = gathering power, η = spread). This ratio is the square of the figure of merit Ψ defined in Section V.

where

$$f(\alpha)=2(3+\cos^2\alpha\,\tan^2\beta)^{-1}\sin^2\alpha. \tag{21}$$

The function $f(\alpha)$ is plotted in Fig. 20. This curve has a maximum at $\alpha=45°37'$, where $f=0.197$. The existence of this maximum suggests, as was pointed out by one of us,[59] giving α a value much bigger than those usually adopted before (which were around 18°): however, as the maximum is rather flat, not much is lost if, for convenience of construction, α is kept a little below the optimum value. In the optimum conditions for a point source, η and ω are related by:[55]

$$\eta/\omega^2=5.07. \tag{22}$$

An interesting modification of the solenoid spectrometer has been recently proposed by P. Hubert.[60] In it the entrance and the exit slit are no longer completely distinct: the beam is limited internally by a unique baffle placed at the ring image, and externally by two or more other baffles. In this way, according to the author, the resolving power could be increased by a factor of about 4/3 with the same peak transmission.

B. The Solenoid Spectrometer with Disk Source

If the source cannot be made of negligible dimensions compared with X_r, then the beam falling on the exit slit is thickened not only by the spherical aberration but also by the width of the source, and the line profile is changed in shape.

Suppose the source is a disk of radius s and of uniform specific activity. In many practical cases it is the specific activity, and not the total activity, that is important; for instance, because of the necessity of reducing the broadening of the spectral line by the thickness of the radioactive layer; see Section IV. In these cases the performance of the spectrometer is measured not by the gathering power but by the *luminosity* $L=\pi s^2\omega$, and s, ω and α must be determined so as to get the maximum resolving power for a given luminosity. This problem has not yet been rigorously solved, but it seems probable that the following conditions, illustrated by Fig. 21, are not far from the optimum:[61]

$\alpha=40°25'$ $s=2.84D_0\epsilon^2$
Entrance slit: $z_a=1.02D_0$ $r_a=0.630D_0$ $h=0.881D_0\epsilon.$
Exit slit: $z_f=1.63D_0$ $r_f=0.544D_0$ $X_s=12.3D_0\epsilon^2.$

Minimum radius of the counter window: $w=1.74D_0\epsilon^2$.

The position of the entrance slit has been chosen so as to have an exit slit exactly "horizontal" (see preceeding section): therefore $X_r=0$.

The gathering power is $\omega=0.648\epsilon$, the luminosity $L=16.5D_0^2\epsilon^5$ and the spread $\eta=3.56\epsilon^2=8.46\omega^2$. The value of D_0 must be chosen according to the availability of electric power and the acceptable weight and bulk of the instrument. By choosing the aperture 2ϵ one can adjust the luminosity to the source specific activity. The spread and the luminosity are related by

$$\eta=1.16(L/D^2)^{2/5}=2.32(L/l^2)^{2/5}. \tag{23}$$

where $l=2z_m=2.39D_0$ is the distance between source and counter.

If we assume for the line profile the shape of Fig. 22 (calculated by DuMond for $\alpha=45°$ and a "vertical" exit slit) the *over-all luminosity* turns out to be $L^*=0.60L=9.83D_0^2\epsilon^5$, and is related to the spread by

$$\eta=1.43(L^*/D^2)^{2/5}=2.86(L^*/l^2)^{2/5};$$

the base spread is approximately $\eta_0=2.5\eta$.

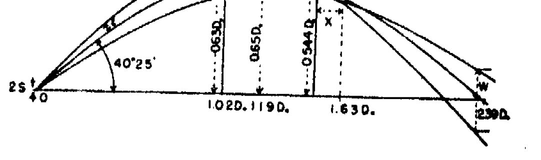

FIG. 21. Optimum conditions for a solenoid spectrometer with disk source. The admittance slit has been placed so as to have the exit slit parallel to the axis. The aperture 2ϵ has been arbitrarily chosen equal to 12°, corresponding to a spread $\eta=4$ percent and a luminosity $L=0.215\times10^{-5}D_0^2$.

---

[59] E. Persico, Phys. Rev. 73, 1475 (1948).

[60] P. Hubert, Comptes Rendus 230, 1464 (1950).

[61] They are calculated by taking for α the optimum value for a *disk* source as calculated by Persico (see reference 55), and for s the value which minimizes the *half-maximum* width of the line profile following DuMond (see reference 56). The position of the entrance slit has been so chosen as to have the exit slit parallel to the axis (that is $X_r=0$, $X_s=X$).

A precision solenoid spectrometer which will realize very nearly the optimum conditions is at present being built by DuMond (private communication).

C. The Short Lens Spectrometers

In these instruments the source and the counter are outside the region where the field is appreciable, so that the traces of the electrons are composed of two straight lines joined by a sharply bent curve (Fig. 23). These traces cannot, in general, be calculated analytically but must be determined by numerical computation.[62] For this reason, not very much has been published till now on the theory of these instruments. As we have noted in the introduction, the ring focus exit slit has been adopted in short lens spectrometers only very recently.

A simplified theory of the short lens spectrometer with circular exit window has been made by Deutsch, Elliott, and Evans:[19] we give here the essentials of this theory, using the notations explained in Fig. 23 (where the ring slit E must now be supposed absent).

Let us call u the distance of the source from the symmetry plane of the lens, and 1 the distance between the source and the exit window: then $M=(l-u)/u$ is the "magnification" of the lens. In addition, let s be the source radius, w the exit window radius, and r_1, r_2 the internal and external radii of the entrance slit. Neglecting spherical aberration, Deutsch, Elliott, and Evans have shown that the highest peak-intensity for a given resolving power is obtained when the window is large as the source image ($w=Ms$) and r_2/r_1 is equal to $\sqrt{2}$. Under these conditions, one finds that the "base spread" is given by

$$\eta_0=2.42\frac{M}{M+1}\frac{s}{r_2}$$

and the "luminosity" L (as defined by us) by

$$L=0.54(M+1)^2s^2r_2^2/l^2,$$

$$L=0.092\frac{(M+1)^4}{M^2}\frac{r_2^4}{l^2}\eta_0^2,$$

which can be written, if we introduce the average[63]

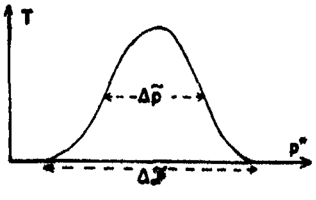

FIG. 22. Shape of the line profile with a disk source.

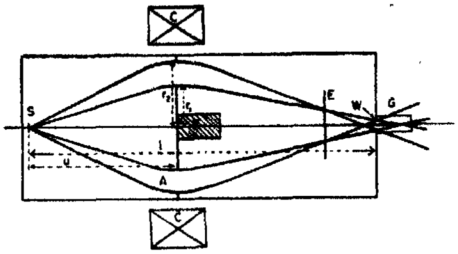

FIG. 23. Scheme of a short lens spectrometer (S=source; C=coil; G=Geiger counter; K=lead shield against direct radiation; A=admission slit; E=exit slit; W=counter window (acting as exit slit if E is absent).

emission angle $\alpha\cong r_2/u$ (supposed $\ll 1$), as:

$$\eta_0=3.3M\alpha^{-2}(L/l^2)^{\frac{1}{2}}.$$

This last formula shows that, given α, the magnification M must be made as small as conveniently possible. However, if the activity of the sources available is so great that a loss of luminosity is no objection, the authors advise making $M=1$, since this symmetrical arrangement minimizes some of the causes of spread, such as inaccuracy of alignment, aberrations, and stray magnetic fields.

The last formula also shows that α must be as large as possible, but if it is made larger than a few degrees the spherical aberration can no longer be neglected and the ratio L/η_0^2 becomes much smaller than indicated by the formula (in instruments of this type, α is usually not larger than 12°).

When an annular exit slit is used, it is possible to give α a larger value and to achieve a much greater luminosity for a given resolving power. A theory of the short lens with annular exit slit has been given very recently by Grivet.[64] He finds that for a given α and a disk source of the optimum radius, the luminosity is proportional to $\eta_0^{5/2}$, as in the solenoid type (see Section III B). A comparison with the latter type shows that the short lens can give the same resolving power and luminosity than the uniform field, with less expenditure of electric power. However, when the radioactive substance can be concentrated in a source of negligible dimensions, the solenoid spectrometer is the more advantageous.

In all the short lens spectrometers, to insure that the axes of the various baffles coincide *in direction* and *in position* with the symmetry axis of the field, one connects the source, the baffles and the counter rigidly to the walls of the vacuum chamber: this rigid unit can be slightly displaced with respect to the coils, by means of micrometer screws, to get the proper alignment. This adjustment is very critical and can be made by trial and error, or by a method described by Verster.[23] It may be noted that in the solenoid spectrometer the adjustment is much easier, because in it only the direction of the

---

[62] The technique of these calculations is described in various books on electron optics, for instance: Zworykin *et al.*, *Electron Optics and the Electron Microscope* (John Wiley and Sons, New York, 1945).

[63] The curvature of the traces in the vicinity of the lens compensates almost exactly for the difference between r_2 and $(r_1+r_2)/2$.

[64] P. Grivet, Comptes Rendus 230, 936 (1950). Also private communication.

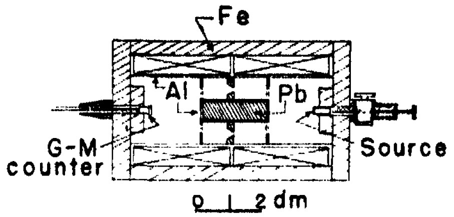

FIG. 24. A long lens spectrometer with "closed" magnet (Siegbahn, reference 27).

axis must be adjusted: parallel displacements are of no consequence.

D. The Long Lens Spectrometers

Attempts to reduce the spherical aberration of lens spectrometers by means of a suitable distribution of the field have lead to the consideration of other arrangements.

In the usual magnetic lenses the spherical aberration may be defined as follows. Call $z(\alpha)$ the distance, from the source, of the (first) intersection with the axis of the trace with emission angle α: if this function is developed in MacLaurin's series, it gives

$$z(\alpha)=z(0)+\alpha^2z''(0)/2+\cdots$$

because, by reason of symmetry, $z'(0)=0$. The "longitudinal aberration" is $z(\alpha)-z(0)=\alpha^2z''(0)/2$. The "tranversal aberration" (that is, the ordinate r of the intersection of the trace with the plane $z=z(0)$) is, in the same approximation, $r=\alpha^3z''(0)/2$. It is the latter that limits the resolution in a spectrometer if a *circular window* is used instead of a ring exit slit and if α is not very large. It has been proved[65] that an axially symmetric magnetic field for which the aberration coefficient $z''(0)$ is zero must have some singularities on the axis, so that it cannot be produced by coils placed at the exterior of the electron beam.[66] However, it is possible to approach this field by a regular one, obtainable by such coils, and so to reduce appreciably the spherical aberration. This approximate field varies, along the axis, in such a way that its diagram as a function of z is a curve *concave* upward.

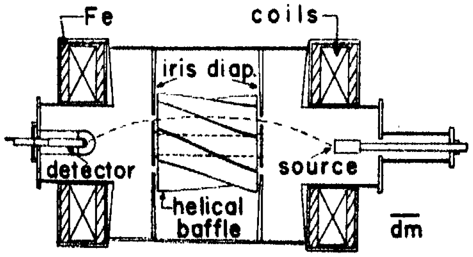

FIG. 25. The long lens spectrometer of Agnew and Anderson (reference 68).

One method of obtaining such a "concave" field of reduced aberration is the "closed" cylindrical magnet first devised by Siegbahn,[27] a section of which is shown in Fig. 24. It is a cylindrical iron tube, closed at the ends by iron disks bearing at the center two pole pieces directed inward: the coils are inside the tube.

Another method of obtaining a concave field is by means of two equal flat coils, placed on the same axis some distance apart. This method has been recently applied by Lauritsen and Christy,[67, 28] who, by varying the separation between the coils, have investigated the effects of various shapes of the concave field. On the same principle, Agnew and Anderson,[68] have constructed a long lens spectrometer in which the source and the counter are each at the center of the two equal coils, and the entrance and exit slit (both annular) are symmetrically located with respect to the median plane (Fig. 25). The traces shape is particularly favorable to the suppression of scattered radiation.

A new, and very promising, type of long lens spectrometer is that with "intermediate image" constructed by Slätis and K. Siegbahn[69] (Fig. 26). In it the magnet is of the "closed" type, and the field is such that the traces form a ring image midway between source and detector and then concentrate again on a point of the axis, where a small G-M counter is located. The entrance slit is rather near the source, and the exit slit is located at the median plane, where the intermediate ring image is formed. The performance of this instrument is very remarkable (see part V). Two interesting modifications of it have been proposed by Bothe[70] and by Grivet.[71] A theory of the two coils long lens spectrometers has been made by G. Paquien and P. Grivet[72] and a more general theory, with application to the Slätis and Siegbahn instrument, by P. Grivet.[72]

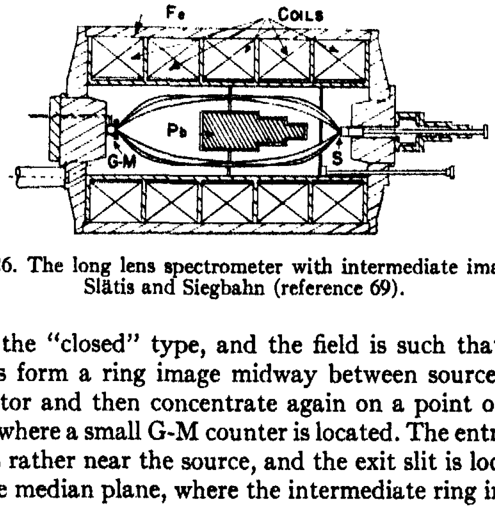

FIG. 26. The long lens spectrometer with intermediate image of Slätis and Siegbahn (reference 69).

We must finally mention a different principle that can be used to build a magnetic lens spectrometer: to utilize not the "chromatic aberration" of the lens, but the *rotation* of the image, which is a phenomenon typical of magnetic lenses. If the source (at $z=0$) is a line normal to the lens axis, its image (at $z=z'$) is a similar line but rotated of an angle Θ, given (for small α values) by

$$\Theta=\frac{1}{2p^*}\int_0^{z'} H(z)dz$$

where $H(z)$ is the value of the magnetic field on the axis. If a slit of the proper orientation is placed at the plane $z=z'$, it will select electrons of a given p^* (of course, the source must not extend in the vicinity of the axis). The principle of this spectrometer has been discussed by Butt[73] and by Georgesco[74] (who enumerates many of its advantages). Very recently it has been utilized for registering the pairs of positive and negative electrons produced by very hard gamma-rays: the two electrons of a pair are rotated by 90° in opposite directions and received on two G-M counters, whose coincidences are recorded.[75]

IV. ELECTRICAL AND MECHANICAL DEVICES

A. The Magnetic Field

The necessary field for beta spectrum analysis is achieved through the use of solenoidal coils, iron magnets or Helmholtz coils. The first ones are used in helical types; if a homogeneous field is needed, the homogeneity is insured over the whole electron path by designing the solenoid longer than the necessary length[16] or by correcting the end effects with auxiliary coils. For non-homogeneous fields in helical spectrometers, one or more flat coils or a closed magnet can be used (see Section III C, Fig. 24).

Most of the flat types utilize iron magnets; in spectrographs a permanent magnet is often used in which part of the yoke is of Alnico.[76] The exciting coils are used to establish a residual field of a desired value which may be changed at will; the great stability of the field and the simplification in auxiliary equipment compensate for any minor inconvenience in operation. In spectrometers, the variable magnetic field is obtained in the usual way; though circular pole pieces[37] are very common, recent spectrometer designs favor the annular form (Fig. 27) with the coils in the center (double mushroom magnet), as first used by Cockroft for an alpha-spectrometer. This form which allows a larger radius without increasing the magnet size, necessitates lower fields; it is also perfectly suitable for the shaped field models.[40, 41, 44] Here designers make use of the fringing field to obtain the desired field shape. The pole pieces may be machined in different manners, in a continuous or discontinuous surface (Figs. 27 and 28).

The iron used is not necessarily of high grade since with relatively large radii high fields are not required.

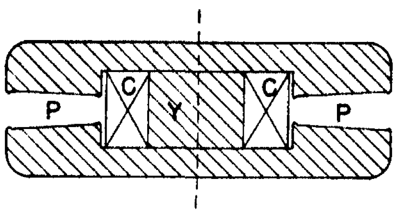

FIG. 27. Double-mushroom type magnet with bevelled pole pieces P. The coil C is wound around the central part of the yoke Y.

One must take care however that the first part of the yoke to saturate be that surrounded by the coils; the contrary may cause inhomogeneity or variations in the field shape. Another practical rule to insure constancy of the desired field shape is to have the pole piece width equal to the maximum beam width plus twice the air gap.[77] Variations from the ideal field of one part in a thousand may be tolerated, although for the spectrograph field, where various momentum electrons follow different trajectories, the homogeneity should be better.

The exciting coils are made either of a great number of small diameter wire turns or of a small number of large diameter wire turns; both methods require the same power and the first one, which requires less current, is more practical with an electronic power supply, while the second one is more suitably supplied from batteries since it requires less voltage.

A different method of obtaining the magnetic field is the use of Helmholtz coils.[31, 78] This method gives, however, only weak fields and is utilized in spectrometers designed for the study of low energy spectra.

B. The Spectroscope Chamber

The spectroscope chambers must be vacuum tight and are usually made of brass or even of aluminium; with an annular magnet, the pole pieces are often used as the upper and lower sides while the vertical sides are made of brass with special joints for vacuum sealing.[9, 44]

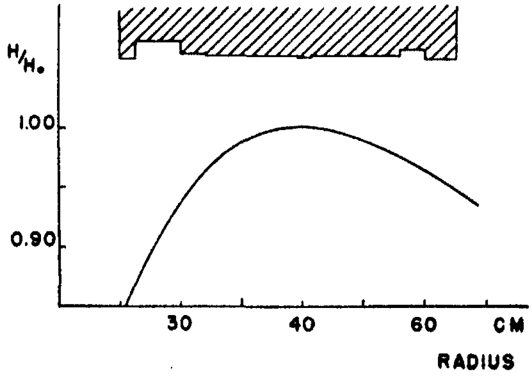

FIG. 28. Shaped pole pieces of Langer's and Cook's magnet (see reference 40).

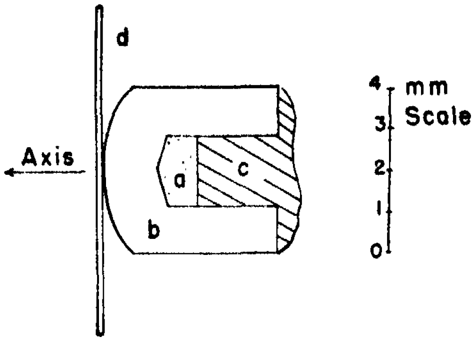

FIG. 29. Deutsch's design of a secondary β source (see reference 19): a, gamma-source; b, brass or copper capsule; c, wax; d, radiator.

The baffles contained in the chamber are generally made of Lucite or aluminium, or of lead coated with these materials, so as to diminish wall scattering, which causes distortion in beta-ray spectra,[79] and to absorb the most energetic electrons. The slit apertures are adjusted through vacuum-tight doors and in many cases a Wilson seal or other special device[80] allows the source to be changed without affecting the chamber vacuum.

Spectroscopists generally employ a diffusion pump backed by a mechanical pump to maintain the vacuum in the chamber;[81] various types of flanges with grease, or rubber *O*-rings insure vacuum-tight doors and tube joints.[82] Vacuum measurements are made with thermocouple and ionization gauges together with adequate circuits;[83] a vacuum of at least 10^{-4} mm Hg is required so that the electron mean free path, a few meters, be much longer than the electron trajectory. In this way, scattering from the residual gas will be minimized.

C. The Source

One of the most important causes of error in beta-spectrum analysis may be the source; its thickness, unevenness, and support modify the electron energies disproportionately and so influence the spectrum shape particularly at low energies.[84] The influence of the source thickness has been studied recently by Langer, Motz, and Price;[78] they found that for a source of less than 11 micrograms/cm^2, the deviation of the shape occurs at 8 kev and that it rises as the source thickness increases.[85]

Homogeneity of the source is also desirable since local concentrations of radioactive material produce electrostatic effects due to local charges; however this homogeneity is difficult to realize as pointed out by the same authors. They found in fact that sources chemically prepared and apparently uniform showed variations of intensity of as much as one hundredfold; they described a technique by which they were able to reduce these variations 25 times.[78]

To diminish the total charging effects, thin foils of nickel or aluminium have been used as source supports; however their thickness is always too great and produces backscattering.[84] Thin films of zapon, Nylon, Formvar, or collodion are now prefered as source backing since their backscattering is practically negligible, if thicknesses of a few micrograms/cm^2 [78, 86] are employed. The electrostatic effects are then reduced by framing the source with aluminum strips.

Special sources have also been designed[19] for the energy measurement of gamma-rays by their photo-ejected electrons (Fig. 29). The gamma-source is placed in a dense metal cup such as copper which absorbs all the primary betas; the filtered gamma-beam then radiates a thin foil of a heavy element such as Au, and the energy of the emitted secondary electrons is measured. To obtain the correct gamma-energy, one must correct the measured electron energy for its atomic binding energy, which varies with the radiated substance, and for the loss of energy due to the electron source thickness, which in this case is greater than for the beta source in order to secure sufficient efficiency of secondary electron production; the latter correction, however, is a minor one.

For analyzing very hard gamma-rays it is more convenient to utilize the materialization pairs, instead of the photoelectrons, registering them by means of a coincidence spectrometer (see, e.g., the end of Section III D).

D. The Detector

In a spectrograph the spectrum is registered on a photographic plate and the relative blackening of the plate, as measured by a microphotometer, is translated into an electron intensity distribution.[87] The photographic action of beta-rays on different types of plates has been studied particularly by Plesset, Harnwell, and Seidl[76] who concluded that a linear relationship exists between electron intensities and the relative blackening they produce, for all practical purposes. Cranberg and Halpern[88] have also made calibration of photographic emulsions for low energy electrons. With the uses of special plates recently developed in America and in England this method is thus perfectly suitable for beta-ray analysis.

In spectrometers, the detector most commonly used is the Geiger-Müller counter; the use of scintillation counters and of electron multipliers is just at its start, owing to the difficulty of operating them in a magnetic field. Usually the counters require no special features[89] except for the thin window wall. This can be a side window or, especially in helical spectrometers, a front window; in this case, the anode is a rigid wire held at one end only. The window wall must be as thin as possible to avoid absorption at low energies, uniform enough to avoid gas diffusion through it and also strong enough to support the counter gas pressure. All of these requirements are met in windows of thin mica foil[90] or of several layers of very thin films of Nylon, zapon, or collodion.[78, 86] Thicknesses as small as a few micrograms/cm^2 are realized for window walls; for large window apertures fine copper grids (such as Lektromesh[78]) are often used to reinforce the film. A few authors have employed a gas ballast tank to compensate for gas loss by diffusion.

Windowless counters have been used[78] with success; the counter pressure was dynamically maintained and the equivalent window thickness of the diffused gas was of the order of one microgram/cm^2. In order to register low energy electrons, which are absorbed by the counter window, accelerators have been designed[40] in which electrons coming through the exit slit are accelerated to 20 kev before reaching the counter and being registered.

Besides the beta-ray counter, one or many gamma-ray counters may be used either near the source for coincidence measurement[91] or close to the beta-counter in order to diminish the background effect by anti-coincidence methods.[92]

E. Magnetic Field Measurements

Absolute magnetic field measurements are always delicate and in most cases not necessary, as pointed out in Section I A3; this is fortunate since differential measurements always afford higher accuracy than absolute ones.

Measurement of the magnetic field with a search coil is frequently employed by spectroscopists. The electrical pulse from a flip coil may be measured directly with a fluxmeter or a ballistic galvanometer,[44] or compared to the pulse coming from a standard mutual inductance whose secondary is rotated simultaneously with the search coil; the necessary primary current together with instrument characteristics permits calculation of the field strength. The second method is more accurate than the first and allows field measurements of one part in a thousand.[31]

Other methods have been recently perfected: continuously rotating coils with which changes of 0.01 gauss can be observed,[93] vibrating wires driven by a quartz crystal,[94] a fluxball allowing point measurement,[95] a search coil with electronic fluxmeter,[96] a null reading fluxmeter,[97] an alternating probe current utilizing the permalloy incremental permeability,[98] and a magnetic field strength meter employing the Hall effect in germanium.[99]

The bismuth spiral does not seem to be popular, probably due to its temperature sensitivity and to the relatively small values of the magnetic field to be measured: for the same last reason the very accurate nuclear resonance method, so adequate for high field measurements, does not seem to have yet been applied in beta-ray spectroscopy.

V. SOME BETA-RAY SPECTROSCOPES AND THEIR PERFORMANCE

In this section, we have collected the more relevant data on some of the beta-ray spectroscopes of which a description has been available. This collection does not claim to be complete nor to include all of the most important instruments. Some of the recorded values have been calculated by us on the basis of other data contained in the original paper or have been deduced from drawings. Since any spectrometer can usually work under different conditions (as to aperture, source dimensions, etc.) only one or a few of the possible sets of data have been recorded.

The meaning of the symbols in Tables II and III is the following:

Type: Sh.l. = short lens; L.l. = long lens; Sol. = solenoid; Spg. = 1st-order focusing spectrograph; Spm. = 1st-order single-focusing spectrometer; 3 s.f. = 3rd-order single-focusing spectrometer; D.f. = double-focusing spectrometer. The letter *r* indicates a ring exit slit.

Iron: y = yes; n = no;

$E_{\max}$ = maximum energy of electrons that can be focused (in Mev);

l = distance, along the axis of a helical type, between source and counter (in cm);

a = radius of curvature of the median trajectory, for flat types (in cm);

α = average emission angle;

ϵ = half-range of emission angles (half-aperture);

$\eta = \Delta p/p$ = spread in the momentum scale (at half-maximum of the line profile);

$\omega = \Omega/4\pi$ = gathering power;

$L = \sigma\omega$ = source area × gathering power = luminosity;

$T_{\max}$ = peak transmission (or over-all gathering power);

$L^* = \sigma T_{\max}$ = over-all luminosity.

In Tables II and III we have entered two dimensionless quantities Φ and Ψ, that can be considered as *figures* of *merit* of a spectrometer and are defined as follows:

$\Phi=\eta^{-5/2}L/a^2$, $\Psi=\eta^{-1}\omega$, for all flat types except third-order focusing types;

$\Phi=\eta^{-9/4}L/a^2$, $\Psi=\eta^{-3/4}\omega$, for third-order focusing types (Section II C);

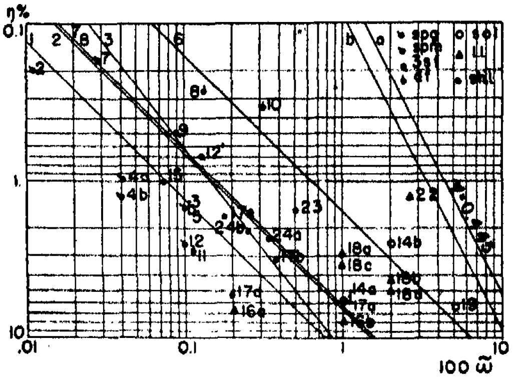

FIG. 30. Spread (η) *versus* gathering power (ω). Straight lines represent the behavior of the various types under optimum conditions: curve numbers refer to flat types of corresponding numbers of Table I; curve letters refer to (a) the solenoid helical type with point source and to (b) the solenoid helical type with a disk source. Point numbers refer to the existing models tabulated in Tables II and III. Note that the positive direction of the η-axis is downward. See the text for more details.

$\Phi=\eta^{-5/2}L/l^2$, $\Psi=\eta^{-1/2}\omega$, for all helical types with ring exit slit.

In a few cases in which the over-all luminosity L^* and the over-all gathering power $T_{\max}$ were known, instead of L and ω, we have replaced Φ and Ψ by Φ^* and Ψ^* defined in the same way except for the substitution of L^* and $T_{\max}$ in the place of L and ω.

The choice of these definitions has been suggested by the following considerations. If the specific activity of the source is the limiting factor, and if the source and exit slit dimensions are chosen according to the optimum conditions, it has been proved in Section II B 6, II C 5, II D 5, III B that the quantities Φ and Φ^* are independent of the aperture. If, instead, the total activity is the limiting factor and the source can be made of negligible dimensions, the quantities Ψ and Ψ^* are independent of the aperture. In addition, all four of these quantities are independent of the geometric scale of the instrument.

The maximum theoretical values for Φ and Ψ for flat types have been given in Table I (Section II E); those for an ideal solenoid spectrometer of optimum emission angle are given by formulas (23) and (22): $\Phi=2.32^{-5/2}=0.12$, $\Phi^*=2.86^{-5/2}=0.072$; $\Psi=5.07^{-1/2}=0.445$ (point source). For a point source solenoid spectrometer with arbitrary α the value of Ψ is given by formula (21) or Fig. 20, where $f(\alpha)=\Psi^2$.

In the case of helical spectrometers with non-uniform fields we have adopted the same form of Φ and Ψ as for

the solenoid type, although their independence of aperture has not been proved in this case. When a circular exit window is used instead of a ring slit, this independence is certainly not true: we have nevertheless also calculated Φ and Ψ for such instruments.

Some of the data of Tables II and III are graphically represented, in doubly logarithmic diagrams, in Figs. 30–32: in all of these we have plotted as ordinates the quantity $-\log\eta$ (that is the logarithm of the resolving power). In Fig. 30, we have taken as abscissas $\log\omega$: so, this diagram may serve to compare the performance of various instruments (or various modifications of the same) as far as the attainable intensity is limited by the total activity of the source. In Fig. 31 which refers to flat spectrometers, the abscissae are $\log L/a^2$, and in Fig. 32, which refers to helical types, $\log L/l^2$: both these diagrams serve for comparisons in which the specific activity of the source is the limiting factor. When the value of L^* replaces that of L, we have enclosed the number of the apparatus in brackets.

As it is seen from the definitions of Φ and Ψ, the lines $\Psi=$const. in the first diagram, and $\Phi=$const. in the other two, are straight lines of different slope, depending on the type: we have traced a few of them, corresponding to optimum conditions. By changing the aperture of an instrument (with the corresponding alterations in the source and exit slit dimensions) its representative point could be displaced (within certain limits) along a straight line having the slope that corresponds to its type.

An Orbit-Bender to Assist Injection into Betatrons

LEVERETT DAVIS, JR.
California Institute of Technology, Pasadena, California

(Received July 18, 1950)

It is suggested that the fraction of the beam in a betatron or synchrotron that is lost by striking the injector might be decreased by a suitable transient bending of the steady-state orbit during injection.

THE motion of an electron in a betatron or synchrotron is usually described as being a harmonic oscillation about a circular (or race-track shaped) orbit called the instantaneous circle.[1] A more accurate description, that allows for deviations from the ideal magnetic field, replaces the instantaneous circle by the steady-state orbit, that closed orbit for which the path taken on the second revolution is identical with that taken on the first. No static bending of the steady-state orbit will assist injection, since the electrons oscillate about it with an amplitude at least as great as the distance of the injector from the steady-state orbit. Thus the amplitude is always great enough so that after a few revolutions the electrons strike the injector and are removed from the beam unless the oscillations are rapidly damped or unless the steady-state orbit is shifted away from the injector. Hence it is necessary to make some significant change in the situation during injection. Among the changes that have been used or considered are an increase of the main field[1] (which both shifts the steady-state orbit and damps oscillations), the use of an orbit contractor,[2] the exploitation of mutual interactions as electrons are added to or removed from the beam[2,3] (which has the same effect as an orbit contractor), and the use of transient inhomogeneities in the magnetic field[4,5] (thus damping oscillations having a favorable phase without shifting the phase so far that oscillations are amplified). The purpose of this note is to suggest that a transient bending during injection of the steady-state orbit in the neighborhood of the injector by magnetic or electric fields might be an efficient and convenient means whereby one could increase the fraction of the electrons that do not strike the injector of a betatron or synchrotron.

Two ways in which this could be done are suggested by Fig. 1, which is drawn for an injector placed in the straight section of a race-track machine, although the procedure could be adapted to any machine. S represents the normal position of the steady-state orbit and I the position of the injector when the orbit-bender is not used. S' represents the position of the steady-state orbit when it is given the maximum bending by means of the magnetic fields caused by currents in the coils M M M or by means of electric fields caused by the condensers E E E. During the injection process the excitation of the orbit-bender is varied from its maximum value to zero so that for the first electrons injected the steady-state orbit is at S', while for the last it is at S. Thus the steady-state orbit is continuously receding from the injector, which could perhaps be placed at I'. The amplitude of the oscillations about the steady-state orbit is not appreciably increased by its motion; hence the recession will make it less likely that an electron will strike the injector. The shifting shown could be either radial or axial, or both.

The production of a maximum deflection Δ in an orbit-bender whose total length is L requires the use of subsidiary fields at least strong enough to produce, acting alone, the radius of curvature

$$R=(L^2/16\Delta)[1+(2\Delta/L)^2] \tag{1}$$

in the beam at injection. It is easy to estimate the fields required. If one uses magnetic fields produced by the current loops M M M (or by a more complicated system that confines the lines of force and produces better focusing properties), the average field must be

$$B=B_I R_S/R, \tag{2}$$

where B_I is the magnetic field needed at injection to produce the radius of curvature R_S in the steady-state orbit. On the other hand, electrostatic fields caused by condensers E E E placed inside the doughnut could be used to bend the steady-state orbit. The potentials required would be of the order of

$$V_E=\frac{V_I t}{R}\frac{(V_I+2V_R)}{(V_I+V_R)}, \tag{3}$$

where V_I is the injection voltage, t is the distance

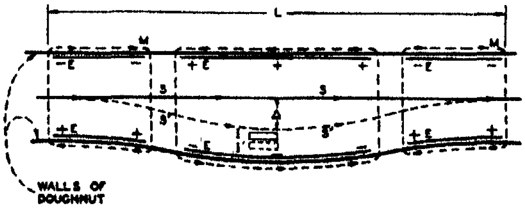

FIG. 1. Schematic representation of an orbit-bender.

between the plates of the condenser, and eV_R/c^2 is the rest mass. It probably would be necessary to control the shape of the electric field by longitudinal conductors at intermediate potentials along the top and bottom of the doughnut inside the condensers. In this way the electric fields could be given both radial and axial focusing if desired. Deflection by means of electric fields has the disadvantage that high potentials will be required unless L is long. The use of magnetic fields might lead to difficulties with eddy currents or with getting rapid enough changes in the field.

It does not appear profitable to discuss here details of design such as dimensions, the distance that the steady state-orbit must shift for each revolution, the accuracy of the timing required, and the voltages and currents needed, since to do this a specific machine would have to be considered. It is obviously desirable that the design allow as many revolutions as possible before a collision with the gun would be expected in the absence of any bending of the orbit.

The orbit-bender suggested in Fig. 1 has the advantage that S and S' coincide throughout most of the orbit, thus allowing the use of a doughnut of relatively small cross section except in the bender. If one uses a large enough doughnut so that S' can be shifted from S everywhere, then one can use one set of coils, or condenser, instead of three. With a circular machine and for n in the usual range, it then appears best to place the single orbit-bender 180° around the machine from the injector, since the maximum deflection of the steady-state orbit then seems to occur 180° from the orbit-bender.

It is interesting to speculate on the possibility that transient electrostatic charging of the walls of the doughnut during injection and transient currents in the trimming coils may have produced effects similar to those discussed above in some operating machines.

The author is indebted to Professor R. V. Langmuir and Mr. M. A. Ruderman for helpful discussions and suggestions.

An Improved Electrical Network for Determining the Eigenvalues and Eigenvectors of a Real Symmetric Matrix

ABRAHAM MANY
Department of Physics, The Hebrew University, Jerusalem, Israel

(Received July 31, 1950)

An electrical computor for determining the eigenvalues and eigenvectors of real symmetric matrices up to the tenth order is described. It is an enlarged and an improved form of a computor described in a previous paper. The time required for solution is considerably reduced, and the accuracy is ten times higher. The solution of a matrix of the tenth order takes four hours, as compared to a hundred hours by computational methods. The accuracy of the eigenvalues is about 0.01 percent of the difference between the greatest and smallest eigenvalues, and the accuracy of each eigenvector is better than one percent of its greatest component.

INTRODUCTION

In a previous paper[1] an electrical network for determining the eigenvalues and eigenvectors of real symmetric matrices up to the fifth order was described. We shall henceforth refer to it as paper I. The network consisted of five LC-circuits, each one coupled to each of the others by two equal condensers. The values of the condensers were adjusted according to the elements of the matrix. The network was excited by a variable frequency source. It was shown that the eigenvalues were given by the resonance frequencies of the network, and the components of the eigenvectors by the voltages across the coils.

The instrument as constructed was primarily intended for studying the behavior of the network, and was inadequate for routine work. In this paper an improved instrument is described, capable of solving matrices up to the tenth order. The electrical network of the new instrument is essentially the same as that described in paper I, but the mechanical construction has been improved leading to a considerable reduction in the time required for solution. In addition, new methods of operating procedure have been developed, rendering higher accuracy obtainable.

CONSTRUCTION

In order to realize a matrix in the electrical network, the values of the network condensers should be adjusted according to the elements $a_{\alpha\beta}$ of the given matrix (see Eqs. (5) in paper I). As these adjustments constitute a major part of the time required for solution, the instrument was constructed in view of making this time as short as possible. The capacitors used are of the molded mica type (Cornell Dubilier) having values from 100 mmf to 1000 mmf (in steps of 100 mmf), and from 1000 mmf to 10,000 mmf (in steps of 1000 mmf). All the capacitors were brought to the same geometrical dimensions (23 millimeters square and 8 millimeters thick), by inserting them in suitable formers. Two metal rings were fitted to the ends of each capacitor and soldered to the terminals. In this way the capacitors can easily be plugged into the network.

---

[1] A. Many and S. Meiboom, Rev. Sci. Inst. 18, 831 (1947).

The capacitors forming each network condenser are plugged into a "capacitor holder." Each of the capacitor holders intended for the diagonal elements consists of a pertinax plate fitted with two prongs and carrying two vertical metal T-shaped frames. Each frame contains six spring clamps similar to fuse holders, so that six capacitors can be plugged into the pair of frames. In addition a mica trimmer, whose value may be varied from 100 mmf to 200 mmf, is connected at the top of the two frames. By suitably choosing the capacitors and adjusting the trimmer, any value between 100 mmf and 50,000 mmf can be obtained.

The two sets of capacitors corresponding to an off-diagonal element are plugged into a similar capacitor holder, provided with four prongs, and carrying four vertical metal T-shaped frames. A trimmer is connected on top of each pair of frames. Every frame contains three spring clamps, so that three capacitors can be plugged into a pair of frames, and any value between 100 mmf and 20,000 mmf can be obtained for each condenser. A photograph of such a capacitor holder is shown in Fig. 1.

By introducing these fittings, a great deal of time is saved. The suitable capacitors are quickly plugged into the holders, and the latter plugged into the bridge and adjusted. The adjustment of each network condenser is performed in less than one minute.

The capacitor holders are plugged into a series of jacks mounted on a horizontal pertinax plate, 70 centimeters square and 0.8 cm thick. The jacks are arranged and connected in a similar manner to that shown in paper I (Figs. 2 and 3). But in the present instrument the bridge for adjusting the condensers is incorporated in the plate in order to facilitate the adjustments. Moreover, in the eleventh isolated *LC*-circuit used for measuring the eigenvalues, the condenser C consists of a decade with a trimmer connected in parallel, and so may be varied continuously from 100 mmf to 80,000 mmf. An eigenvalue is given by the value of C at a resonance frequency, and may be measured by switching to the bridge without removing the decade from its position.

Ten toggle switches are fitted along the diagonal of the plate, by means of which each coil can be short-circuited (see next section).

ACCURACY

In this section we shall discuss the methods employed to increase the accuracy of the new instrument. Equations (5) in paper I were obtained by assuming that the coils of the network were identical. This cannot be attained in practice, and the coils used by us differ among themselves by as much as 0.3 percent. However the theory can readily be adapted to this case. Let $L_1, L_2, \cdots, L_{10}$ denote the values of the self-inductances of the ten coils, and let L denote the self-inductance of the eleventh isolated coil. The equations governing the behavior of the network at resonance (Eqs. (4) in paper I) now become:

$$\begin{aligned}\{2C_\alpha+{\textstyle\sum_\beta}'(A_{\alpha\beta}+B_{\alpha\beta})-2/\omega_i^2L_\alpha\}V_\alpha&\\ +{\textstyle\sum_\beta}'(A_{\alpha\beta}-B_{\alpha\beta})V_\beta=0,\quad \alpha=1,2,\cdots,10&\end{aligned}\tag{1}$$

where the term $2/\omega_i^2L_\alpha$ is different for different values of α. Multiplying each equation by $(L_\alpha/L)^{\frac{1}{2}}$, it can readily be seen that the equations obtained become identical with Eqs. (1) in paper I if

$$\begin{aligned}a_{\alpha\alpha}&=(L_\alpha/L)[2C_\alpha+{\textstyle\sum_\beta}'(A_{\alpha\beta}+B_{\alpha\beta})]\\ a_{\alpha\beta}&=(L_\alpha L_\beta/L^2)^{\frac{1}{2}}(A_{\alpha\beta}-B_{\alpha\beta}),\quad(\alpha\neq\beta)\\ \lambda_i&=2/\omega_i^2L,\quad x_k=(L/L_k)^{\frac{1}{2}}V_k.\end{aligned}\tag{2}$$

It is essential to determine L_α/L accurately. It was found that the measured ratios L_α/L vary slightly with frequency, the reason for this being the inequality of the stray capacities of the windings of the different coils. In order to measure these stray capacities, we determined the resonance frequency of each coil when tuned with its own stray capacity only. The resonance frequencies of the coils by themselves were approximately 25,000 cycles. The self-inductance of each coil being about 88 mh, we inferred that the stray capacities in each coil have the approximate value of 450 mmf. We added to each coil a small capacitor so that all the coils resonate at the same frequency (25,000 cycles). Let $C(L_\alpha)$ and $C(L)$ denote the stray capacities of the coils L_α ($\alpha=1, 2, \cdots, 10$) and L, respectively, together with the added capacitors, then:

$$C(L)/C(L_\alpha)=L_\alpha/L.\tag{3}$$

Next we connected in parallel with each coil L_α a capacitor C_α, and in parallel with the eleventh coil L a capacitor C, such that all the eleven *LC*-circuits obtained resonate at the same frequency. It is seen that

$$L_\alpha/L=[C+C(L)]/[C_\alpha+C(L_\alpha)],$$

and using (3) we obtain

$$L_\alpha/L=C/C_\alpha.\tag{4}$$

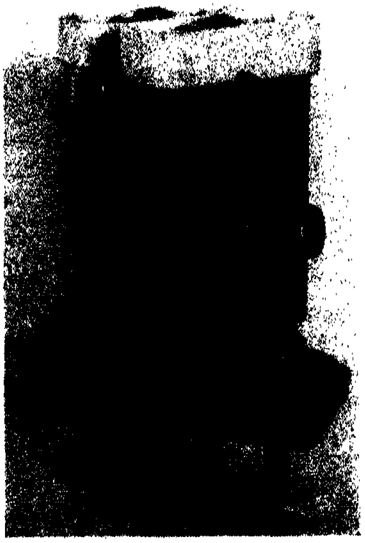

FIG. 1. A photograph of a capacitor holder.

This ratio is now independent of frequency. By measuring C and C_α in the bridge we got the required values of L_α/L correct within one part in 10,000.

It is necessary to correct for the stray capacities of the wirings of the network. Most of these capacities are in parallel with the diagonal condensers and may cause an error of about one part in a thousand in the measured eigenvalues. This can be corrected for by reducing the diagonal condensers by corresponding amounts; to determine which we employ the above mentioned toggle switches. After adjusting all the network condensers to the values given by (2), according to the elements of the given matrix, we short-circuit all the coils except one, say the αth coil. In this way we obtain an LC-circuit consisting of the coil L_α and the condenser $C_\alpha+C(L_\alpha)+C_\alpha'+\frac{1}{2}\sum_\beta' (A_{\alpha\beta}+B_{\alpha\beta})$, where C_α is the diagonal condenser, $C(L_\alpha)$—the stray capacity of the coil's windings, C_α'—the effective capacity across the coil caused by the stray capacities of the wirings of the network, and $\frac{1}{2}\sum_\beta' (A_{\alpha\beta}+B_{\alpha\beta})$—the capacity arising from the coupling condensers corresponding to the matrix elements in the αth row (see Fig. 2 in paper I). The resonance frequency ω_α of this LC-circuit is determined, and keeping the oscillator at this frequency, it is applied to the eleventh isolated LC-circuit; the condenser C is adjusted until resonance is again obtained. We then have

$$1/\omega_\alpha^2 L=C+C(L),$$
$$1/\omega_\alpha^2 L_\alpha=C_\alpha+C(L_\alpha)+C_\alpha'+\tfrac{1}{2}\textstyle\sum_\beta' (A_{\alpha\beta}+B_{\alpha\beta});$$

using (3) and (2) we obtain

$$C_\alpha'=(L/L_\alpha)(C-\tfrac{1}{2}a_{\alpha\alpha}). \tag{5}$$

In practice the correction for the stray capacities of the wirings is performed as follows: we adjust the condenser C on the bridge to the value $\frac{1}{2}a_{\alpha\alpha}$, and then determine the resonance frequency of the eleventh LC-circuit. Keeping the oscillator at this frequency, it is applied to the αth coil, and the diagonal condenser C_α is reduced until resonance is obtained. This procedure is repeated for each row of the network.

Two important factors determine the accuracy of the measured eigenvalues and eigenvectors. The first factor is the losses in the coils. By taking these losses into account, it was shown in paper I that in matrices where the eigenvalues are widely separated, the losses involve an error of order D^2 in the eigenvalues, and an error of order D in the eigenvectors, where $D=1/Q$. A more rigorous treatment showed that these estimates for the errors are not quite accurate. It was found that the maximum fractional error $\Delta\lambda/\lambda_i$ involved in the measurement of an eigenvalue λ_i is the smaller of the two terms $g(\lambda_i/|\lambda_i-\lambda_i'|)D^2$ and D, where g is usually smaller than unity, though its maximum possible value is $n-1$ (n being the order of the matrix), and λ_i' is the nearest eigenvalue to λ_i. The value of D over the range of frequencies used in exciting the network (2000 to 6000 cycles) is lower than 0.005. In ordinary matrices the roots are widely separated, and the error is given by the first term, and usually amounts to less than one part in 10,000. The same error is obtained for a truly multiple eigenvalue. In this case λ_i' denotes the nearest eigenvalue to the multiple eigenvalue λ_i. For matrices whose eigenvalues become closer (but do not coincide) the error increases, but is never larger than D, i.e., 0.5 percent. This error is obtained for eigenvalues lying so close together that the difference between the corresponding resonance frequencies is of the same order of magnitude as the resonance width. It is thus seen that if $\Delta\lambda/\lambda_i$ is plotted as a function of $|\lambda_i-\lambda_i'|$, the curve will show a maximum, whose value is 0.5 percent, for $|\lambda_i-\lambda_i'|=\lambda_i D$, and will decrease on both sides of this point to a value of about 0.01 percent.

The error involved in the measurement of a component of an eigenvector belonging to λ_i, in the case of ordinary matrices, was found to be $g(\lambda_i/|\lambda_i-\lambda_i'|)D$, which usually amounts to less than one percent. In the case of quasidegenerate eigenvalues, the eigenvectors belonging to such roots are very labile and large errors are involved in their measurement.

The second factor affecting the accuracy of the results is the accuracy with which the given matrix is realized in the network. This realization consists of the adjustment of the condensers according to (2), and the correction for the stray capacities. The ratios L_α/L are correct within an accuracy of 0.01 percent, and the adjustment of the condensers on the bridge is made with the same accuracy. Hence, after the correction for the stray capacities, the values of the condensers are correct within an accuracy of about one part in 10,000.

From the above discussion we can expect that in ordinary matrices, the accuracy of the eigenvalues will be mainly determined by the accuracy of adjustment of the condensers, while in matrices having close eigenvalues the errors caused by the losses in the coils will predominate. In the first case we obtained for the eigenvalues an accuracy of about 0.01 percent of the difference between the greatest and smallest eigenvalues. As for the eigenvectors, we obtained for their components an accuracy of better than one percent of the greatest components.

CONCLUSION

At present the instrument described is extensively employed in our department for the solution of matrices arising from spectroscopic problems. The solution of a matrix of the tenth order takes about four hours as compared to a hundred hours by computational methods.

This paper and paper I are a summary of a dissertation submitted to the Senate of the Hebrew University in Jerusalem in fulfilment of the requirements for the degree of Doctor of Philosophy.

The author wishes to acknowledge his indebtedness to Professor G. Racah for his continued assistance during this work, and to Dr. E. Alexander for his interest and encouragement.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 12 DECEMBER, 1950

Distributed Coincidence Circuit

CLYDE WIEGAND
Radiation Laboratory, University of California, Berkeley, California

(Received July 31, 1950)

A coincidence circuit using the traveling wave principle as applied to distributed amplification is described. The resolving time is about 10^{-8} sec. when the device is used in connection with scintillation detectors.

AN electronic coincidence circuit employing the traveling wave concept as applied to distributed amplification[1] has been developed and used in the Radiation Laboratory. When the circuit is used in connection with scintillation crystal detectors, photo-multiplier tubes, and distributed amplifiers, the resolving time is about 10^{-8} sec. The response to single pulses in either channel is satisfactorily small and is independent of the height of the single pulses.

The circuit employs conventional miniature pentagrid converter tubes (type 6BA7) and makes use of the fact that their plate current can be practically cut off by biasing either of the two control grids a few volts negative with respect to their cathodes. Consequently, a positive pulse on either grid alone will not allow plate current to flow, whereas if positive pulses are applied simultaneously to both control grids, plate current will flow during the time both grids are sufficiently less negative with respect to the cathode.

The principle of distributed amplification is applied by using a series of tubes and connecting separate artificial transmission lines to each set of control grids. The schematic circuit is shown in Fig. 1. The grid-to-other tube-elements (ground) capacitances serve as the shunt capacitances of the transmission line sections. The plates are connected to a third transmission line in the usual manner of distributed amplifiers.

Type 6BA7 tubes were chosen because the two control grids and the plate are quite well shielded from each other and thus interaction among the grid and plate lines is minimized. The type 6BA7 was preferred to type 6BE6 because of the higher current and transconductance ratings and only slightly increased capacitances.

A coincidence circuit for particle counting should ordinarily have the two input channels equal to each other. The circuit is thus required to be symmetrical so that its behavior is unchanged upon interchanging the two input leads 1 and 2. However, the input capacitances of the two control grids are not equal and their effectiveness in controlling the plate current is different. Therefore, the staggered connection is used as indicated in the schematic diagram where one input grid line is shown connected alternately to grids No. 1 and No. 3 and the capacitances are made equal by adding external condensers to the No. 1 grids.

Two other requirements should be met to assure effective traveling wave amplification. These are that the velocity of the waves be equal on the grid and plate lines and that there should be no discontinuities in the value of the impedance upon which the waves are incident. Neglecting losses the velocity of propagation of the waves will be equal when

$$L_{g1}C_{g1}=L_{g2}C_{g2}=L_pC_p,$$

where L_g refers to the series inductance and C_g the shunt capacitance of the grid line sections and likewise L_p and C_p refer to the plate line.

The corresponding impedances are

$$Z_{g1}=\left(\frac{L_{g1}}{C_{g1}}\right)^{\frac{1}{2}},\quad Z_{g2}=\left(\frac{L_{g2}}{C_{g2}}\right)^{\frac{1}{2}},\quad Z_p=\left(\frac{L_p}{C_p}\right)^{\frac{1}{2}}.$$

In order for the circuit to be symmetrical we must have $Z_{g1}=Z_{g2}$. It is not necessary that $Z_{g1}=Z_p$, since the plate line will generally work into an arbitrary impedance such as a pulse-height discriminator stage.

The coincidence circuit has thus far been used in connection with distributed amplifiers having output impedance values of 200 to 400 ohms. The grid lines should be designed to match the output impedance of the amplifiers. The coincidence circuit can then be coupled directly to the amplifiers. Present designs incorporate the amplifiers and coincidence circuit on a common chassis.

A typical design makes use of m-derived[2] filter networks as suggested in reference 1. The coils are wound on $\frac{1}{4}$-in. diameter pregrooved polystyrene rods with bare copper wire of about 0.015-in. diameter. The coil con-

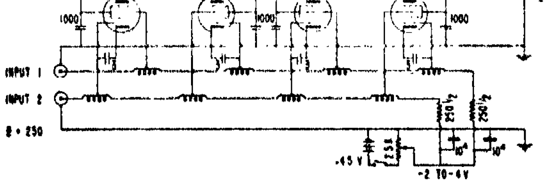

FIG. 1. Schematic diagram of the coincidence circuit. Capacitances are ceramic type with values indicated in micro-micro-farads. Resistance values are in ohms.

TABLE I. Sample coil data.

	C μμfd	L_1μH	L_2μH	n	turns/inch	m	Z_0 ohms
Grid line	10.5	0.25	0.63	12	40	1.27	250
Plate line	9.3	0.31	0.76	14	40	1.24	290

stants were calculated by the formula for the inductance of a single layer solenoid (Handbook of Chemistry and Physics). The values of the shunt capacitances are those of the tube manufacturer plus an allowance of 1 μμfd for socket capacitance. Effort was made to maintain inductances to ±10 percent of the calculated values.

A sample of the coil data is presented in Table I. L_1 refers to the inductance of half of the coil, L_2 to the whole coil. n is the total number of turns and m is the parameter of the m-derived filter. $Z_0=(L_2/C)^{\frac{1}{2}}$ is the nominal iterative impedance.

The lines should be terminated by a resistance equal to their iterative impedance. Ordinary carbon resistors are satisfactory, although some improvement might be realized by using half-sections at the terminations. Satisfactory operation has resulted for grid biases of −2 to −4 volts when using a minimum pulse input level to the coincidence circuit of about 10 volts. The non-linearity of the coincidence circuit provides sufficient discrimination against small pulses.

For further discussion of the design and adjustment of distributed amplifiers the reader is referred to a paper by G. G. Kelley[3] on the construction of a high speed synchroscope.

This work was performed under the auspices of the AEC.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 12 DECEMBER, 1950

A Continuously Sensitive Cloud Chamber

T. S. NEEDELS* AND C. E. NIELSEN
Mendenhall Laboratory of Physics, Ohio State University, Columbus, Ohio

(Received July 20, 1950)

A particularly simple cloud chamber is described that is continuously sensitive to ion tracks. The chamber operates on the principle of vapor diffusion from a hot to a cold surface. The sensitive region is a shallow horizontal layer near the cold surface. The chamber has been placed in a magnetic field and curved tracks of β-particles from a radioactive source have been photographed. Pictures of such electron tracks are shown.

EXPANSION chambers as invented by C. T. R. Wilson have always suffered from the essential intermittency of their expansion-recompression mechanism. One would like a chamber that maintains a continuously supersaturated region in which tracks form and fall out to be replaced by tracks from the next event with no insensitive period or dead time ever intervening. A notable attempt in this direction was made by Langsdorf[1] but his rather complex apparatus has never come into use. We have been studying this problem and recently we have set up a particularly simple device. We have used the principle of vapor diffusion from a hot to a cold surface employed by Langsdorf. This diffusion mechanism produces a shallow region between these two surfaces that remains continuously supersaturated.

The chamber we have set up consists of a glass beaker that sits on a cake of dry ice (cold surface) and is covered with a cardboard wet with alcohol that stays at room temperature (hot surface). The wet cardboard provides the vapor, which can be either ethanol or propanol, or mixtures of either of these with water. Ion tracks of excellent quality are observed in a shallow layer near the cold bottom of the beaker. Sharp tracks of both electrons and protons are seen in air.

Our experience with this simple beaker chamber has been that best operation is obtained when a clearing field is placed across the sensitive region. Both horizontal and vertical fields have been tried and a vertical field works best. Here, of course, the clearing field cannot sweep old ions away as in a Wilson chamber but, instead, it forces additional tracks from above and below into the permanently sensitive region. This adds more ionizing events to those occurring originally in this thin layer. The additional ion load helps keep the supersaturation from increasing to the fog limit and makes chamber operation much more satisfactory. We have used fields of about 50 to 100 volts/cm with equal results.

For better seeing from above (through a 4-in. diameter hole cut in the cardboard and covered with a glass plate) we have put a piece of black velvet cloth in the bottom of the beaker; and to keep any white frost from forming on top of the velvet we have added alcohol sufficient to cover the velvet. This arrangement provides a very satisfactory black background that stays black at dry ice temperatures. Incidentally, the thickness of the cold alcohol layer can be varied so as to vary the temperature attainable at its upper surface. This in turn determines the maximum supersaturation attained in the sensitive region, giving some control of the optimum track load. Reducing the maximum supersaturation, however, also makes the sensitive layer thinner; and this may or may not be an advantage in a particular experiment.

* Now at Los Alamos, New Mexico.

[1] A. Langsdorf, Rev. Sci. Inst. 10, 91 (1939).

After one first puts the beaker on the dry ice cake, a thin fog forms near the cold bottom and the fog particles grow and gradually fall out *in a very few minutes.* This fog is due to the dust, present in ordinary air, that must be removed before one can see ion tracks. Tracks begin to show usually about five to ten minutes after the beaker is first put on the dry ice. Those who have operated Wilson cloud chambers, and have struggled with making the air dust-free by tedious repeated slow expansions, will recognize here another remarkable property (besides the simplicity) of this type of chamber. Tracks continue to be visible after this short dust-clearing period as long as one keeps the cardboard wet and the dry ice supply adequate. We find that if the dry ice block covers less than about two-thirds of the beaker bottom, operation begins to deteriorate and the tracks become fragmentary and diffuse.

We have put this chamber with its horizontal ion tracks into a vertical magnetic field (air core coils, $H\simeq 1000$ oersted) and observed the characteristic circular paths of electrons and positrons of energies up to a few Mev. (See Fig. 1.) With a γ-ray source we have enjoyed watching the development in the chamber gas of ion clusters and longer range recoil electrons from the Compton process, and some events that look like electron-positron pairs. With a 5 mc Po-Be neutron source outside the beaker at the level of the sensitive region we have observed many sharp bright straight tracks of proton recoils and an occasional nuclear reaction occurring in the chamber gas. A proton recoil frequently shows its characteristic sharp small angle bend near the end of its range. The nuclear reactions are distinguished from the protons by the appearance of a short bright track that has a large angle bend near one end. In this case the apex of the bend always faces the neutron source.

We have found this beaker chamber to be useful for looking at samples of very weak radioactive isotopes made in the cyclotron. The weak sample spread thin behind a zapon film is merely lowered on a string through the hole in the top cardboard all the way to the level of the sensitive region. Any electrons, positrons or γ-rays from the sample make themselves immediately evident. We have put also a bit of uranium oxide into a tiny zapon bag, lowered it on a string into the sensitive layer, and watched the α-particles shoot out from the bag.

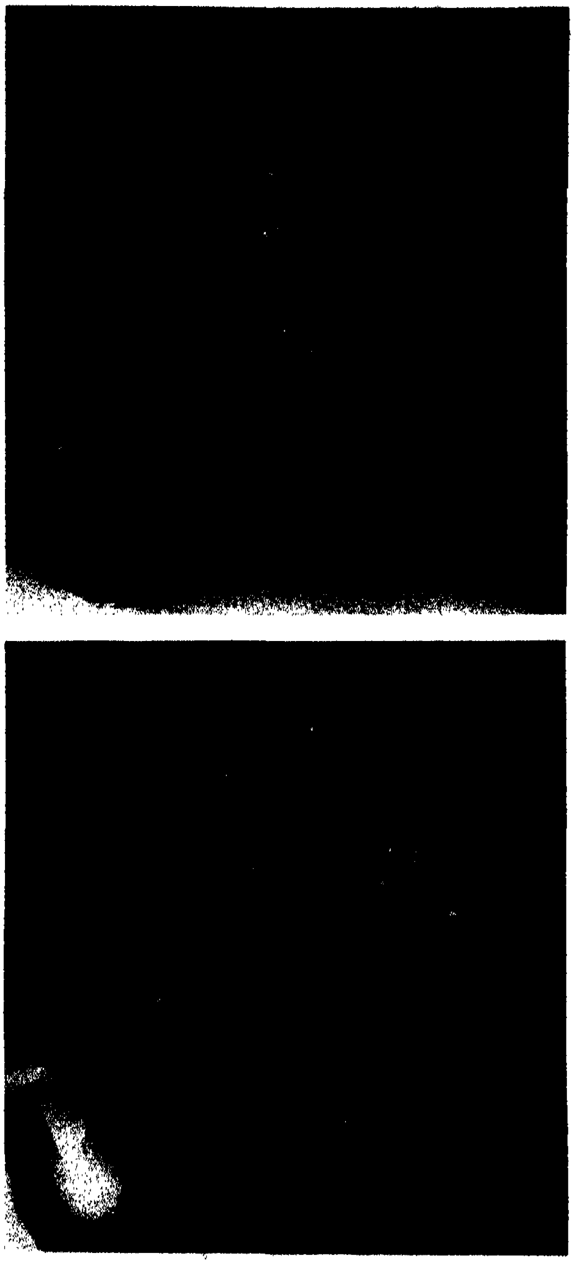

FIG. 1. Two photographs of β-particles from $Sr^{90}+Y^{90}$. The active material is evaporated on zapon film and placed at the level of the sensitive region. The active source is the diffuse object at the left in each photograph. In addition to the β-particles, there are present stray diffuse tracks of electrons from cosmic ray background. In most of the pictures we have obtained, these stray electrons can be distinguished easily from the β-electrons.

The different radiations produced by a β^+-emitter that emits also x-rays from K-capture may readily be distinguished because the positrons describe circular arcs in the magnetic field which originate at the *surface* of the sample whereas any γ's or x-rays form Compton recoils at random distances from the sample. It is interesting to note that the sensitive region is sensitive to ions very close to the sample surface. As far as we can tell, the visible tracks of β-particles start at most about 1 mm from the sample. Moreover, the observation of what is coming from a radioactive sample is continuous because we have found that it disturbs nothing to leave an incandescent light source focused on the sensitive region all the time. Thus the detection by the continuous cloud chamber of just what radiations are being emitted from radioactive substances becomes especially simple and satisfying.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 12 DECEMBER, 1950

A Semi-Automatic Device for Analyzing Events in Nuclear Emulsions

MARIETTA BLAU,* ROBERT RUDIN, AND SEYMOUR LINDENBAUM
Columbia University, New York City

(Received June 16, 1950)

An apparatus is described the basic element of which is a microscope with a motor-driven stage. The operator controls the direction and speed of motion by a steering wheel and an accelerator pedal and drives the track to be analyzed through a target. Range, grain density, and geometrical orientation of tracks, etc., are automatically recorded on charts. Methods of measurements and results are discussed.

I. INTRODUCTION

NUCLEAR emulsion techniques have become quite important in modern physics. A wide range of commercially available emulsions together with suitable development procedures make possible the registration of all charged particles crossing the emulsion, and under favorable conditions also their identification. One obtains all the useful information about the tracks making up an event by determining the geometrical history of the tracks and the grain density along the tracks. Although for many purposes it is necessary only to identify certain types of particles, which an experienced worker can do by mere observation, it is necessary in other problems to measure accurately grain density, range, scattering, and also the exact geometrical orientation of tracks, especially those connected with an event. The various methods of performing these measurements are very well known to workers in this field, and it is, furthermore, well known that these methods are intrinsically lengthy, exacting, to a certain degree subjective, and also require experienced observers. Therefore, we felt that there is a need for an apparatus which simplifies the various measuring procedures necessary in nuclear emulsion experiments. We achieved this by incorporating in the apparatus mechanical, photoelectric, and recording devices which minimize manual operations and personal error while at the same time increase the speed and ease of measuring.

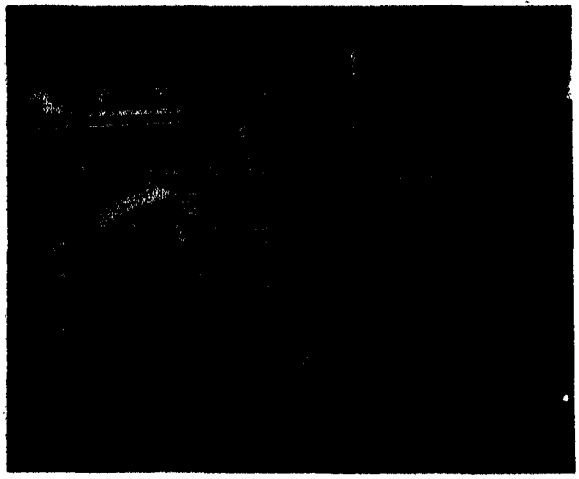

FIG. 1. A general view of the apparatus.

II. DESCRIPTION OF THE APPARATUS

The whole instrument (see Fig. 1) is built around a microscope with a motor-driven stage, moved by selsyn motors in two dimensions (x and y). The accuracy of the gears, feedscrews, etc., is such that dimensions can be measured to within 0.2 of a micron. These selsyn motors are fed from identical selsyn generators which are driven by a steering unit so that the photographic plate under observation can be moved in any direction and with any desired speed, up to approximately 25 microns per second. For convenience the arrangement is such that the direction of movement is controlled by a steering wheel (like the steering wheel of an automobile) and the speed is adjusted by a foot pedal. The schematic diagram (Fig. 2) shows how this steering arrangement works: a d.c. motor M with permanent field magnet is fed from a rectifier connected to the secondary winding of a variac transformer. This transformer is controlled by the foot pedal against the torque of a spring so that it delivers zero voltage when the pedal is released and increases voltage when the pedal is depressed. The motor M drives two turntables T (the figure shows only one of two identical units). A friction wheel F is connected to the shaft of a selsyn generator S, and can be displaced along the diameter of the turntable T by a crank C. It is clear that the direction and speed of the rotation of the generator depends on the relative position of T and F, and disregarding for the moment second-order differences, the speed of the generator is proportional to the sine of the angle α, the displacement of the crank. The generator S_1 drives a selsyn motor S_2 which moves by gears G_x the feedscrew for the x-movement of the mechanical stage, and a counter which gives number of revolutions to the nearest tenth. Therefore, the magnitude of the movement of the stage is proportional to the product of the speed (V_M) of the motor M and the sine of the angle α. The ratio of the gear and worm drive to the feedscrew was chosen so that one revolution of the selsyns corresponds to a stage movement in any direction of 1 micron.

FIG. 2. A schematic drawing of the driving unit.

A second identical set of turntables, friction wheel, selsyns, feedscrew, etc., is driven by a second crank, but with a displacement of 90° between the two cranks; the two cranks are driven by the steering wheel. Obviously the movement of the stage in the y direction is proportional to the cosine of α and we can write: $V_x = V_m \sin\alpha$, $V_y = V_m \cos\alpha$. The resulting speed of the stage and therefore of the photographic plate or the event under observation is $V_e = (Vx^2 + Vy^2)^{\frac{1}{2}} = V_m(\sin^2\alpha + \cos^2\alpha)^{\frac{1}{2}} = V_m$. That means that the speed with which an event in the emulsion, for instance a trajectory of a particle passes through the eyepiece, is independent of the angular displacement of the crank and the position of the steering wheel determines the direction of travel.

Because of the finite length of the connecting rods between crank and selsyn generator, the movement is not a pure sine movement in this schematic setup. In the model constructed (Fig. 3) the simple crank drive is replaced by a planetary gear arrangement, consisting of a stationary inside gear and a planetary gear of one-half of the diameter; when the inner gear rotates and rolls along the inside of the stationary gear, a certain point of the pitch-circle moves in a straight line with a pure sine movement. The photograph (Fig. 3) shows the working model of the steering unit using the planetary gear drive.

The recording chart is moved by a selsyn motor connected to a selsyn generator which rotates with the speed V_m of the turntables. The movement of the chart is thus proportional to the stage movement, and the gearing is such that the chart speed is 2000 times that of the stage; therefore 2 mm on the chart correspond to 1 micron in the photographic plate.

The image of the plate is observed by the operator through an eyepiece and at the same time projected upon a small slit before a photo-multiplier tube. The position of the slit coincides with an optical target in the eyepiece and one merely needs a short training period to learn to steer the track under investigation through the center of the target (consisting of two concentric circles) (Figs. 4, 5), while the photo output is recorded on the moving chart (Fig. 6). The chart records also the angular position of the steering wheel and the vertical movement of the objective (Fig. 6). The operator of the apparatus has to follow the track in three dimensions and therefore must also keep the image in focus. Since the chart is driven with a speed proportional to the track displacement in the x-y plane and the z-movement is recorded by a displacement of a steady line across the moving sheet, the length of this line, when measured for instance by a map reader, determines the three-dimensional length of the track.

For some investigations, especially measuring of straight line lengths, angles, scattering, etc., another set of selsyn generators is used driven by individual motors governed by the accelerator pedal, whereby the movement goes only in the x or y direction, and the direction is chosen by a four position switch. The movements of the three selsyn motors connected with the stage (x, y, and z components) are measured by counters connected to these motors. One revolution of the counters corresponds to a movement of 1 micron and as the first number wheel contains 10 figures, a reading can be made to 1/10 of a micron of plate displacement.

To make it unnecessary for the operator to shift his eyes from the microscope to the counter and write down readings, another set of three selsyns with counters is connected in parallel to the stage motors and these auxiliary counters arranged side by side. A simple photographic arrangement pictures the counter readings on a sheet of pack film through a slot. A button control moves the film for the width of the slot, so that fifteen exposures can be made on a sheet of film. After development the coordinates of these fifteen points can

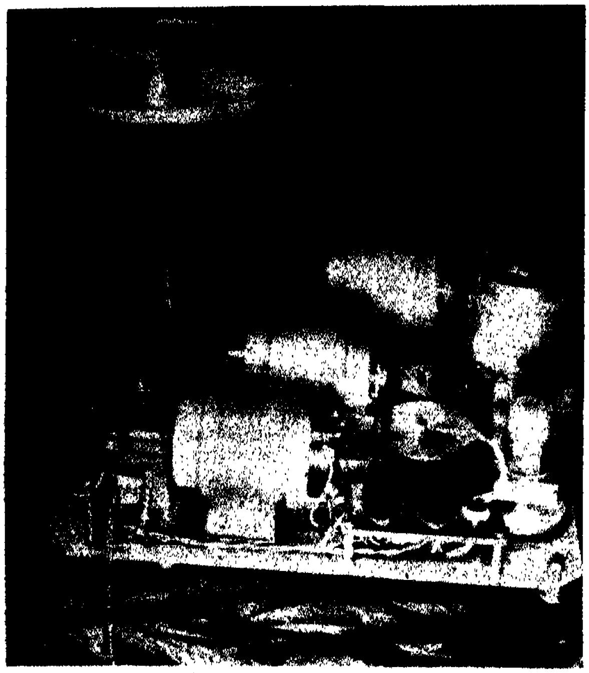

FIG. 3. Photograph of the driving unit.

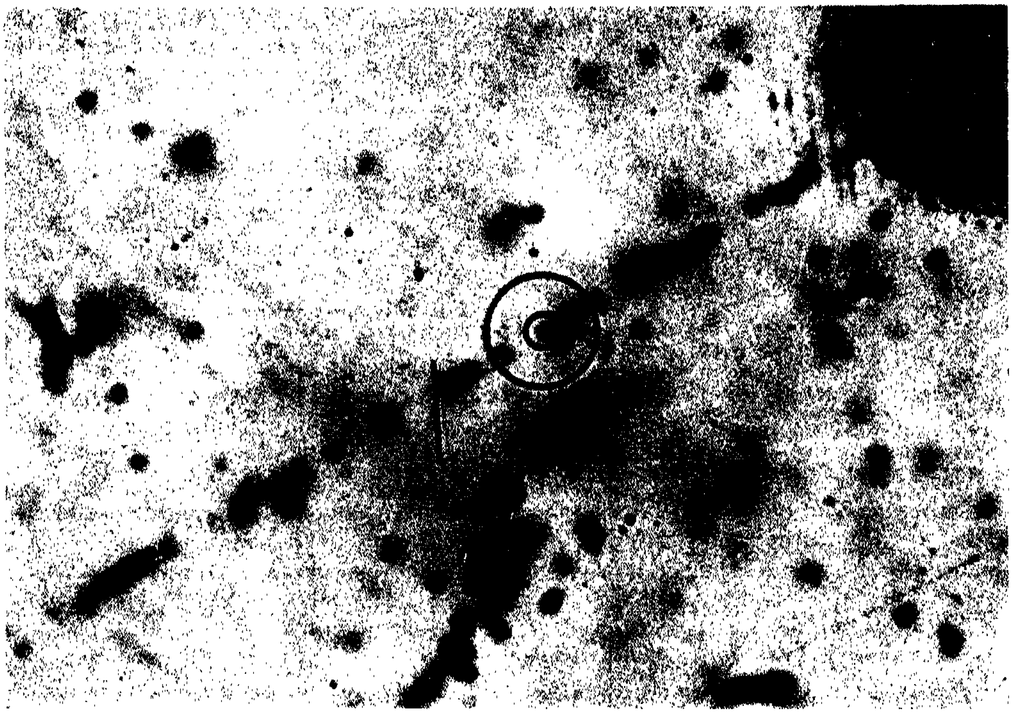

FIG. 4. A microphotograph of a track going through the bull's eye target.

be read easily. This counter photographing device is useful for taking the coordinates of various points of a track and calculating curvature and scattering.

For counting grains, the slit before the photo-multiplier is positioned across the track. This is accomplished by mounting two small pins connected with the observation eyepiece, which can be rotated to be approximately parallel to the track and by an arrangement of bevel gears which simultaneously rotate the slit to its proper position.

The smallest slit used up to now is 1 mm long and 0.03 mm wide, covering an area of the plate of approximately 0.7×0.02 microns (for the 2-mm immersion objective). This slit yields good resolution and with it the recording chart shows a distinct fine structure even for overlapping grains. The use of still smaller slits could not improve the resolution because of optical limitations.

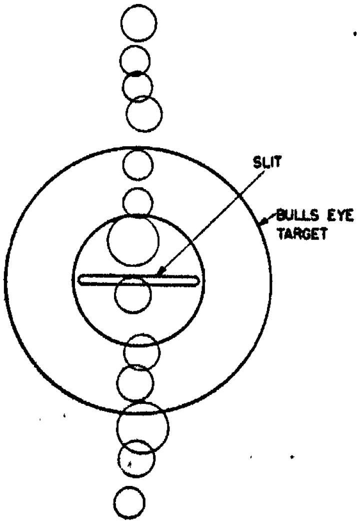

FIG. 5. A schematic drawing depicting the operation of the grain counting slit.

In cases where the accumulation of grains in the track is too heavy to be analyzed by counting individual grains (heavy tracks, dense shower cores), the apparatus can be used for direct photometric comparison of the track against the surrounding background.

This instrument as it stands now is only an experimental model. Improvements to increase ease of operation, extend the automatization, reduce over-all size, etc., have already been planned to be incorporated in another model.

III. RANGE AND GRAIN DENSITY OF TRACKS

Measurements of range and grain density of tracks are performed in the following way. First, a magnification is chosen, sufficient to give satisfactory resolution. Then a rectangular slit is placed in the image plane before the photo-cell. The width of the slit is a small fraction of the grain diameter in the image plane; the length corresponds to about several grain diameters. The slit can be rotated and is positioned so that its length is perpendicular to and bisected by the track. In the eyepiece we have a centered bull's eye target; the inner circle corresponds to the length of the slit. Therefore the track is projected through the slit on to the photo-cell as long as it is positioned within the inner circle of the target (Fig. 5).

With the mechanism previously described the track is driven through the bull's eye and simultaneously the photo-cell output is traced on the moving chart by a Brush pen motor which moves proportionally to the amplified photo-cell output in a direction perpendicular to the chart motion. Since, as previously explained, the chart movement is proportional to the stage displacement, which in this case is equal to the length driven along the track, we obtain the photo-cell output as a function of this length or range interval. Since, as previously mentioned, the width of the slit is only a fraction of the grain diameter, we can expect to get a clear distinction in the photo-cell output for every grain passing through the slit. Figure 7 gives 4 charts of the same proton track, driven by different operators including one driven in the opposite direction. Figure 8 gives 3 charts of the same meson track. These comparisons show how reproducible the results are. The narrow peaks in these charts correspond to individual grains which can be resolved under high magnification. The wider peaks correspond to groups of grains which are not individually resolvable. An estimate of the number of grains in such groups must be made, using both the fine structure and the width of these peaks as

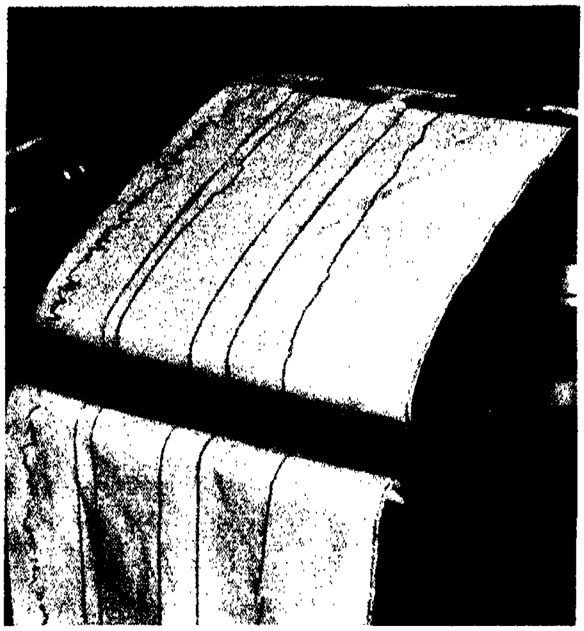

Fig. 6. A photograph of the recording chart, the length of which is 2000 times the projection of track length in the $x-y$ plane. The upper curve is the photo-multiplier output. The middle curve is the variation of driving angle (a). The bottom curve is the variation of focusing movement.

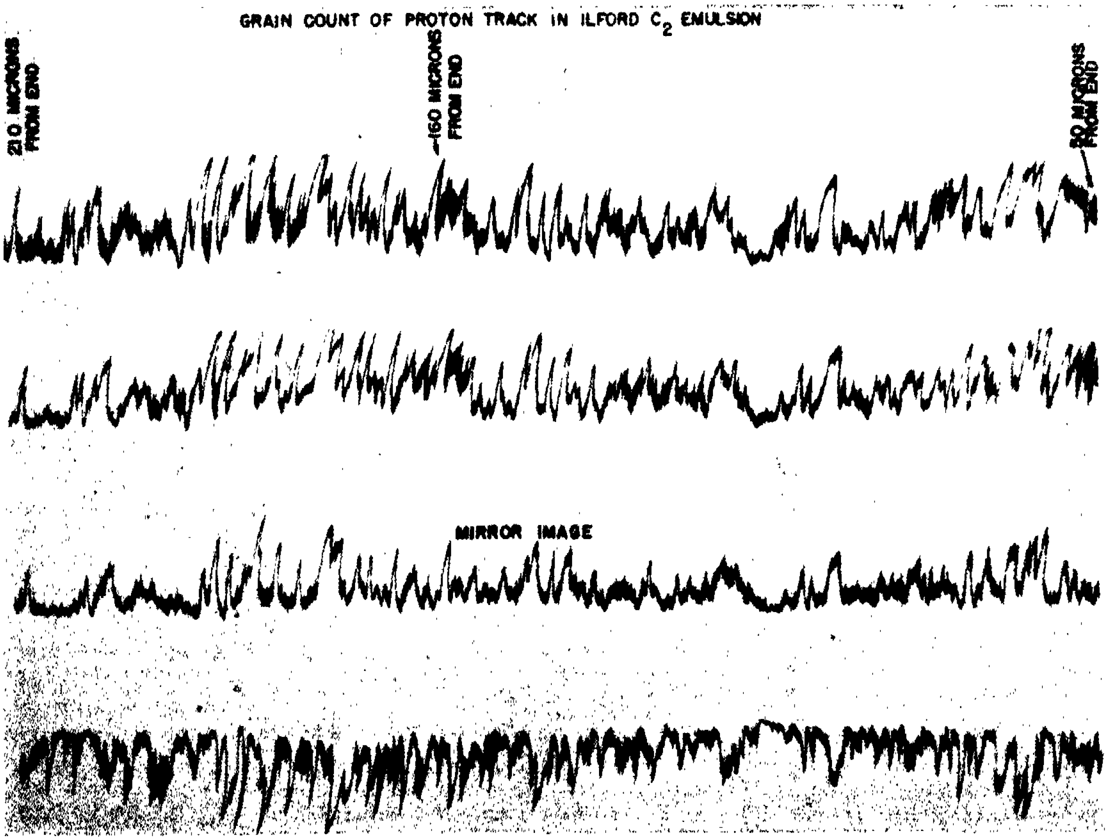

Fig. 7. Grain density record of proton track.

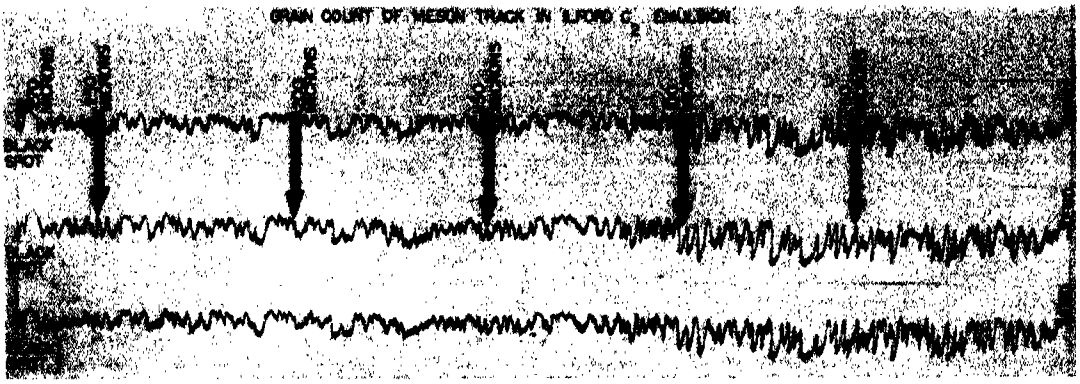

FIG. 8. Grain density record of meson track.

criteria. Grain counts of the same tracks by both our method and the conventional microscope method were in good agreement. It is obvious that in both cases background grains increase the grain count. The length of the slit used here corresponds to about two grain diameters so that the conditions for adding background grains are similar to those in usual grain counting methods. A correction could be made in our case by running along the background in the vicinity of the track.

One advantage of our method is the reproducibility of the results which do not depend on the experience of the operator. The only requirement is that he learn how to drive. His driving abilities can be easily checked by inspecting the record of the steering angle and focusing movements which are also given automatically by our charts (Fig. 6). Another advantage is the objectivity with which interpretation criteria can be established and applied to the charts; these can be inspected by any number of people at any time.

The measurements can be done quite rapidly and easily. For example, a conservative estimate of the driving time for a grain density record of a 2000μ-track is about 10 minutes. The evaluation of the chart can be done at any convenient time and simply involves counting and weighing of peaks on the regions of the chart one is interested in. In many cases merely an inspection of the patterns as a function of range will be sufficient for the identification of the particle.

The reproducibility, accuracy, and speed of our method is especially convenient if one wants to obtain large statistics, for instance upon the relation between grain density and energy loss.

In case the identity of the particle causing the track is known and only range measurements are necessary for determining the energy, the driving speed can be increased appreciably because the limiting speed factor in grain density measurements is the frequency response of our recording system and the necessity of using high magnification. It may be that at higher speeds one does not follow the track exactly; however, as long as one drives smoothly so that the maximum angle formed with the direction of the track is small, the error introduced is not appreciable. For instance, if one continuously wanders across the track with an angle of 10°, the error introduced is $1\frac{1}{2}$ percent.

IV. ACCURATE DETERMINATION OF COORDINATES

The counters connected with the x, y, and z movements read to 1/10 of a micron. We have found that we can center one grain in our bull's eye, record its coordinates, then wander around the plate at random, and recenter the same grain so that the difference between the coordinates is not greater than 0.2 micron. The deviation read on the counters connected with the stage movement is mainly due to the difficulty in judging the center part of a grain.

The counters are therefore used to determine the coordinates of a series of points connected with tracks, if highest accuracy is needed. Such problems are present in measurements of multiple scattering of tracks. From the coordinates which we record with the photographic system mentioned before, the data necessary for mean scattering angles can be determined. Because of the motor-driven stage and automatic recording, these measurements can be done fairly easily. Coordinate intervals can be selected and preset by utilizing microswitches on the stage driving selsyns. This procedure can be further simplified by using punching counters instead of photographic recording and then analyzing the charts by machines.

Another method used for scattering measurements[1] can be incorporated in our apparatus. In this case we install a line in the eyepiece which by rotation is aligned along the track and the angle of rotation is magnified and recorded together with the coordinates. Furthermore, to increase the accuracy of alignment we intend to introduce a slit in the image plane before the photocell, rotating parallel and simultaneously with the eyepiece line and use the photo-cell output maximum as indicator for alignment.

It is clear that large angle scattering or any geometrical relationship between track directions in stars can be calculated after having obtained a suitable sequence of coordinates.

---

[1] Y. Goldschmidt-Clermont, Como Conference, September, 1949, Nuovo Cimento (to be published).

V. PHOTOMETRIC MEASUREMENTS

There are cases in which counting of individual grains is not necessary or may even be impossible because of an excessively high grain density. In order to identify the particle it is necessary to determine the rate of decrease of grain density along the track. In these cases we use a slit before the photo-cell having in the image plane a width equal to about two grain-diameters and a length corresponding to about 6–10 grains. We then drive the longer side of the slit parallel to the track and record the photo-cell output along the track (V_{track}) using a proportional amplifier. In order to obtain the amount of light absorbed by the track, the photo-cell output on either side of the track corresponding to the empty background is also recorded ($V_{\text{background}}$). The ratio $\frac{V_{\text{track}}-V_{\text{background}}}{V_{\text{background}}}$ determined from the charts with the aid of a planimeter is a function of the grain density within the track and its variation along the track a measure for the change in energy loss with the range of the particle.

VI. HEAVY TRACKS

The photometric method is especially indicated in investigations of heavy tracks.[3] The tracks produced by heavy charged particles ($3 \leqslant Z \leqslant 26$) have in addition to the usual track core (single line) a conglomeration of many grains on both sides extending out from the center, due to the ejected electron tracks (δ rays). In analyzing these tracks one needs to determine the number of δ-rays[2] per unit length along the track, since this count is a function of the charge and velocity of the particles. The number of δ-rays in a given energy and geometric interval is proportional to Z^2 and increases with decreasing velocity up to a maximum value. The velocity where the maximum occurs depends upon the δ-ray interval chosen. As the velocity continues to decrease, the number of δ-rays drops; furthermore, the particle captures electrons and the track thins down (thin down length).

Visual δ-ray counting is lengthy and quite subject to personal judgment. Therefore we have attempted to develop a rapid photometric method of analyzing heavy tracks. We drive along the track with a wide slit or set of slits placed before the photo-multiplier, so that only selected regions of the track cross section are visible to the photo-cell.

Thereby one can choose the δ-ray interval one intends to measure (choice of slit) and determine its photometric density which will be a function of the number of δ-rays and the geometry of the slit. The output from the photo-multiplier is linearly amplified and automatically recorded on the chart moving with a speed 2000 times the driving speed. Thus we obtain a record of the amount of light transmitted by the track through the slit as a function of the length of the track. We then drive along the empty background on both sides parallel to the track and obtain the light transmitted by the background.

With the cooperation of Dr. H. Bradt and Dr. B. Peters of Rochester University we were able to perform a preliminary investigation using some of the heavy tracks found and analyzed by these authors.

With a 4-mm objective (650 times magnification) and a slit which projected on the object plane which defines an opening 18 microns long and 6 microns wide, we measured the percentage of light transmitted by 10 tracks ranging from carbon to iron, all having $\beta = v/c = 1$. In Fig. 9 the percentage of light absorbed is plotted *versus* the number of δ-rays per unit length, determined by Bradt and Peters. The relationship appears to be linear within the possible experimental accuracy. It is clear that the percentage of light absorbed by the track should be an increasing function of the number of developed grains which fall within the area covered by the slit. Provided that saturation, packing, and contagious development effects are negligible, it is to be expected that both the number of grains and the percentage of light absorbed should be linearly related to the visual δ-ray count. The fact that we get an approximately linear relationship shows that in the case of heavy particles with high velocity these effects do not enter, at least not in the type of emulsion and development chosen by Bradt and Peters. The Y-intercept or percentage of light absorbed for zero δ-ray count represents the average contribution of the grains within the core of the tracks.

While the δ-ray count by Bradt and Peters is averaged over track lengths extending through several plates, our results are based on track lengths in only one plate (average length approximately 500 microns). Since we include in our measurements the very great number of short δ-ray tracks, which cannot be counted visually, our statistics per unit track length are greatly increased, and hence it is not too surprising that the results, with the exception of two points, do not scatter too much, considering the short track lengths measured. These two

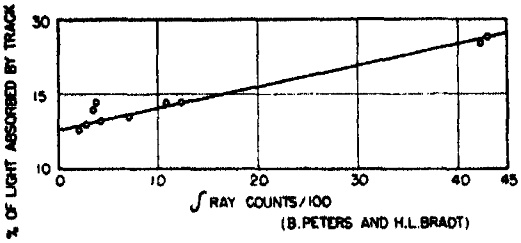

FIG. 9. Percentage of light absorbed by a heavy track as a function of δ-ray counts.

---

[3] H. L. Bradt and B. Peters, Phys. Rev. 74, 213 (1948); Phyllis Freier *et al.*, Phys. Rev. 74, 213 (1948).

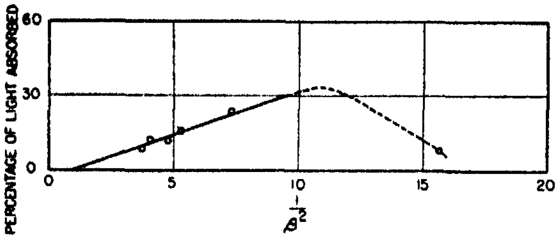

FIG. 10. Percentage of light absorbed by an iron track as a function of $1/\beta^2$.

points may be due to our erroneous identification of tracks measured by Peters and Bradt.

As shown above, saturation effects etc. are small for even iron tracks, if the particle velocity is high, and therefore with a suitable calibration our measurements (percentage of light absorbed) are directly related to the δ-ray counts and can thus be substituted in calculations based on δ-ray count.

It was clear that with lower velocities saturation effects could enter and obscure the relationship between photometric measurements and δ-ray count. Therefore we investigated an iron track starting at $\beta=0.525$ and stopping after passing through 12 plates. We found, using the slit previously described, that the photometric values did not follow the expected $1/\beta^2$ law to the maximum but saturated rather early exhibiting a wide plateau.

We felt that if we excluded the core and the immediate densely blackened neighborhood and measured the δ-rays beyond this region we could obtain the expected relationship. Therefore we used a double slit blocking out a center region of approximately 3 microns and extending 4.7 microns to both sides of the blocked out region. The light absorbed by the δ-rays within this double slit was again compared with the light absorbed in background measurements.

The results for an iron track measured at the average velocities $\beta^2=0.27$, 0.26, 0.25, 0.21, 0.187, 0.138, 0.064 (the intermediate plates were developed differently and therefore not taken into consideration) are plotted *versus* $1/\beta^2$ in Fig. 10. We find an approximate linear relationship up to the maximum. The scattering of the data can be explained by occurrence of staining effects on some of the plates. Unfortunately we do not have a measured point near the maximum; however, it lies within the region to be expected on the basis of calculations taking into account our slit geometry. After the maximum the photometric value drops rapidly to zero due to the contraction of the δ-ray pattern. However, with the single slit previously described we can measure towards lower velocities and accurately determine the thin down length.

Although our investigation has been only of a preliminary nature, it seems reasonable to expect that the proper combination of slits (single slit for low ray density, double slit for higher density) together with suitable calibration curves provides all the information one obtains from visual δ-ray counts. In addition the position of the maximum and the thin down length[*] can be determined. Grain counting along lightly ionized tracks of heavy particles which is sometimes helpful for their analysis can be rapidly done with the arrangement described in Section II.

A great advantage of our method for heavy particles in comparison with visual δ-ray counts is the speed with which the measurements can be performed. The actual measuring time for a track 2 mm long is about 5 to 6 minutes with an additional ten minutes necessary for evaluation of the charts.

The results of the analysis in visual δ-ray counting depend upon the judgment of the observer; furthermore because of the lengthy and exacting nature of the observations the statistics cannot be increased beyond a certain point. On the other hand our method gives reproducible results, and since both the time factor and eyestrain are materially reduced, the statistics and therefore the accuracy can be increased.

It is clear that the photometric method gives the best results when the emulsions are uniformly developed without stain or other inequalities. However, to some degree these fluctuations in transparency are averaged out through background measurements in the immediate vicinity of the track.

If confronted with a problem involving the accurate analysis of a great number of heavy particle trajectories, the above described method is of definite advantage.

SUMMARY

It has been our purpose to develop a measuring apparatus for nuclear emulsions which permits the operator of the machine to follow as simple a procedure as possible and thereby have all the necessary measurements performed and recorded automatically. By this procedure we hoped to achieve reproducibility, speed, accuracy, and a reduction of the fluctuations due to personal judgment. Although the apparatus herein described is only an experimental model, it has proved useful for rapid accurate measurements of range, grain density, delta-ray density (photometric method), multiple scattering, and geometrical relationship of trajectories in emulsions.

Since all the measured quantities are indicated by mechanical movements and electrical voltages, it is clear that we can also utilize computing machines etc. to calculate desired results. Furthermore, we are at present considering an extension of its use by incorporating automatic scanning and recording features for selected events.

---

[*] The thin down length is determined from the chart of photometric value *versus* length which exhibits a marked drop over the effective thin down length.

ACKNOWLEDGMENTS

The authors are indebted to Dr. B. Peters and Dr. H. L. Bradt of Rochester University for their cooperation and helpful discussions on the heavy particle work.

We wish to thank Dr. J. R. Dunning and Dr. P. Mitchell of Columbia University for their interest in the development of the apparatus.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 12 DECEMBER, 1950

A Double Thin Lens Beta-Ray Spectrometer*

C. M. Van Atta,† Sydney D. Warshaw,‡ Joses J. L. Chen,§ and Samuel I. Taimuty
University of Southern California, Los Angeles, California

(Received July 31, 1950)

The description of the performance of a double thin magnetic lens beta-ray spectrometer is given. A detailed investigation of the separate distortions introduced by chamber misalignment, internal scattering, charged source and poor resolution has been made, and the results are presented qualitatively. An alignment procedure is presented, and also the arrangement of baffles to minimize scattering.

A. INTRODUCTION

THE purpose of this communication is first, to describe the construction of a new beta-ray spectrometer, and second to indicate, more or less precisely, some of the more pronounced sources of error in the use of this instrument for the measurement of beta-ray spectra.

Neither the basic design nor the interpretation of errors and distortion is original with us. The instrument itself has been patterned after a design first given by Quade and Halliday[1] which, in turn, was a modification of the original thin lens design of Deutsch and his coworkers.[2] Since the first-mentioned authors have not, to our knowledge, published any measurements made with their instrument, we think that such a description and discussion is worth while as a measure of the performance of the design.

Many authors (to be referred to in the text) have indicated the sources of error common to all kinds of magnetic spectrometers: the thick source, window absorption, effect of the earth's field, scattering in the chamber, and charged source all play a role in introducing distortions. However, it seems useful to repeat these observations for a single spectrum and on a single instrument, both to make the interpretation easier and to collect these data in a single paper for convenient reference. For these purposes the Cs 137 spectrum was chosen because its shape is accurately known;[3] the strong and conveniently located conversion line has been precisely measured[4] and the prominent Auger lines at low energy offer a further convenience.

B. DESCRIPTION OF THE INSTRUMENT

Figure 1 shows a schematic layout of the spectrometer. The chamber proper consists of a 54-in. long brass tube, 8-in. i.d. mounted inside a brass sleeve 9-in. i.d. The mounting was effected simply by allowing the inner chamber to ride on four leveling screws placed at both ends of the sleeve. This allows the inner chamber to be moved with respect to the sleeve (which also serves as a mounting for the coils) and gives an additional degree of freedom which proved to be useful in the alignment process.

The baffle system inside the main chamber is somewhat more elaborate than is customary in instruments of this type. Baffle L in the figure is a lead assembly for gamma-ray shielding. Mounted on it are three thick aluminum disks which serve to define the inner limit of the electron trajectories. At each end of the tube are installed the cone baffles; these are constructed of four

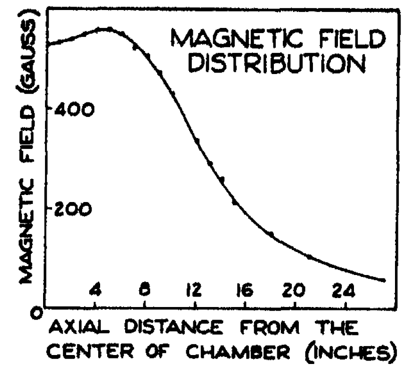

FIG. 2. Magnetic field distribution on the axis of the chamber.

aluminum disks each mounted perpendicular to the chamber axis and several inches apart. They limit the extreme peripheral rays from the source and their net effect is to put the source at the apex of a cone of angle about 22°. The central portion of the chamber is lined with a series of rim baffles in the form of circular channels placed $\frac{3}{8}$ in. apart and projecting $\frac{3}{8}$ in. into the chamber. These were formed of $\frac{1}{32}$-in. aluminum sheet bent to fit the inside of the tube snugly. In addition a single axial aluminum disk was installed at the counter end of the chamber 5 in. from the counter window.

The four field coils are placed in two pairs as shown in the figure. These are constructed of $\frac{1}{2}$-in. copper tubing, spiral wound in two layers and water cooled. The current is supplied by a 12-kw welding generator the field of which is excited by four thyratrons connected in parallel as a full wave rectifier. Stabilization is obtained by comparing the generator output with the voltage of a 24-volt storage battery and feeding the error signal to a direct coupled amplifier which controls the thyratron grid potentials. The coil current is measured in terms of the voltage drop across a shunt by means of a type K potentiometer.

With the coils placed as shown, the field distribution was measured (to about five percent accuracy) with a flip coil on the chamber axis. According to Quade and Halliday[1] this type of field distribution results in relatively small aberration. The field plot is given in Fig. 2.

Since there is no closed form solution of the ray equation for this type of field distribution it is necessary to use numerical methods to compute the trajectories. However, since the ray equation is appropriate only to obtain those paths which lie very close to the axis, and not for obtaining more useful information (like the amount of aberration) it was felt that a simple estimate of the refracting power as calculated from the ray equation with a variational principle would suffice for a design criterion. The more essential information was obtained empirically and by scaling the dimensions of Quade and Halliday's instrument. If one puts $H=hI$ gauss for the magnetic field on the axis, where I is the coil current, and for the momentum of an electron moving close to the axis $p=kI$ gauss-cm, then the ray equation becomes:

$$d^2r/dx^2=-h^2/4(u/k)^2r. \tag{1}$$

Here u is the object distance measured from the center of the lens system, r is the radial distance from the axis to the trajectory, and x is distance on the axis in units of u. In this equation the eigenvalues give directly the value of the constant of the instrument, k; a well-known modification of the Rayleigh-Ritz variational method gives

$$\frac{1}{4}\left(\frac{u}{k}\right)^2=\frac{\int_0^1 (dr/dx)^2dx}{\int_0^1 h^2r^2dx}. \tag{2}$$

Any value of k, calculated with some trial function for r in Eq. (2) will be smaller than the value calculated with the true eigenfunction. If trial functions like $\cos\pi x/2$ (the solution for the solenoid case) or $(1-x)$ (bending through a very small region) are used in (2) the result is a value for k which is much lower than the observed value. The usual thin lens formula can be obtained from (2) by noting that for this case the factor r^2 is slowly varying and, in these units, cancels the numerator; that is

$$\left(\frac{k}{u}\right)^2=\frac{1}{4}\int_0^1 h^2dx. \tag{2'}$$

Using $u=68.6$ cm and applying Simpson's rule for numerical quadrature, one gets $k=43.4$, which is quite close to the measured value. Hence the designation of the instrument as an equivalent thin lens seems justified.

The calculations were used only as a point of departure. The calibration was achieved with the Cs 137 K conversion line momentum value given by Langer[4] and cross-checked with the most recent measurement[5] on the conversion lines of In^{114}, using a rather thick In source. A further check was obtained using several lines from a lead radiator in front of a radon seed. All of the values for k, so measured, clustered around the Cs 137 line value to better than 0.5 percent.

The image rotation, as calculated from the thin lens formula, is about 102° as compared with the measured (see below) 122° for focused rays.

The source is introduced into the chamber through a vacuum lock assembly and is mounted on a thin Lucite shell which supports the Nylon source backing. The counter is a conventional pressure-seal, end-window type with the seal provided quite satisfactorily by an 0-ring. The thin Nylon window, the Nylon films made according to the recipe of Brown *et al.*,[6] is supported on a brass grill consisting of a hexagonal array of 0.040-in. diameter drilled holes which provides about 75 percent transmission. The counter is connected through Saran tubing to a pressure regulating system[7] to compensate for any loss of counter mixture due to window porosity and normally operated with an argon-10 percent alcohol mixture at about 5 cm Hg, although pressures as low as 3 cm can be used without loss of efficiency.

C. PERFORMANCE OF THE INSTRUMENT

1. Scattering

With a reasonably thin source mounted on a very thin Nylon backing and supported by a thin Lucite shell, the whole assembly being loaded with Aquadag to prevent charging up, the Cs 137 spectrum was run with the result shown in Fig. 3a. At this point, the only adjustments of the instrument were an initial lining up by means of an electron gun, and the only baffles installed were a central (peripheral) baffle and the lead baffle. Note that on this curve, the Auger lines are quite indistinct and the resolution is poor. If this curve at the low energy end is compared with the good measurement made by Agnew[2] there is a pronounced deviation which may be partially explained by scattering. The first step in the adjustment was to eliminate the scattering distortions. C. S. Cook[8] has already indicated that this distortion can be removed by defining the beam by a sufficient number of baffles. In the present case enough baffles were introduced one at a time in such a way that, finally, the only straight line more than about 6 in. long that could be drawn starting from the counter window, without intersecting a baffle, was essentially in the direction of the trajectory. As partially indicated in the curves of Fig. 3 each addition of a baffle assembly had a definite and pronounced effect on the entire appearance of the spectrum, in particular, on the low energy end. All of these curves were run with the same thin source. Not all of the individual steps of improvement due to the separate additions are shown. In particular, the baffles fixed to the lead shield and the central peripheral baffle were originally made of brass. The simple device of replacing these with aluminum made a noticeable improvement, indicating a degree of scattering from the edges of the baffles themselves. Installation of the "rim-baffles" (*R*) also improved the low energy spectrum by preventing scattering from the chamber wall proper. An alternative method for eliminating chamber wall scattering by making the diameter of the chamber very large was followed by Agnew and Anderson.[3]

The two conical baffle assemblies (*C*) are mounted on ¼-in. aluminum rods which pass through Wilson seals on the chamber end plates. The position of these baffles was varied until the electron trajectories, defined by the small annular opening at the center, just missed grazing the edges of the disks. On the source end, there is also a movable baffle (*W*) mounted on similar rods which pass through both *C* and the chamber end-plate which can be used to vary the solid angle. (For the dimensions used, the variation produced in this way is too small to be very useful.) The final baffle was the small central disk (*A*) mounted axially on a rod projecting from the lead shield toward the counter and placed a few inches in front of *GM*. No special provision, like the use of a helical baffle, or a sector baffle was used to eliminate higher harmonics. Rather than reduce the already low transmission of the instrument, we simply note that the second harmonic has a node at the center of the lead shield, and the third harmonic should be (and apparently was) reduced by the smaller annular opening left by baffle *A*. The final result is shown in Fig. 3b. The almost complete absence of scattering was further confirmed by photographic means, a technique which was primarily used for the alignment of the chamber axis with the magnetic axis.

For indicating alignment of the chamber with the magnetic field a photographic plate, placed at the position of the counter window, recorded the image of the source. A comparative microdensitometer study of this image and a radioautograph of the source (neither of these are shown) indicated that the aberration was quite small and the scattering negligible, since the image was very sharply defined and actually slightly smaller (although with the same outline) than the autograph of the object. The image spot was taken using the coil current that corresponded to the *K*-conversion line. With about 100 microcuries activity the Eastman 103a-0 *UV* plates used required about a three-hour exposure for a good image. The solid angle was about 0.4 percent of a sphere.

2. Alignment and the Effect of Earth's Field

The instrument has been so placed that the axis of the chamber is lined up with the direction of magnetic north. Quade and Halliday[1] have shown that for this arrangement, the correction to the focusing coil current is just one-half the difference of the currents required to focus a line spectrum with the field aiding and then bucking the earth's field. This correction they showed to be a constant for all focusing currents. For the arrangement described in this paper the correction is found to be 0.20 amp., which is quite insignificant compared to the rather large currents that were used; e.g., Cs 137 conversion line is focused at about 75 amp. However, the vertical component of the earth's field is quite important with respect to the proper behavior of the electron trajectories, especially for the lower energy groups. For its compensation a set of Helmholtz coils of rectangular shape is mounted about the chamber, symmetrically with respect to the axis of the chamber. These coils are 3 ft.×16 ft., spaced 3 ft. apart. Each coil is made of a six-conductor cable connected to give six turns in series. The current source is a set of storage batteries of high capacity, and the current may be varied continuously with a rheostat. A current of 5.9 amp. in the coils gave complete compensation of the earth field at the center of the chamber, while the error in the off-center region within the chamber is computed to be less than 2.3 percent of the vertical field at the center.

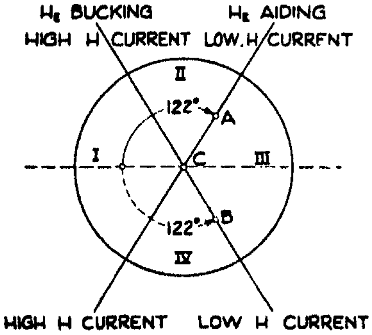

FIG. 4. Image space sketch showing the effect of sweeping Helmholtz coil current.

During the initial alignment of the focusing field, by making slight changes in the orientation of each of the four field coils, the Helmholtz coil field was found to be a convenient tool. The monoenergetic beam from an electron gun was used to give a focused image on a fluorescent screen at the detector end. Sweeping the Helmholtz coil current (hereafter the *H* current) through its compensating value moved this spot across the screen. The same observation was then repeated for reversed focusing field. The swept lines are shown in Fig. 4 which is drawn from observation and later confirmed by measurement on the burned marks on the inside surface of the fluorescent screen. The inclination of these lines with the horizontal axis corresponds to a rotation of 122°. The point of intersection of the two lines is taken as the center of the image plane after proper adjustment of the field coils. It should be understood that the precision of this method is limited by the finite size of the image and the necessity for the use of visual judgment of intensity.

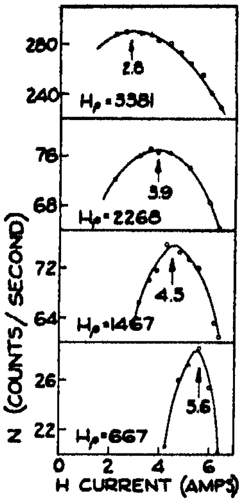

FIG. 5. Energy dependence of *H* current setting indicating imperfect alignment.

When the baffles and detector were completely installed, the possible existence of a slight misalignment was then sought for by a systematic variation of the *H* current. First the focusing current was set on a convenient point of the familiar Cs 137 spectrum, and the number of counts at the detector plotted against *H* current. This was repeated for a few points of the spectrum. If the maximum of this curve appears at a different value, in general, than the *H* current needed for exact compensation, then this indicates that the magnetic axis of the coils and the axis of the chamber are not identical. Further, a comparison of the maxima for different focusing fields will show an energy dependence as is illustrated in Fig. 5. With the field reversed the procedure was repeated to help in the approximate location of the apparent focal spot relative to the center of the counter. For example, if for the focusing field both aiding and bucking the earth's horizontal field, the maxima appear at higher *H* currents, the apparent focal spot is in region *I* of Fig. 4 and the chamber should be adjusted to shift the counter toward that region. The actual adjustment was accomplished by means of the set screws which support the chamber in the sleeve. At each adjustment the counts *versus H* current curve for a given focusing field was plotted. A correct move was indicated by both an increase in the number of counts at peak and an approach of the *H* current for peak to the correct compensating value. A few typical curves taken in the process of adjustment are shown in Fig. 6. Here the direction of motion of the counter for each move is indicated on the line connecting the maxima of the two associated curves. After final adjustments, a complete set of curves like those in Fig. 5 but with no energy dependence of the maxima (both for the aiding and the bucking case) were taken

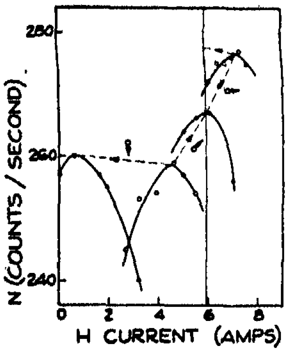

FIG. 6. Some maximizing curves taken during final alignment of the chamber.

to confirm the satisfactory centering of the detector with respect to the magnetic axis. An improvement of some 0.25 percent (out of 2.5 percent) in the resolution was obtained after this adjustment. The final check on the alignment was obtained by the photographic method mentioned above, with the addition of a reticle, drawn on the edges of the plate before exposure, and accurately located with respect to the center of the end plate of the chamber.

3. Resolution

As noted above, the final figure for the resolution was 2.1 percent with a solid angle of 0.4 percent of a sphere. At present the solid angle can be increased at the expense of resolution only by replacing the central baffle system or by reducing the distance between source and counter. Therefore, with the present arrangement, the only possibilities of increasing the number of detector counts are an increased total activity with a corresponding increase in source thickness and an increased total activity with an increased source diameter. Several authors[9] have pointed out the undesirability of the thick source. For low energy spectra, a thick source may make an unambiguous interpretation of the result impossible. This leaves only the possibility of increasing the source diameter, while keeping the thickness as small as possible; in effect this spoils the resolution and a correction must then be made. To check on the amount of distortion produced in this way, we ran several curves with the source diameter varied from about 4 mm to about 15 mm and with a corresponding variation in the counter window opening. (Deutsch[8] has shown that the optimum condition for unit magnification is to have the source size and the window size the same.)

In Fig. 7 the uncorrected spectrum is given for the 15-mm source, of about three-quarters the total activity of the source used in the 2.1 percent resolution case (Fig. 2). The resolution was now 5.4 percent (twice the half-width at half-maximum). While this resolution figure is not excessive, Owen and Primakoff[9] have emphasized that the distortion in the continuous spectrum that can be produced by this is not negligible.

If the poor resolution curve of Fig. 7 is normalized to the "good" curve of Fig. 2 (normalization at about 2580 gauss-cm, as explained below) it is found that the necessary correction is less than two percent except very near the end point, and that the "poor" curve is higher than the good curve for momenta greater than the normalization point and lower for smaller momenta. For the quantitative correction at least two, not unrelated, methods are available. As formulated by Owen and Primakoff[9] the number of counts at the detector, $M(p)$, per unit momentum interval is given by

$$M(p)=\int_0^\infty N(p')K(p,p')dp', \tag{3}$$

where $N(p)$ is the true momentum distribution, and K, the kernel of the integral equation, is obtained from a study of the shape of an internal conversion line. In the case where source thickness may be neglected, K is simply the transmission function of the instrument. For an arbitrary line shape the integral equation cannot be solved in closed form. Owen and Primakoff express the true counts N in terms of M and its derivatives and the moments of K about its maximum. In the case they first investigated, they used a 180° spectrometer for which the line shape was asymmetric and represented by an exponential. In our own case the line is very nearly represented by a Gaussian function (Fig. 8). For this symmetric shape, the first moment vanishes, making the distortion smaller for this type of instrument. A good fit to the line is obtained with $\exp-(p-p_0)^2/2a^2$, and with $a=0.0155p_0$, $p_0=3381$ gauss-cm. Although the width was not measured for any lower energy line, this value of a is not inconsistent with the shape of the Auger lines at the low end of the spectrum. If we put $a=0.0155p_0+b$, where b may be a roughly constant addition to the width due to, e.g., scattering, it is found that b is no more than seven percent of a at as low a value of energy as 26 kev. The Owen-Primakoff correction is then

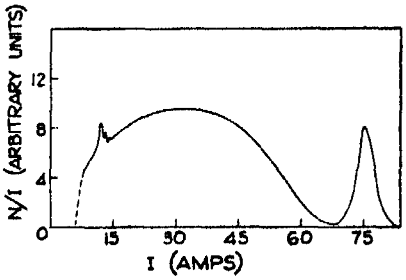

FIG. 7. Cs 137 spectrum with "poor" (5.4 percent) resolution.

$$N(p)=M(p)\left[1-(0.0155p)^2\frac{M''}{M}\right], \tag{4}$$

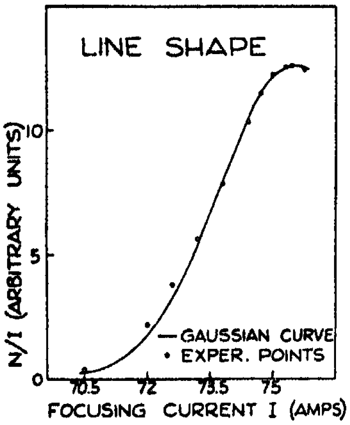

FIG. 8. Line shape for 5.4 percent resolution.

where the second derivative is obtained by numerical methods. For the 5.4 percent case the measured curve has an inflection point at about 2580 gauss-cm where the correction factor is therefore unity; the application of this factor in general results in a satisfactory fit of the poor resolution case to that with good resolution. (In the 2.1 percent case the correction is of course, about one-sixth that of the situation with 5.4 percent resolution.) The alternative correction is a graphical "cut-and-try" method first used by Hughes and Alburger[10] for the measurement of the low activity Be^{10}. Here the end point is first determined and then a plausible assumption is made about the shape of the true spectrum, $N(p)$. The integral in Eq. (3) is then calculated graphically by using the actual rather than an analytically fitted line shape. The result is a prediction of the distortion produced in a definite theoretical spectrum by the resolution used. The value of N at a point, divided by the predicted value of M is then taken to be the correction factor which multiplies the observed value of M. The application of this method to the 5.4 percent curve gave a correction very nearly equal to that given by the analytical method, but somewhat larger near the end point. Probably the small (but not statistical) discrepancy is due to the neglected contribution of the low intensity high energy group of the Cs 137 spectrum. In the case of an unknown degree of forbiddenness (the first-forbidden correction factor was used here) the procedure is repeated using different correction factors until a straight line Fermi plot results. There is, therefore, some uncertainty in whether at least part of the "distortion" is real, i.e., produced by some unknown degree of forbiddenness, or whether it is experimentally produced by poor resolution. The analytical method, although it involves a number of mathematical approximations that restrict its validity, seems to be more straightforward.

4. Charging-Up of the Source

The erratic behavior of a charged source is well known.[11] For a systematic study we deliberately made some sources on ungrounded film and/or ungrounded holder, while a control source of identical size and activity was mounted on a well-grounded backing—the Lucite shell holder painted with Aquadag in alcohol, and the back side of the Nylon film smeared with a foggy coating of Aquadag in dilute insulin solution—the resistance across the support being about 100 megohms. The sources were about 20 μc in activity and 0.2 mg/cm^2 in thickness. The ungrounded source usually gave a nearly correct transmission curve for the K conversion line (with the L line on the upper side) when a reading was taken right after introducing the source through the vacuum lock. With an improperly grounded Lucite shell, a second curve taken after a short time was similar except for a definite shift of both K and L peaks downward of about 50 gauss-cm (corresponding to about 13 kev in energy), and a corresponding distortion of the continuous spectrum. After longer intervals of time, the peaks shift slightly further. Generally if the Lucite holder is well grounded but the Nylon is not, the shift of peaks will be gradual, taking many hours to reach equilibrium value. Evidently in the former case the surface conductivity of the Lucite holder is the main factor, while in the latter the aging of the Nylon film in vacuum seems to decrease its conductivity. It is certain that even for a weak source the charging-up effect will disturb not only the low energy portion but the whole spectrum to the extent of 10 kev or more, depending on the source activity and the insulation property of the backing materials.

ACKNOWLEDGMENT

It is a pleasure to acknowledge the assistance given by Dr. Alfred W. Einarsson for the design and construction of the field control circuit and field calibration and to Mr. John M. Leffler for participation in the design and construction of the instrument.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 12 DECEMBER, 1950

Continuously Sensitive Diffusion Cloud Chambers*

E. W. COWAN
California Institute of Technology, Pasadena, California

(Received August 20, 1950)

The following types of continuously sensitive diffusion cloud chamber have been built and successfully operated: a chamber designed to be photographed through the top for use with a particle accelerator; a chamber designed to be photographed from the side for cosmic-ray studies; and a very simple chamber for demonstration purposes. The construction and best operating conditions are described.

SEVERAL models of cloud chambers are described here which are of the same general type of continuously sensitive diffusion chamber described by Langsdorf.[1] Supersaturation is obtained by the diffusion of alcohol or water vapor from the warm roof of the chamber downward through an inert gas to the cold floor. Condensation occurs on ions in a sensitive layer of several inches depth near the floor of the chamber. Considerable simplification in the design and also some improvement in the results have been obtained.

The following general considerations apply to all of the specific types that will be described later. A pad of black velvet or other cloth soaked with alcohol and warmed by contact with a metal plate that forms the top of the chamber has been found to be the best vapor source. The deepest sensitive layers have been obtained with mixtures of methyl alcohol, ethyl alcohol, and water. However, since the composition of the mixture changes with evaporation, and since methyl alcohol alone gives very good results, pure methyl alcohol usually has been used.

As the temperature of the roof is increased, the depth of the sensitive layer increases until an optimum temperature is reached above which the sensitive volume splits into two layers. Since the exact temperature depends upon the dimensions of the chamber and the vapor used, numerical values will be given later only for specific instances. Droplets which form about ions in the upper sensitive layer grow very rapidly because the concentration of vapor is greatest near the source of vapor at the top of the chamber. These droplets fall to the bottom, and remove vapor that would otherwise increase the supersaturation of the lower part of the chamber so that below the top layer the supersaturation is not sufficient for ion condensation, except in a shallow layer near the bottom where the temperature gradient is large. As the temperature of the top plate approaches the value at which the vapor pressure of the liquid nears the total pressure in the chamber, which might appear at first sight to be the best temperature, the upper layer approaches the top of the chamber and fills the chamber with a general rainfall. The very rapid growth of droplets in the top layer results in a competition for vapor in which only a relatively few of the ions near the top of the layer are in regions of sufficient supersaturation to form droplets. No recognizable tracks are formed in this layer, and the fact that the condensation is actually on ions can be ascertained only by careful observation of the effect of an electric sweep field. A pulsed electric field, of one of the types to be described later, is of some value in preventing the splitting of the sensitive layer.

This type of general rainfall may have been the cause of some of the difficulties with Langsdorf's chamber attributed to droplet nuclei produced by the vapor source.[1] Although a general rainfall is produced by heating the vapor source above the boiling point, at the normal operating temperature "streamers" of droplets which sometimes appear have been traced to leaks that permit contaminated air from the outside to enter

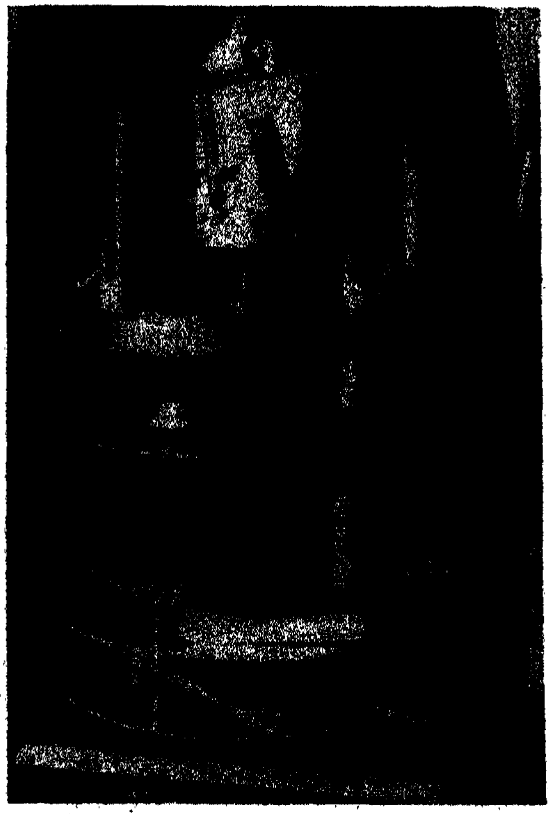

FIG. 1. Continuous chamber with camera mounted above.

[1] Alexander Langsdorf, Rev. Sci. Inst. 10, 91 (1939).

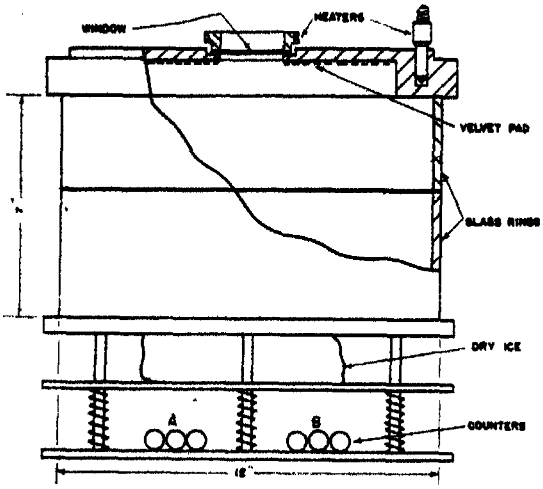

FIG. 2. Construction of chamber shown in Fig. 1.

the chamber, or to corona from fine points if a high sweep voltage is used. Streamers resulting from the circulation of contaminated air through leaks, which are especially likely to occur when the top is cooling, appear like small waterfalls in the chamber and may be stable over considerable periods of time. Brass, aluminum, rubber, Neoprene, and several types of cloth have all been placed in direct contact with the liquid in the top of the chamber without causing any apparent trouble.

Air may be used as the inert gas in the chamber, although argon gives better results, especially if ethyl alcohol is used in the mixture. If the molecular weight of the vapor is heavier than the molecular weight of the inert gas, there will be some unstable motion of the gas near the top of the chamber, resulting in considerable condensation on the walls of the chamber. However, the lower layers of gas in the chamber will still be stable, and tracks have been observed even using combinations such as helium and ethyl alcohol. Experiments made to determine the optimum pressure in the chamber showed that in the range of 0.1 to 2 atmospheres the difference in performance, which was difficult to measure because the optimum temperature and height vary with pressure, was not sufficient to justify the added difficulty in operating at a pressure different from one atmosphere.

The floors of the chambers have been made of aluminum blackened by an anodizing process or of black Bakelite. When the bottom becomes covered with alcohol, the black surface makes an excellent background for photography or viewing if the source of illumination is arranged so that its reflection is not

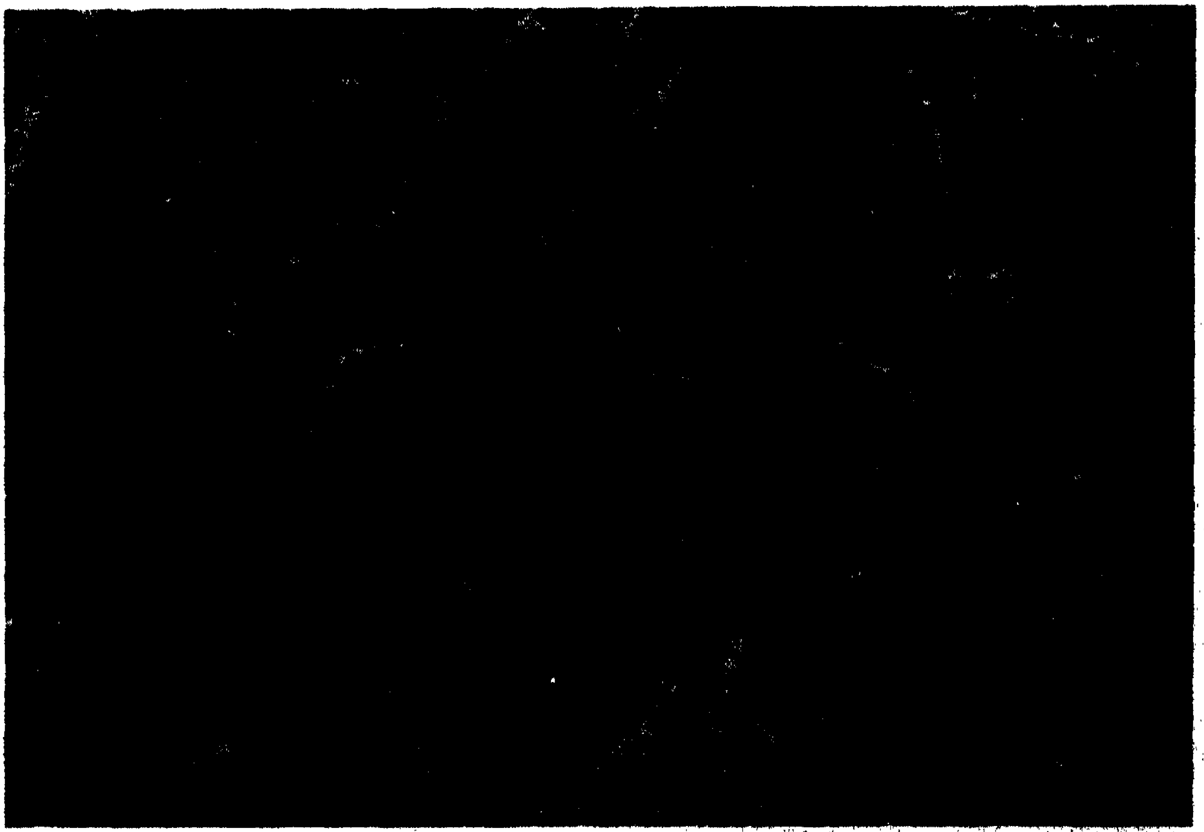

FIG. 3. Tracks produced in chamber by exposure to radium source.

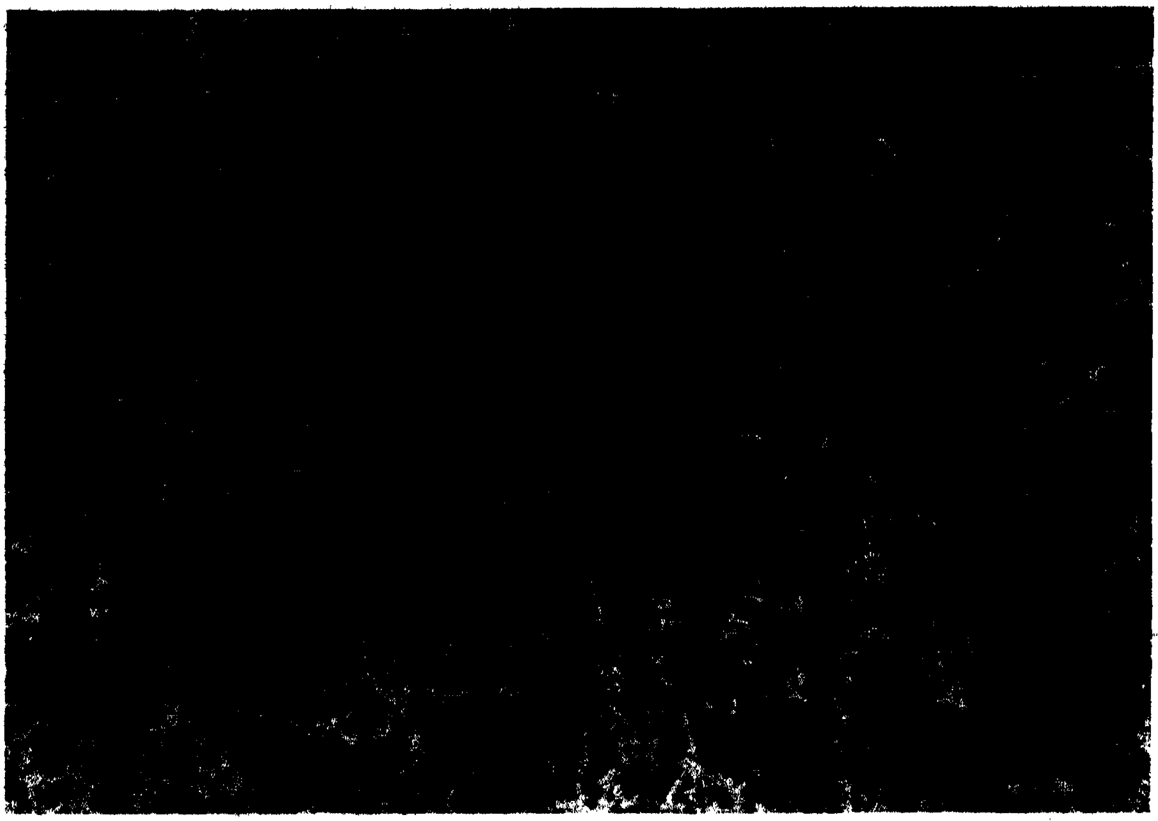

FIG. 4. Photograph of chamber after heavy exposure to radium source.

visible in the bottom. The temperature of the floor of the chamber is not at all critical. Tracks are first observed as the temperature is lowered below about −30°C, and below −70°C (with methyl alcohol) droplets begin to form without ion nuclei, producing a thin cloud layer about one-eighth of an inch deep on the floor. The most convenient method of cooling the bottom is by direct contact with a block of dry ice (−78°C). If the illumination is such that the cloud layer on the floor forms an objectionable background, a thin heat insulator between the dry ice and the bottom may be used to raise the bottom temperature slightly. Another method of cooling is by partially submerging the bottom of the chamber in a bath of alcohol and dry ice, which gives a temperature just above that necessary for the cloud layer on the floor to form.

With a pressure of one atmosphere in the chamber, the height of the chamber giving the deepest sensitive layer is about eight inches. If the diameter is considerably larger than this height the sensitive layer is uniform in depth except near the walls. With a diameter about the same as the height, the layer becomes mound shaped with the greatest thickness at the center.

The chamber shown in Figs. 1 and 2 was designed with the idea of possible use with the synchrotron now under construction at the California Institute of Technology. A camera with a wide-angle lens of 28-mm focal length is mounted above a small window in the top of the chamber, which has a cylindrical glass wall. The construction is shown in Fig. 2. A velvet pad with a hole in the center is sewed to a piece of perforated sheet aluminum that is in turn fastened to an aluminum top plate, which is sealed to the glass ring forming the walls of the chamber. This plate is heated by three pencil-type soldering iron tips inserted into holes around the edge of the metal plate. About 40-watts power is needed for normal operation. A small additional heater is wound around the clamping ring for the top window to prevent vapor from condensing on the window.

The alcohol is contained in a reservoir and fed through a needle valve to the velvet pad, over which the alcohol becomes uniformly distributed. The bottom of the chamber is made of anodized aluminum, and dry ice is held in contact with it by a spring-supported plate. The cylindrical glass wall is made of two twelve-inch diameter glass rings, the lower one being four inches high and the upper three inches high. These rings are separated by a conducting rubber gasket which is one of the sweep-field electrodes. The other sweep-field electrode is formed by the top and bottom of the chamber connected electrically. This arrangement removes the ions from the upper part of the chamber without pulling them down into the sensitive layer.

Rubber gaskets are used to seal the rings to the top and bottom of the chamber, which may be pulled tightly against the rings by Bakelite rods running from the top to the bottom. When the chamber is used at atmospheric pressure the Bakelite rods may be omitted and the chamber clamped together only by the weight of the top plate. If the rings are accurately ground the leaks are small enough not to disturb the operation of the chamber seriously, although the displacement of inert gas out of the chamber by vapor may change the operating conditions. The outside of the lower ring occasionally must be wiped with a cloth moistened with alcohol to remove the frost that accumulates.

When the chamber is used with the synchrotron, it is planned to pulse the sweep field by applying a voltage to remove the ions after each burst of particles from the synchrotron. The photograph in Fig. 3 was taken after the chamber was exposed to a sudden pulse of radiation from a radium source. With a properly synchronized sweep-field voltage pulse of about 600 volts amplitude, the chamber will recover sufficiently fast to be sensitive to a large pulse of radiation, such as shown in Fig. 4, at intervals of three or four seconds. Although a continuous background of ionization reduces the height of the sensitive layer, the chamber operates satisfactorily with a background several times the normal background ionization at sea level.

With argon and methyl alcohol in the chamber, the sensitive layer is about three inches deep in the center of the chamber at the optimum roof temperature of 39°C. With air and methyl alcohol the sensitive layer is about three inches deep at a roof temperature of 44°C, but there is some turbulence near the top of the chamber which limits the depth of the sensitive layer. The addition of water to the alcohol causes the droplets to grow more slowly. With a liquid mixture of about equal parts of methyl alcohol, ethyl alcohol, and water, it is possible to obtain a sensitive layer five or six inches deep after a pulse of sweep voltage. The tracks in the upper part of the layer, however, are diffuse, indicating that the supersaturation is barely sufficient for ion condensation, and, except for a small time after the pulse of sweep voltage, the sensitive layer divides into the two parts mentioned earlier. A roof temperature of 55° to 65°C is best for the mixture given above when using argon in the chamber.

This chamber also has been operated with the coincidence-counter arrangement shown in Fig. 2, which tends to select cosmic-ray showers of two or more particles. A coincidence between any counter in group *A* and any counter in group *B* triggers a flash lamp after a 180-millisecond delay. Figure 5 shows a small cosmic-ray shower photographed with this type of counter control. Since the tracks are very sharp this arrangement operated at high altitudes could provide an

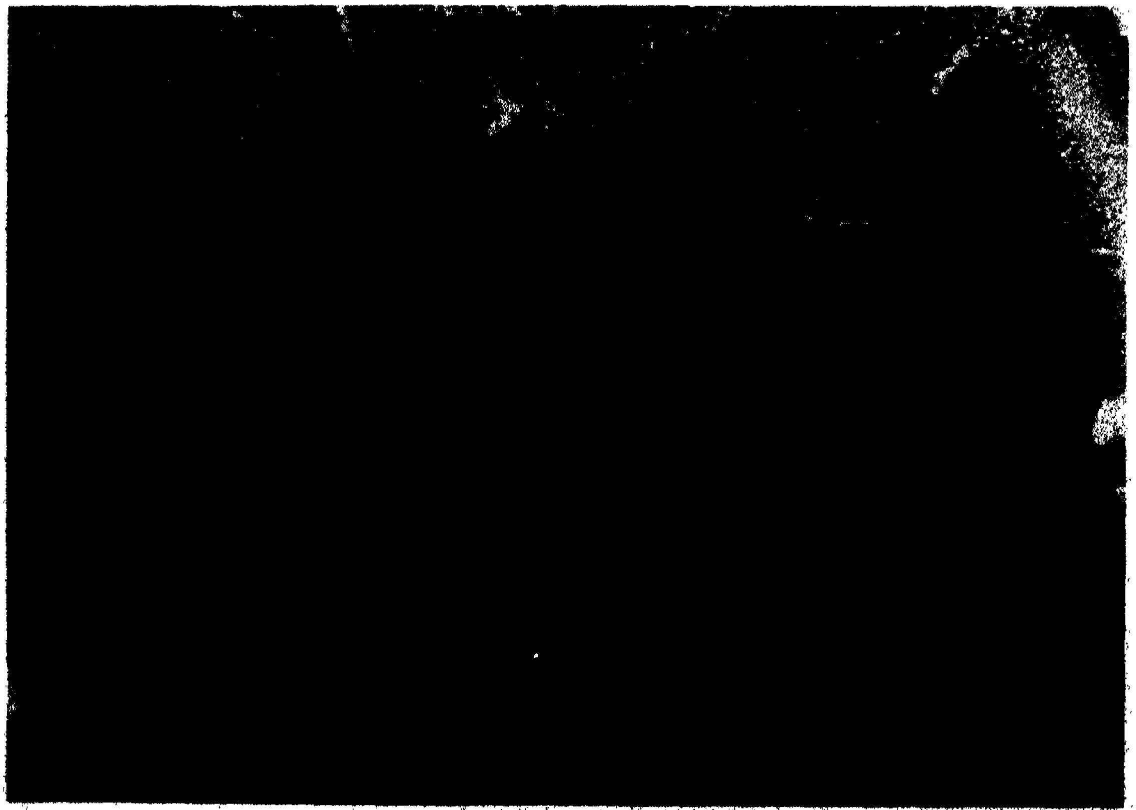

FIG. 5. Small cosmic-ray shower photographed with counter control.

FIG. 6. Sharp cosmic-ray track photographed with 20-msec. light delay (actual projected length of track as viewed by camera about 6 cm). Crooked track was made by low energy electron at an earlier time, and droplets have separated while falling.

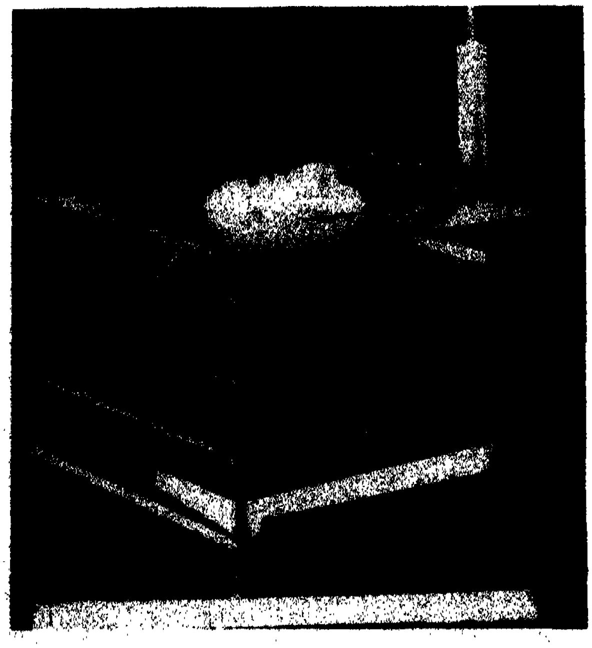

FIG. 7. Continuous chamber designed to be photographed from side.

effective means of studying the cores of large air showers.

The flash lamp is a General Electric Type FT-422, connected to 250 μf charged to a voltage of 2000 volts. Only the region from $\frac{1}{4}$ in. to $2\frac{3}{4}$ in. above the floor is illuminated by the flash. A lens aperture of f/8 gives adequate exposure on Linagraph Pan or Linagraph Ortho film. Under these conditions the photograph may be taken as soon as twenty milliseconds after the counters are tripped, although a very short delay is not essential since the diffusion chamber is not troubled, as is the expansion-type cloud chamber, by the diffusion of ions before droplet growth begins. The stable atmosphere of the diffusion chamber also alleviates the problem of distortion. Figure 6 is an enlarged photograph of a sharp cosmic-ray track photographed 20 milliseconds after the counters were tripped. When the chamber is operated with counter control, a sweep voltage pulse of 1.5 seconds duration and 600 volts amplitude is applied every 45 seconds.

The rectangular chamber shown in Fig. 7 was designed to be photographed from the side for studies of cosmic rays. With the thought in mind that this chamber might be used later in a magnetic field, the smallest dimensions consistent with good results were used. The inside dimensions are 9×9×5 in. high, and the maximum depth of the sensitive layer, using methyl alcohol and argon, is 2½ in. with a roof temperature of 34°C. A window of black glass in the back provides a background for taking a photograph through the front window, and the sensitive volume is illuminated through the side windows. The windows are mounted in Bakelite frames that are held together with screws and Bakelite cement to form the walls of the chamber.

The construction of the top and bottom of the chamber is very similar to that of the first chamber described except that the heater consists of the heating element from a coffee percolator clamped to the center of the top. A pulsed sweep voltage of 600 volts is applied between the top and bottom plates.

The continuously sensitive diffusion chamber makes an ideal demonstration unit, both because the continuous operation makes the tracks easy to observe, and because of the simplicity of construction. A glass ring resting on a black Bakelite base placed on a cake of dry ice makes a very simple demonstration chamber. The vapor source may be a doubled layer of black cloth tied over the top and saturated with warm alcohol. If operation for a considerable time is desired, a metal plate warmed by a flat iron may be placed on top of the cloth. The chamber floor should be covered with a layer of alcohol to seal the bottom to the glass ring and to provide a good viewing background. A battery of several hundred volts may be connected by clip leads between the cloth and the Bakelite (with the clip in contact with the alcohol puddle around the ring) to provide a sweep-field, although this is not essential. With a good source of parallel light projected horizontally through the chamber, a large group can observe the tracks from all directions except when looking directly into the light. A continuously sensitive demonstration chamber has been used for several lectures, and for several months it has been one of the regular demonstrations shown visitors to this laboratory.

I would like to express my appreciation for the encouragement and advice in this work by Dr. C. D. Anderson, who, in 1936, made some of the first investigations of this type of chamber.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 12 DECEMBER, 1950

A Rapid Method for Calculating and Using Platinum Thermohm Tables

R. A. Buerschaper
Taylor Instrument Companies, Rochester, New York

(Received July 18, 1950)

A method is described whereby resistance-temperature tables can be calculated in a few hours using punched cards. The method is much simpler and quicker to use than the "platinum temperature" tables. An example is given for reducing resistance measurements to temperature and a method for checking bridge and thermohm drift with respect to the tables is proposed.

THE THERMOHM AS THE INTERPOLATION INSTRUMENT

THE International Temperature Scale of 1948 defines the temperature °C from the ice point to the antimony point by the formula

$$R_t = R_0(1 + At + Bt^2),$$

and from the oxygen point to the ice point by the formula

$$R_t = R_0(1 + At + Bt^2 + C(t-100)t^3).$$

R_t is the resistance of the thermohm at any temperature t°C and R_0 is its resistance at the ice point. The constants A, B, and C are obtained by measuring R_t at the steam, sulfur, and oxygen points. The constants for any thermohm may be obtained by having the thermohm certified at the National Bureau of Standards. From these constants, a table may be calculated of values of R_t/R_0 *vs.* t°C and t°F whereby the resistance may be converted to temperature. The thermohm and its table, together with a Mueller Bridge, form one of the primary temperature standards from the oxygen point to the antimony point.

CALCULATIONS FROM THE OXYGEN POINT TO THE ICE POINT

The following constants were obtained from a National Bureau of Standards Certificate for one of two thermohms in use at present.

$$A = 3.9821 \cdot 10^{-3};$$
$$B = -5.862 \cdot 10^{-7};$$
$$C = -4.351 \cdot 10^{-12}.$$

Write the formula as

$$\begin{aligned} R_t/R_0 &= 1 + At + Bt^2 + C(t-100)t^3 \\ &= 1 + At + Bt^2 + Ct^4 - 100Ct^3. \end{aligned}$$

By setting $t = 0, -1, -2, -3, -4$, and -5°C in the expression for R_t/R_0, we may obtain the successive differences. The fourth difference is a constant as the equation is of the fourth order.

t°C	R_t/R_0	X_1	X_2	X_3	X_4
0	1				
		$-A+B+C+100C$			
−1	$1-A+B+C+100C$		$2B+14C+600C$		
		$-A+3B+15C+700C$		$36C+600C$	
−2	$1-2A+4B+16C+800C$		$2B+50C+1200C$		$24C$
		$-A+5B+65C+1900C$		$60C+600C$	
−3	$1-3A+9B+81C+2700C$		$2B+110C+1800C$		$24C$
		$-A+7B+175C+3700C$		$84C+600C$	
−4	$1-4A+16B+256C+6400C$		$2B+194C+2400C$		
		$-A+9B+369C+6100C$			
−5	$1-5A+25B+625C+12500C$				

X_1, X_2, X_3, and X_4 are the first, second, third, and fourth differences.

At this point it may be well to list the punch card machines used in calculating and tabulating the results: (1) Key Punch Machine which is a hand machine to punch the information into the cards, (2) Reproducing Summary Gang Punch Machine which reproduces, punches common information in cards and also summarizes totals from a group of cards, and (3) Tabulating Machine which adds, subtracts, and prints. With the aid of these machines the sets of differences and the function R_t/R_0 may be calculated and tabulated.

The steps in using the punched cards and machines are given below for the fourth-order equation.

The fourth difference, X_4, must be calculated first using data from the certificate.

$$24C=-104.424\cdot 10^{-12}.$$

This value is gang punched into 200 cards to cover the range 0 to −200°C.

Calculate the first, third difference, X_3

$$X_3=36C+600C=-2767.2\cdot 10^{-12}.$$

This value is now key punched into a lead card of another color and the 200 fourth-difference cards precede the third-difference cards, tabulate and summary punch. Mathematically this step is equivalent to subtracting algebraically the fourth difference from the first third difference 200 times, to form a set of third differences.

Next, calculate the first, second difference $2B+14C+600C$.

$$X_2=2B+14C+600C=-1.1751\cdot 10^{-6}.$$

This value of the first X_2 is key punched into a lead card of a still different color. Precede the third-difference cards (X_3) with this second difference and tabulate and summary punch. Again this step is mathematically equivalent to subtracting algebraically the set of third differences from the first second difference.

The next step is to calculate the first, first difference, X_1.

$$X_1=-A+B+C+100C=-3982.7\cdot 10^{-6}.$$

Precede the X_2 or second difference set with the X_1 lead card, tabulate and summary punch. Gang a 1 and a 1.8 in the summary cards. This step is equivalent to subtracting algebraically the set of second differences, X_2, from the first, first difference. The 1 and 1.8 ganged in the summary cards are for the differences in °C and °F, respectively, for which the function R_t/R_0 is to be given.

Now, key punch a 1 in the lead card of the function R_t/R_0 and a 0 for °C and a 32 for °F. These are the starting temperatures in this table. Precede the first difference cards with this function card and tabulate. This step is, in effect, subtracting algebraically the values of the set of first differences in sequence from 1, which is the value of R_t/R_0 at the ice point and also subtracting 1 from zero and 1.8 from 32 each time. This tabulation gives the values of R_t/R_0 for every °C and every 1.8°F from 0 to −200°C or 32 to −328°F.

CALCULATIONS FROM THE ICE POINT TO THE ANTIMONY POINT

The constants for the equation are given above. The calculations are made in the same manner as for the fourth-order equation. The calculations are simpler as we are now dealing with an equation of the second order.

$$R_t=R_0(1+At+Bt^2)$$
$$R_t/R_0=1+At+Bt^2.$$

Set $t=0$, 1, and 2 in the equation above and obtain the various differences in terms of the constants A and B.

t°C	R_t/R_0	Y_1	Y_2
0	1		
		$A+B$	
1	$1+A+B$		$2B.$
		$A+3B$	
2	$1+2A+4B$		

Y_1 and Y_2 are the first and second differences. Here the second difference is a constant as the equation is of the second order.

Calculate the second difference, Y_2

$$Y_2=2B=-1.1724\cdot 10^{-6}.$$

Gang punch this value, $2B$, in 500 cards to cover the range 0 to 500°C. Also, gang punch a 1 and 1.8 in these cards.

TABLE I.

Date	Benz. acid cell No.	Thermohm No.	R_t/R_0	°C	Benz. acid freezing pt. °C	Corr. to benz. acid pt.
9/ 1/49	N.B.S. 15	446899	1.478463	122.357	122.359	+0.002°C
1/31/50	N.B.S. 15	446899	1.478443	122.352	122.359	+0.007°
5/ 5/50	N.B.S. 15	446899	1.478448	122.353	122.359	+0.006°
6/23/49	N.B.S. 15	671634	1.478570	122.360	122.359	−0.001°
3/ 3/50	N.B.S. 15	671634	1.478573	122.361	122.359	−0.002°
7/ 6/50	N.B.S. 15	671634	1.478566	122.359	122.359	0.000°

Next, calculate the first, first difference $A+B$.

$$Y_1 = A+B = 3981.5\cdot 10^{-6}.$$

Key punch this value of $A+B$ in a card of another color and key punch a 1 and a 1.8 for the increments of °C and °F in this card. Precede the 500 second-difference cards with the first difference card, tabulate and summary punch. This step is equivalent to adding algebraically the 500 values of the second difference to the first, first difference to form the set of first differences.

Now, key punch a card with 1, the value of R_t/R_0 at 0°C or 32°F. Also, key punch a 0 and 32 in this card for the initial temperatures. This is the function card.

Precede the first difference cards with this function card and tabulate. The results are tabulated values of R_t/R_0 *vs.* °C and °F from 0° to 500°C. As the thermohms were not guaranteed above 500°C, the tables were terminated at 500°C, and not the antimony point. The tables may be checked at convenient temperatures by direct substitution in the equations, using the constants from the N.B.S. Certificate.

VALUES OF R_t AND R_0 CONVERTED TO TEMPERATURE

Assume the resistance of the thermohm to be measured with a Mueller Bridge and that the corrections to the bridge are already applied to the values of the resistances given below.

Let $R_0 = 25.5358$ ohms.

Let $R_t = 37.6311$ ohms.

$$\text{Then } R_t/R_0 = \frac{37.6311}{25.5358} = 1.473660.$$

From the table, we have

°C	°F	R_t/R_0	Diff.
121	249.8	1.473254	
			0.003840
122	251.6	1.477094	

Interpolating, $1.473660 - 1.473254 = 0.000406$.

$$\text{Then } t\text{°C} = 121 + \frac{0.000406}{0.003840} = 121.106\text{°C}.$$

In using the table, R_0, the resistance at the ice point, should be measured at the time of test.

CHECK OF THERMOHM DRIFT

The drift of the thermohm, with respect to the table, must be checked at some point other than the ice point as the resistance at the ice point is already explicitly used. The freezing point of benzoic acid is a good one to use. Benzoic Acid Cells may be purchased from the National Bureau of Standards, certified to ±0.003°C. The freezing point is about 122.36°C. Freezing point checks may be made with these cells every 3 to 4 months and the temperature as calculated from the thermohm table compared with the freezing point temperature for that particular cell. Table I shows the history of two thermohms and the deviation of the temperature calculated from the certified temperature of the Benzoic Acid Cell.

The largest correction to date is +0.007°C for thermohm 446899. Assuming straight line error curve with zero error at the ice point, we would have an extrapolated error at 500°C of 0.029°C for the top of the range and 0.015°C error at the low end of the range, −200°C. This error is due to drift with respect to the table. To date, the rate of drift of this thermohm is 0.004°C per 8 months or 0.0005°C per month. Thermohm 671634 shows no apparent drift. The drift, with respect to the table, may be due to the change in resistance of the components of the Mueller Bridge as well as a change in resistance of the thermohm. It is good practice to certify the Mueller Bridge yearly.

CONCLUSION

The method described for calculating the tables of R_t/R_0 *vs.* t can be accomplished in a few hours as against several weeks for the former method of direct computation of the successive differences, using a calculator and having two people independently compute the tables. This type of table is easier and quicker to use than the tables involving the "platinum temperature" as there are no successive approximations involved as are in the latter table. The Benzoic Acid Cell furnishes an accurate and reproducible point for checking the drift from the table. This error due to drift may be extrapolated to the extreme temperatures of the table using the error at the Benzoic Acid Point and zero or negligible error at the ice point. This zero or very small error at the ice point assumes the R_0 was measured in a precision ice bath.

ACKNOWLEDGMENT

The author wishes to thank Mr. T. J. Price of the Taylor Instrument Companies Tabulating Dept. for his help and cooperation in preparing the tables.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 12 DECEMBER, 1950

An Electronic Recording Analytical Balance

IDAS W. LOHMANN
Southern Regional Research Laboratory, New Orleans, Louisiana*

(Received September 5, 1950)

An electronic recording analytical balance is described which is free of mechanical connections with the balance beam, direct reading, sensitive, and rapid. All mechanical and electrical contactors have been eliminated from the instrument proper, using electronic means as a substitute for mechanical. A relay and two cam-operated microswitches are, however, used in the range extender. The construction is simple, being made up, for the most part, of available standard commercial units. For work requiring a continuous record of changes in weight with respect to time, the instrument should prove to be most valuable.

IN the course of physical studies of the mechanics of impregnated resins, an instrument was needed which would automatically record, with respect to time, changes in weight due to volatilization. An electronic recording analytical balance designed and built by R. H. Müller and R. L. Garman[1] suggested a ready means whereby this might be accomplished. Ewald,[2] Oden,[3] Svedberg and Rinde,[4] and others have designed and built recording balances. Desirable features of the instrument to be described are that there are no mechanical or electrical connections with the beam of the balance, the recordings are linear, the chart speed is uniform and accurately timed, the chart speeds can be changed easily, the sensitivity of the balance can be varied (a knob control), slow or fast rates of changes of weight can be recorded, and a minimum number of controls is used. This instrument is operated through a servo mechanism, and although the idea is not new, it is presented as a means for accomplishing this task.

The balance may serve many other purposes besides the one specifically mentioned such as to follow the rate of sorption, desorption, evaporation, oxidation, and decomposition by automatically weighing the substance placed on the pan with the pan in normal position or with the pan suspended in a conditioned chamber below the balance.

A general view of the instrument is shown in Fig. 1. A standard 36-inch relay rack provides the framework for supporting the chainomatic balance and the accompanying amplifier and servomechanism. The recorder is wall-mounted in close proximity to the balance. Necessary controls are at a minimum and mounted on the front panel. The rear glass window of the balance is replaced by a one-quarter inch plywood panel. This acts as a support for the photo-tube, light shield, and also the range extender mechanism.

The assemblage consists essentially of the following parts—optical system, discriminator, amplifier, balancing mechanism, recording potentiometer circuit, recorder, and range extender.

The optical system (Fig. 2) is simple, requiring only a reflector (B) at the source (A), a tubular light shield (C), and a photo-tube (F). All parts were painted black where necessary to reduce light reflections. The target is so cut that when the balance is in equilibrium about one-half of the light from the source falls on the photo-tube. Compensation for ageing of the light source and the photo-cell is accomplished by varying R_6 (Fig. 3). Variations in light on the photo-tube owing to movement of the pointer of the balance actuate the balancing mechanism. In order to detect these changes a discriminator is used.

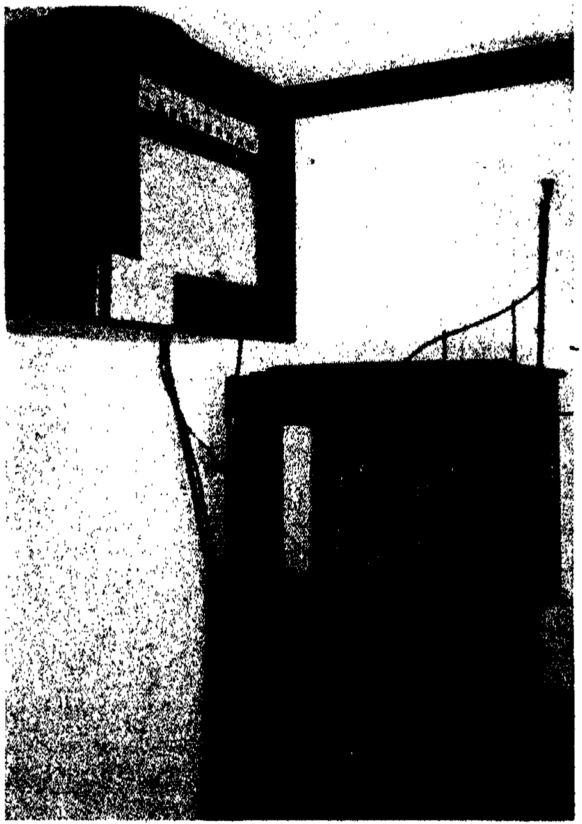

FIG. 1. Electronic recording analytical balance.

The discriminator (Fig. 3) functions in the following manner. When the balance is in equilibrium, the current flow in the plate circuit of each No. 89 tube (V_1 and V_2) is such that the voltage drops across R_a and R_b (see Fig. 3) are equal. The bias for the tubes is furnished by the photo-tube (V_3) through a resistance network. When the equilibrium of the balance is disturbed, the bias on the tubes is changed through the variation in the amount of light falling on the photo-tube. This bias change causes the plate current to vary thereby making the voltage drops across R_a and R_b unequal. The direction in which the bias changes determines whether the voltage drop across R_a or R_b will be the larger. The difference in the voltage drops across R_a and R_b is the signal voltage input to the servo-amplifier (A). The amplitude of this signal voltage is dependent upon the amplitude of the change in bias on the No. 89 tubes. Any pentode power output tube will serve the purpose as well as the No. 89 tube. Batteries were used to offset the effect of line voltage fluctuations and for simplicity.

The signal voltage is fed into a servo-amplifier,†‡ which converts the input voltage into an alternating output voltage. The phase and magnitude of the output voltage are dependent upon the polarity and magnitude of the input voltage. The 2-phase balancing motor (M) has one leg excited by the servo-amplifier and the other by the 60-cycle line. Thus, a change in phase (or polarity of input voltage) means a change in direction of the motor's rotation. This amplifier† responds to a signal of about 50 microvolts and has provision for reducing this sensitivity when necessary. This two-phase motor is the driving force for the balancing mechanism.

The balancing mechanism is controlled by the balancing motor which has been geared down to increase the sensitivity of the instrument. The gear reduction allows the motor to make several revolutions in order to compensate for a small change in weight and return the balance to equilibrium. The reduction gear makes only one revolution for a weight change of one hundred milligrams on the balance. To accomplish this, sprocket gears connected through a ladder chain are attached to the crankshafts of the balance and the reduction gear. The ratio of the gears is slightly greater than the number of turns of the balance crank as a stop is placed on the reduction gear which permits about a 350° revolution in either direction.

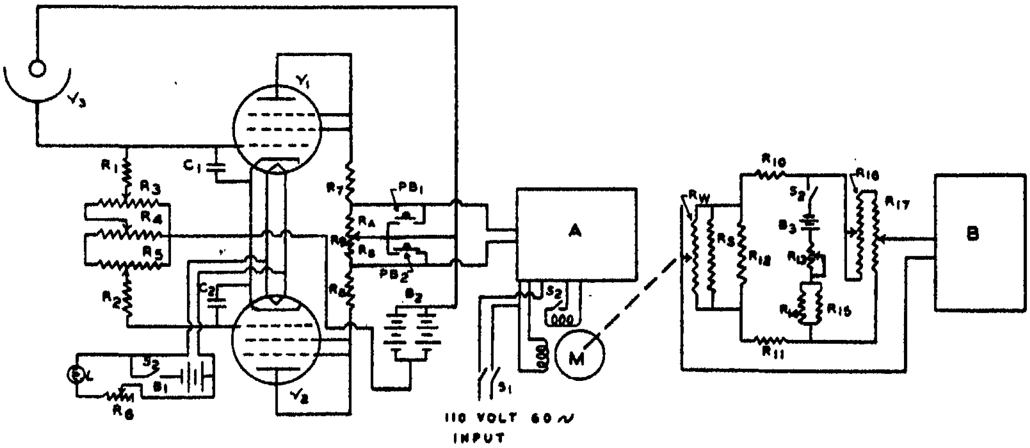

FIG. 3. Circuit diagram. R_1, R_2—4.7 megohms, ½ watt. R_3—1000-ohm helipot. R_4—50,000-ohm potentiometer. R_5—25,000-ohm potentiometer. R_6—25 ohms, 25 watts. R_7, R_8—22,000 ohms, 1 watt. B—Recording potentiometer, 7.5-mv range, strip chart, 12 sec. full-scale travel. M—Two-phase balancing motor. L—Lamp, Mazda No. 31, 6.2 volts, 0.3 ampere (optical light source).

---

† Servo-amplifier from Brown Instrument Recorder Model No. 851325.

‡ The mention of firms' names or trade products does not imply that they are endorsed or recommended by the Department of Agriculture over other firms or similar products not mentioned.

The drive cable pulley is also attached to the reduction gear so that balancing the analytical balance and moving the contact on the recording potentiometer circuit's slidewire is accomplished simultaneously. Thus as the reduction gear is moved to place the balance in equilibrium, the output of the potentiometer bridge network is varied and is at all times directly proportional to the movement of the reduction gear. The output of this network is fed to the recorder. Provision is made in this circuit for "zeroing" (both coarse and fine controls) the recorder and also for adjusting (expanding) the range when calibrating. This facilitates calibrating the instrument. This potentiometer circuit, including the slidewire, is the bridge network from a Brown Instrument recorder† in which the following changes were made. On the resistor terminal board, resistors Nos. 5 and 6 (Brown Instrument numbers) were removed and a thousand-ohm ten-watt resistor soldered across terminals 4A and 4B. The two 500-microfarad 6-volt electrolytic condensers were also removed. The recorder (B) input connections were made between the movable contact on the slidewire and the movable contact on the coarse "zero" control.

The output of the recording potentiometer network is fed into a null-balance type strip recorder§ with a sensitivity of 7.5 millivolts for full-scale deflection and a pen speed of 12 seconds for full-scale travel. This gives a direct reading in milligrams so that no interpolation is necessary. If the changes in weight are greater than 100 milligrams, it becomes necessary to use the range extender.

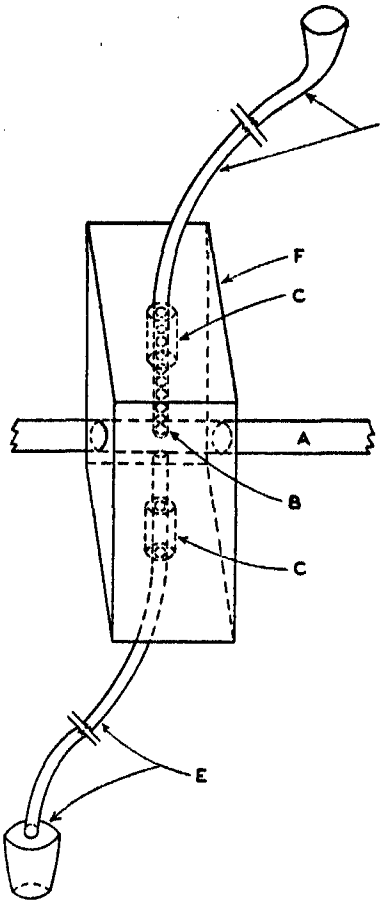

FIG. 4. Range extender. A. $\frac{1}{4}$-in. drill rod used for shaft, driven by 4-r.p.m. motor. B. Hole $\frac{3}{32}$-in.+0.005-in. diameter and $\frac{3}{32}$-in. depth in shaft. C. Hole $\frac{3}{32}$-in.+0.005 in., upper and lower portion cut $\frac{1}{8}$-in. deep to fit outer diameter of copper tubing used for storage and guide. D. Copper tubing, storage and funnel. E. Copper tubing guide to thimble. F. Brass block 1×$1\frac{1}{4}$×2 in.

The range extender (Fig. 4) is so designed that should a change in weight exceed that of the balance chain, a small stainless steel ball would be deposited in a cup (a thimble) supported by the pan hanger. This ball is deposited when the vernier on the balance indicates zero. The weights (balls) are always added to the left-hand pan. The stainless steel balls are $\frac{3}{32}$-in. in diameter and weigh 55 milligrams. Two identical thimbles were used for equilibrium and symmetry, the left-hand thimble being the holder for the balls. The drive mechanism for the range extender is a small synchronous motor whose speed was reduced to 4 revolutions per minute. The motor drives a shaft (A) of $\frac{1}{4}$-in. drill rod with a hole (B) $\frac{3}{32}$-in. deep and 5 thousandths of an inch larger than the $\frac{3}{32}$-in. ball. As the shaft rotates, it removes balls one at a time from the upper tube (D) and drops them into the lower tube (E) which causes them to drop into the thimble. The motor's operation is controlled by a latching relay which in turn is controlled by two microswitches. These microswitches are operated by a cam which is also attached to the reduction gear shaft. They are so mounted that when additional weight is needed to bring the balance into equilibrium, the motor is energized by causing a microswitch to close. After the weight (ball) is added, the system tends to balance itself. In so doing, it opens the first switch, and shortly thereafter closes the second switch momentarily, then opens the second microswitch again to remove power from the relay coil. The motor does not stop until the second microswitch is closed. The delay is used so that the range extender will be almost ready to drop another ball when needed instead of having to wait approximately fifteen seconds. When another weight is needed, the same operation is repeated.

OPERATION

The operational controls mounted on the front panel are the main power switch, balancing motor switch, coarse balance control, fine balance control, "up" push button, and "down" push button. (The push buttons are used only when the beam is off the knife edges.)

The main power switch is turned on and the instrument allowed to heat up for at least 30 minutes. The balance beam is then lifted off the knife edges and the balance switch is turned on. With the fine balance control at about the middle of its range (about 5 turns from either end as it is a 10-turn helical wound potentiometer), the coarse control is used to bring the balancing mechanism to a stop, or as close to a stop as possible, anywhere on the scale. After the coarse control has been adjusted, the fine control is then used to make the final adjustment. With the fine control adjustment, no motion of the chain occurs for about 1 turn of the fine control. When the movement of the chain has been stopped, the fine control is then turned about one-half turn from this point. This places the fine control halfway between operating points. The recorder is then checked against the balance scale. The "down" push button is depressed until the balance scale reads zero; if the recorder does not read zero, the "zero control" (located with range sensitivity just inside of the small door in the rear) is adjusted to give the correct reading. Then the "up" push button is depressed until the balance reads some convenient point on the upper portion of the balance scale. If recorder fails to agree, the range sensitivity control is adjusted. It is then necessary to check "zeroing" again as these controls are interdependent. The balance is now ready for weighings. The balance motor switch is turned off and sample is placed on the balance pan. The equilibrium of the balance is adjusted as closely as possible, with use of standard weights and the beam rider to within 100 milligrams. The balancing motor switch is turned on. The instrument will then automatically keep the balance in equilibrium and will also record the time rate of change of weight of the sample on the chart.

---

§ Brown Instrument recording potentiometer, model No. 153 ×11V—x—27.

CALIBRATION AND REPRODUCIBILITY

The performance of the recording balance was checked by placing 10-milligram weights on the balance pan and allowing the instrument to automatically balance itself. The maximum recorded deviations were of the order of 0.15 milligram.

As a check on the reproducibility of the results, a 10-milligram weight was weighed, removed, then weighed again for a total of 10 times with a maximum deviation of 0.125 mg. This was repeated again with a 20-milligram load and the deviations were within the same range. In checking the constancy of the instrument two different loads were used, one at the lower and the other at the upper end of the recorder scale. There was no observable variation on the chart for the two loads over a period of time, the trace being a straight line. The instrument appears to be free from the effects of line voltage variations, as none has been observed in all the weighings.

RANGE

With the present arrangement, weight changes up to ±11.1 grams may be made automatically. This is accomplished through the use of 200 stainless steel balls weighing 55 milligrams apiece in the range extender.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 12 DECEMBER, 1950

A Capacitance Bridge for High Frequencies*

J. S. Mendousse,† P. D. Goodman, and W. G. Cady
Wesleyan University, Middletown, Connecticut

(Received July 31, 1950)

A type of bridge for measurements at frequencies in the megacycle range is described, containing two fixed capacitors and a variable capacitor. The unknown impedance is connected in the fourth arm as a "load." The unbalanced high frequency e.m.f. is rectified by a germanium crystal rectifier and measured as a small d.c. voltage. The bridge is "balanced" by varying the variable capacitance until the ratio of output d.c. to input h-f voltage is at a minimum. The impedance of the variable capacitor is then numerically equal to that of the load.

In a second and perhaps more important application, the bridge is used for examining vibrational modes and measuring the Q of piezoelectric crystals or transducers. Here the variable capacitor is set at a fixed value equal to the parallel capacitance of the crystal, and the output voltage is observed, or recorded graphically, while the frequency is slowly varied over the resonance range. Some graphical records are shown, illustrating the performance of crystals at various frequencies and under different mechanical loads.

The theory of the bridge is given, and sources of error are discussed.

INTRODUCTION

1. First designed as a mode analyzer for piezoelectric crystals, this device has proved to be useful also for measuring the Q of crystals and crystal transducers and the acoustic resistances of liquids. At present it is also playing a part in a new type of acoustic interferometer for measuring velocities and absorption coefficients. With a given crystal in the load arm the bridge requires practically no retuning over the range from 1 to 50 Mc. Although a balance is more difficult at lower frequencies, the bridge has been used as a mode analyzer down to 35 kc.

* This work was done under contract with the ONR (N6onr-262, T.O. 1) at Wesleyan University, Middletown, Connecticut. The original manuscript appeared as *Technical Report No. 6*, February 1, 1950, under the contract. The present paper, except for a few changes and omissions, is identical with that report.

† Now at The Catholic University of America, Washington, D. C.

The distinguishing feature is the use of a crystal rectifier and direct current voltmeter to measure the potential difference across the bridge. A procedure is described whereby the error caused by non-linearity of the rectifier is eliminated.

Although somewhat similar types of bridges have been described by others,[1–5] the present device differs from them in arrangement of components, purpose, and operation, and requires a different theoretical treatment.

2. A diagram of the bridge is shown in Fig. 1. C_3 and C_4 are fixed capacitors, C_2 a variable capacitor. The load is at Z, in parallel with C_0, the capacitance of the jack to which the load is plugged, together with associated stray capacitances. V_0 is the h-f input voltage. If the load Z contains a resistance, there is no value of C_2 that makes the voltage drop V_{AB} across AB vanish. It is possible, however, to set C_2 so as to make the ratio V_{AB}/V_0 a minimum. As will be shown in the theory, when $C_3=C_4$, X_2, the reactance of C_2, is then equal to the impedance in the load arm DB, that is, the combination of Z with C_0. C_2 is calibrated so as to include the stray capacitance in the arm BE. G is a germanium rectifier, V the d.c. output voltage measured with a vacuum tube voltmeter, C_5 a by-pass capacitor to keep h-f currents from V, while r_1 and r_2 are high resistances. The output circuit between A and B is described in Section 7.

3. In its present form the bridge is in a metal cabinet, 10×5×3 in., containing the capacitors C_3 and C_4, each of approximately 24 $\mu\mu$f; the variable capacitor C_2 with a range up to 36 $\mu\mu$f; a high resistance germanium rectifier; and resistors of one megohm each in the leads from points A and B to the output voltmeter. The input voltage V_0 is taken directly from a signal generator having a maximum output of 5 volts. For higher voltages an amplifier is used. V_0 is measured with a vacuum tube voltmeter.

The usual range of values of V_0 is from a few hundredths of a volt to about 10 volts. Values as high as 60 volts have been used. With a load of high Q, the output voltage may be several times as great as V_0. When Q is small, V may be less than a thousandth of V_0.

In the first tests a microammeter was used to measure V. It was replaced later by a d.c. amplifier, which is more sensitive, has a higher impedance, and can be used with a graphic recorder or sensitive external meter.

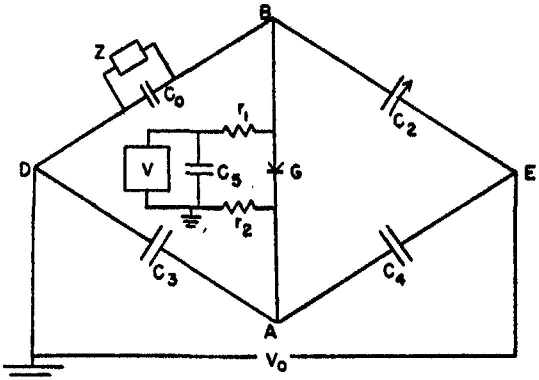

FIG. 1. Schematic diagram of the capacitance bridge.

THEORY OF THE BRIDGE

4. The bridge network is shown in Fig. 2, in which the notation agrees with Fig. 1. For definiteness the load is represented as a piezoelectric resonator or transducer with the customary $RLCC_1$ network. C_1 includes the capacitance C_0 of the arm DB. The expression $Z_s=R_s+jX_s$ used below is applicable, however, to any sort of load.

At present we consider only the ideal case in which the impedance across the branch connecting A and B is infinite. For this reason the rectifying circuit is not shown in Fig. 2.

The following symbols will be used, in which all V's and I's are vectors:

R_s, X_s = equivalent series resistance and reactance of load, including C_0 and r_1 (Fig. 1).
$Z=R_s+jX_s$.
X_2 = reactance of C_2.
Z_5 = impedance of rectifying system between A and B.
V_0 = input voltage.
V_A = potential at $A=jI_3X_3=I_3/j\omega C_3$.
V_B = potential at $B=I_1Z=I_1(R_s+jX_s)$.
$V_{AB}=V_A-V_B$ = potential drop across AB.
V = d.c. rectified output voltage (Section 7).
M = absolute value of V_{AB}/V_0.

We have

$$V_A/V_0=C_4/(C_3+C_4) \tag{1}$$

and

$$\frac{V_B}{V_0}=\frac{Z}{Z+jX_2}=\frac{R_s+jX_s}{R_s+j(X_s+X_2)}. \tag{2}$$

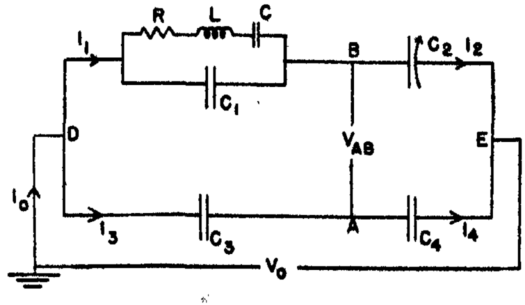

FIG. 2. The basic network of the bridge.

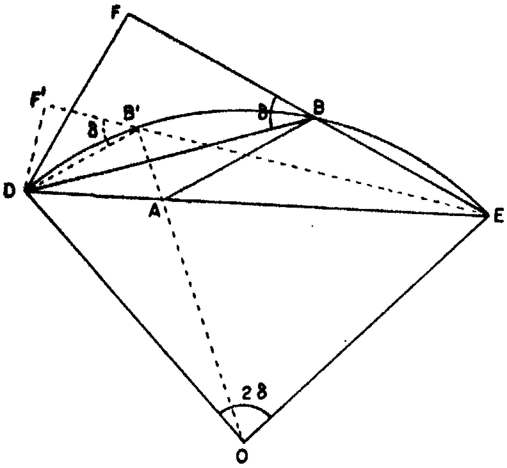

FIG. 3. Vector diagram showing distribution of e.m.f. components.

Hence,

$$\frac{V_{AB}}{V_0}=\frac{C_4}{C_3+C_4}-\frac{R_s+jX_s}{R_s+j(X_s+X_2)}. \qquad (3)$$

5. Equation (3) is general, holding for all loads and for all values of C_2, C_3, and C_4. It can be interpreted by reference to the vector diagram (Fig. 3), drawn for the case in which the absolute value of Z is less than that of X_2. Here $DE=V_0=DA+AE=I_3X_3+I_3X_4$. DE is also the vector sum of DF and FE, where $DF=I_1R_s$ and $FE=FB+BE=I_1X_s+I_1X_2$, with $X_2=-1/\omega C_2$, and $DB=I_1Z$. Then AB represents the potential drop V_{AB}.

The loss angle δ for the load is given by

$$\tan\delta=R_s/X_s=DF/FB. \qquad (4)$$

Since δ is independent of C_2, it follows that when C_2 is varied while DE remains constant, the point B must move along a locus such that the angle $DBE=180°-\delta$ is constant. This locus is a circular arc of radius $OE=V_0/(2\sin\delta)$. When C_2 is varied so that B coincides with B', on the radius passing through A, C_2 has the value that makes V_{AB}/V_0 a minimum. This is because AB' is the shortest distance from A to a point on the arc. At this adjustment for minimal V_{AB}/V_0, the lengths DB', DF', and $F'B'$ are respectively proportional to Z, R_s, and X_s.

If the fixed capacitances C_3 and C_4 are equal, the point A falls midway between D and E, as shown in Fig. 4. The shortest distance from A to the arc is now AB perpendicular to DE, so that B corresponds to the value of C_2 for minimal V_{AB}/V_0, and $DB=BE$. V_{AB} and V_0 differ in phase by 90°. From the geometry of the diagram it is seen that the angle $BDA=\delta/2$.

The fact that $DB=BE$ means that the moduli of X_2 and Z are equal, or

$$|Z|=|X_2|. \qquad (5)$$

In terms of admittance,

$$|Y|=|B_2|. \qquad (6)$$

Equations (5) and (6) show that when $C_3=C_4$ the bridge is "balanced" when the impedances in the other two arms are numerically equal. Owing to the difference in phase between I_1 and I_2 in Fig. 1, however, the balancing consists in bringing V_{AB} to a minimum. V_{AB} becomes zero at balance only when Z is a pure capacitance.

Making $C_3=C_4$ offers the double advantage of expressing the load impedance Z immediately in terms of C_2 by the use of Eq. (5), while at the same time making AB in Fig. 4 (and hence the minimal ratio V_{AB}/V_0) greater than the corresponding distance (as AB' in Fig. 3) for any other ratio of C_3 to C_4. Thus V_0 can be made quite small while still permitting a precise determination of the minimum of V_{AB}/V_0 as C_2 is varied.

In all that follows it will be assumed that $C_3=C_4$. Equation (3) now becomes simplified to

$$\frac{V_{AB}}{V_0}=\frac{1}{2}-\frac{R_s+jX_s}{R_s+j(X_s+X_2)}. \qquad (7)$$

Equation (5) can be derived from (7) by minimizing the modulus with respect to X_2.

6. The following relations, which will also be used later, serve to illustrate the performance and limitations of the bridge. Letting M stand for the minimum of $|V_{AB}/V_0|$ obtained by varying C_2 while V_0 is constant, we have

$$M=\min|V_{AB}/V_0|=\tfrac{1}{2}\tan(\delta/2). \qquad (8)$$

We have also the general relation

$$\tan\delta=R_s/X_s=G/B, \qquad (9)$$

where G and B are the conductance and susceptance of the load.

When the power factor is low enough to permit the approximation $\tan\delta\approx\delta$, we may write

$$M\approx\delta/4\approx R_s/4X_s\approx G/4B. \qquad (10)$$

The smaller δ is, the flatter is the arc in Fig. 4, and the more sharply can the minimum of V_{AB}/V_0 be determined. When $R_s=0$, $\delta=0$, and $V_{AB}=0$. We have then a pure capacitance bridge of the usual type.

On the other hand, as δ increases, the point 0 moves up toward A, the setting of C_2 for minimal V_{AB}/V_0 becomes less sharp, and when $\delta=90°$, $X_s=0$, 0 coincides with A, and the arc is a semicircle. The output voltage

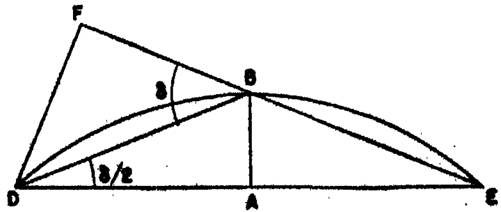

FIG. 4. Distribution of e.m.f.'s after C_2 has been adjusted to make AB/DE a minimum.

V_{AB} is then constant for all values of C_2. Varying C_2 changes the *phase* of V_{AB} with respect to V_0. If C_2 could be varied from zero to infinity the phase would change from $-90°$ to $+90°$. The bridge can thus be made to serve as a constant-voltage phase regulator at any frequency.

When X_s, which is negative as long as the load is capacitive, passes through zero and becomes positive, we have the case of an inductive load which, dropping the former subscripts, may be expressed simply as $Z=R+j\omega L=R+jX_L$. The point 0 is now located *above* A (*cf.* Fig. 3), and the arc is greater than a semicircle, approaching a complete circle as R approaches zero.

This case is illustrated in Fig. 5, where $DF=I_1R$, $FB=I_1X_L$, $DB=I_1Z$, and $BE=I_2X_2$. In contrast to the case represented in Fig. 4, where the load was capacitive, it is no longer possible to set C_2 for a minimum of $V_{AB}/V_0=AB/DE$. On the contrary, it is when this ratio is a *maximum* (point B in Fig. 5) that the absolute values of Z and X_2 are equal. This maximal setting is not sharply defined, as may be seen from the fact that B can move over a considerable range around the circle without greatly changing the distance AB. It should be noted that in setting C_2 for maximal V_{AB}/V_0 we have approximated the condition for series resonance between Z and X_2. When R/X_L is small, DF is almost as large as DE, almost the entire input voltage V_0 acts across R, and the current I is relatively very great.

The capacitance bridge is best adapted to measuring capacitive loads with loss angles not much over 45°.

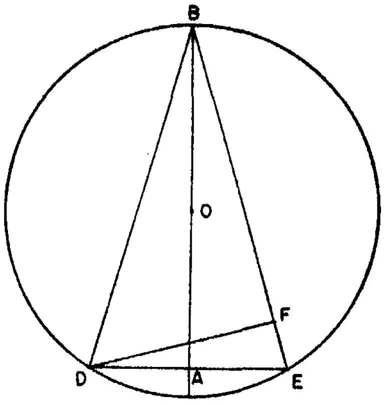

FIG. 5. E.m.f. diagram for inductive load.

THE DIRECT-CURRENT MEASURING CIRCUIT

7. Thus far the potential difference V_{AB} between points A and B (Figs. 1 and 2), has been treated as if there were infinite impedance in the output circuit between these points. Account must now be taken of the impedances in this circuit.

For a rectifier, germanium was chosen on account of its high rectification efficiency, low capacitance, and nearly linear characteristic for all but the lowest voltages. The present unit has nearly constant efficiency (ratio of d.c. output voltage to peak input voltage) for input above 0.05 volt, diminishing rapidly for voltages less than this. When the rectifier is in the bridge, its input voltage is the V_{AB}' of Eq. (11), which in practice may be much less than 0.05 volt. The rectifier then operates on the non-linear part of its characteristic. The rectifier described here has an effective resistance of the order of 30,000 ohms (depending somewhat on frequency and input voltage), shunted by its capacitance of about 0.5 $\mu\mu$f. At 15 Mc the impedance is therefore around 20,000 ohms.

The rectifier is shown at G in Fig. 1. It is connected through resistances r_1 and r_2 of one megohm each and condenser C_5 of a few hundred $\mu\mu$f (located close to G in the bridge cabinet), to an output jack. From here a concentric cable runs to the d.c. vacuum tube voltmeter V. The total impedance between A and B is designated by Z_5. Since this quantity includes the rectifier it is non-linear. Moreover, it depends somewhat on frequency and on V_{AB}. Nevertheless, its value in ohms can be roughly estimated, and it serves as a measure of the ratio of V_{AB}', the actual voltage between A and B, to the ideal voltage V_{AB} for infinite Z_5.

Let Z_t be the impedance of the entire bridge network as seen from AB (Fig. 1). The internal impedance of the input generator may usually be considered as zero. It can be shown that

$$V_{AB}\approx V_{AB}'[1+(Z_t/Z_5)]. \tag{11}$$

Since in general Z_t and Z_5 are complex, V_{AB}' differs from V_{AB} in both magnitude and phase.

For example, in the bridge described here, at 15 Mc, Z_t and Z_5 are of the order of 400 and 20,000 ohms respectively, so that $|V_{AB}'|$ is within about two percent of $|V_{AB}|$.

The current that becomes rectified is $I_5=V_{AB}'/Z_5$. The d.c. output voltage V is a function of V_{AB}', say $V_{AB}'=f(V)$. Then from Eq. (11),

$$V_{AB}=|1+(Z_t/Z_5)|f(V). \tag{12}$$

In the methods described below it is unnecessary to know the form of the function $f(V)$. It is enough to know that it is monotone increasing, so that a minimum of V_{AB} is indicated by a minimum of V.

BRIDGE CALIBRATION

8. For C_3 and C_4 two equal capacitors are symmetrically located in the cabinet. Their values do not appear in the final equations, but for maximum sensitivity they should be of the same order of magnitude as C_2.

C_0 (Fig. 1) is best determined by temporarily severing the connection between C_2 and E and that between G and the junction-point for r_2. When the load jack is connected to a measuring network, C_0 can be measured with C_2 set at various values. The slight dependence of C_0 upon C_2, which is inevitable unless C_2 is well sheilded, is thus determined.

To calibrate C_2 it is only necessary to balance the bridge with various known capacitances C in the load arm. A curve can then be plotted relating the dial setting of C_2 to the total capacitance between B and E (Fig. 1), which is $C_2=C+C_0$.

For measuring an unknown impedance and for obtaining resonance curves and values of Q, no further calibration is necessary.

C_0 can also be measured without severing any connections, by the use of two known loads with two different known loss angles.[6] Owing to the presence of small differences in the formula it is difficult to obtain accurate results, especially for the dependence of C_0 upon C_2.

MEASUREMENT OF THE COMPONENTS OF AN IMPEDANCE

9. In Sections 5 and 6 it was shown that the absolute admittance of an unknown load Y_x can be measured in terms of C_2 when the bridge is balanced; and that the precision is best with capacitive loads in which the loss angle is not too large. To determine the components G_x and C_x of the load one can use a substitution method, as described in reference 6. A second method consists in observing C_2 for balance with the given load, and C_2' when a known capacitance C has been connected in parallel with the load. These data yield two equations from which G_x and C_x can be found.

Enough measurements of various loads have been made to demonstrate the limitations and the possibilities of bridges of this type for absolute measurements. With the present model a precision of from two to five percent in the measurement of a total impedance is attained, but the determination of components with like precision would demand refinements such as are mentioned in Section 12. On the other hand the present model serves well in relative determinations, as in comparing the acoustic resistances of different liquids.

RESONANCE CURVES

Theory

10. With its d.c. voltage V connected to a graphic recording instrument, the capacitance bridge with a crystal in the load arm can be made to serve two useful purposes. The first is to function as a mode analyzer, the second is to furnish a means for measuring the crystal constants. In both cases the bridge is first balanced at a frequency well below resonance by setting C_2 for minimal V/V_0. This adjustment can be made very precisely, since the crystal is now nearly a pure capacitance, and V/V_0 becomes practically zero, unaffected by Z_5. When balance has been achieved, $C_1=C_2-C_0$ (see Section 8). In the equations that follow C_1 will signify the parallel capacitance of the crystal plus C_0. Then, at this low frequency, $C_1/C_2=C_3/C_4$.

The frequency is then slowly varied over the resonance range, while C_2 is left constant. Near any resonant frequency the crystal admittance undergoes characteristic changes which are automatically recorded. Since the delineating of a complete record requires only a few minutes, an exact comparison can be made in a short time between different crystals, or between the effects produced by different mountings or different mechanical loads on the same crystal.

As stated in Section 3, the input to the bridge is taken directly from a signal generator. From the bridge output a short cable runs to the amplifier, which in turn drives the pen of a 5 ma d.c. recorder. The frequency-control shaft of the signal generator is connected by a chain drive to a slow-speed synchronous motor. By this means the change in frequency in one minute with a d.c. recorder can be varied in steps from 0.6 to 10 percent. Since the paper of the recorder is also driven by a synchronous motor, the signal generator and the paper are accurately synchronized, so that successive recordings can be made with exactly the same frequency scale.

Resonance curves can of course also be obtained by a point-by-point method. At each frequency the input voltage V_0 and the d.c. output voltage V are observed; if V_0 is constant, a curve can be plotted for V against frequency. Although slow, this method offers the advantage of enabling the observer to hold V_0 constant at all frequencies. A still greater advantage is the possibility of holding V constant while V_0 is varied, thus yielding a $V_0{:}f$ curve free from distortion due to nonlinearity in the rectifier. This latter method works well over the resonance range. For points far from resonance V_0 becomes inconveniently large.

In the present case it is most convenient to express the output voltage V_{AB} by considering the potentials at A and B with respect to the point E in Fig. 1. Equation (18) below is then easily derived; as in the case of Eq. (3), the assumption is made that Z_5, the impedance of the output circuit, is infinitely great. It is also assumed that V_0 is constant. In the present apparatus the reaction due to the load is negligible, but the characteristics of the signal generator are such that V_0 varies somewhat with frequency. This variation is easily taken into account in determining Q.

$$\frac{V_{AB}}{V_0}=\frac{C_3}{C_3+C_4}-\frac{jX_2}{R_e+j(X_e+X_2)}=\frac{C_3}{C_3+C_4}+j\frac{Y_2'}{\omega C_2}, \quad (18)$$

where $Y_2'=1/[R_e+j(X_e+X_2)]=$ admittance of the crystal and C_2 in series. Equation (18) is only another way of writing Eq. (3). It holds at all values of C_2.

When the network $RLCC_1$ in Fig. 1 is in series with C_2, the combination is equivalent to the series chain $R'L'C'$ in parallel with a capacitance C_1', where, calling

---

[6] For details see Technical Report No. 6, cited above.

$(C_1+C_2)/C_2=n$, we have[7]

$$\left.\begin{array}{l} R'=n^2R \quad L'=n^2L \quad C'=\dfrac{C}{n^2[1+C/(C_1+C_2)]} \quad C_1'=C_1/n \\ Z'=1/Y'=R'+jX' \quad X'=\omega L'-(1/\omega C') \end{array}\right\}. \tag{19}$$

The admittance of $RLCC_1C_2$, expressed in terms of $R'L'C'C_1'$, is

$$Y_2'=\frac{R'-jX'}{Z'^2}+j\omega C_1'\equiv Y'+j\omega C_1'. \tag{20}$$

From Eqs. (18) to (20),

$$\frac{V_{AB}}{V_0}=\frac{C_3}{C_3+C_4}+j\frac{Y'}{\omega C_2}-\frac{C_1'}{C_2}$$

$$=\frac{C_3}{C_3+C_4}-\frac{C_1}{C_1+C_2}+j\frac{Y'}{\omega C_2}. \tag{21}$$

If, as stated above, the bridge is so adjusted that $C_1/C_2=C_3/C_4$, it follows that

$$\frac{V_{AB}}{V_0}=j\frac{Y'}{\omega C_2}. \tag{22}$$

Finally, if, as is the case with the bridge described here, $C_3=C_4$, it follows that $C_1=C_2$, so that Eq. (22) may be written as

$$\frac{V_{AB}}{V_0}=j\frac{Y'}{\omega C_1}. \tag{23}$$

Thus when the ratio V_{AB}/V_0 and ωC_1 (or ωC_2) are known, Y' can be found at any frequency.

The components of Y' could be found at once if we knew the phase relation of V_{AB} to V_0. Since in general this is not known, we take the modulus of Eq. (23). By use of Eqs. (19) and (12) it is found that

$$M=\left|\frac{V_{AB}}{V_0}\right|=\frac{f(V)}{V_0}\left|1+\frac{Z_t}{Z_5}\right|=\frac{|Y'|}{\omega C_1}$$

$$=\frac{1}{C_1}\left[\omega^2R'^2+\left(\omega^2L'-\frac{1}{C'}\right)^2\right]^{-\frac{1}{2}}. \tag{24}$$

The ordinates of recorded curves are proportional to V. As the frequency varies, $Y'/\omega C_1$ varies, and these variations are accompanied by corresponding changes in V. The relation between V and $Y'/\omega C_1$ is approximately parabolic when V is very small, approaching linearity with increasing V.

Equation (24) is for an idealized resonance curve. It is subject to two practical limitations. In the first place it is valid only over a frequency range within which R', L', and C' can be regarded as constant. The frequency spectrum of an actual crystal with small damping usually contains a large number of peaks, one of which can be identified as the main peak to which Eq. (24) especially applies. Still, the equation can be used also for deriving the equivalent constants for any "peak" or vibrational mode sufficiently isolated for R', L', and C' to be considered as constant over a reasonable range.

The second limitation is that in the actual bridge the impedance Z_5 of the output circuit is finite, involving the sources of error discussed in Section 7. Nevertheless this circumstance distorts the curve by no more than a few percent, at least as long as V is greater than 0.05 volt. By the procedure described in the next section, this source of error is eliminated in the determination of Q.

When the crystal radiates into a liquid the damping is so great that a very broad resonance curve results, in which the separate peaks usually lose their identity. In this case Eq. (24) is, to a good approximation, applicable over a wide frequency range.

Whether the damping is large or small, for any peak sufficiently isolated for R', L', and C' to be regarded as constant, we can find the peak frequency f_M by equating to zero the derivative of Eq. (24) with respect to ω. The result is

$$\omega_M^2=\omega_0'^2[1-(1/2Q'^2)], \tag{25}$$

where, if C_1 differs from C_2, with $(C_1+C_2)=nC_2$,

$$\omega_0'^2=\frac{1}{L'C'}=\left(1+\frac{C}{C_1}\frac{n-1}{n}\right)\omega_0^2=4\pi^2f_0'^2. \tag{26}$$

In Eq. (25) Q' is the quality factor of the crystal in series with C_2, defined by

$$Q'=\frac{\omega_0'L'}{R'}=\frac{\omega_0'}{\omega_0}\frac{\omega_0L}{R}=\frac{\omega_0'}{\omega_0}Q \tag{27}$$

where Q is the quality factor for the RLC series chain. The difference between Q' and Q is extremely small.

When, as in the present case, $n=2$, Eq. (26) becomes

$$\omega_0'^2=[1+(C/2C_1)]\omega_0^2. \tag{28}$$

From Eqs. (25) to (28) f_M can be expressed in terms of f_0, the series resonant frequency for RLC, for the case where $C_2=C_1$:

$$f_M\approx\left(1+\frac{C}{4C_1}-\frac{1}{4Q'^2}\right)f_0. \tag{29}$$

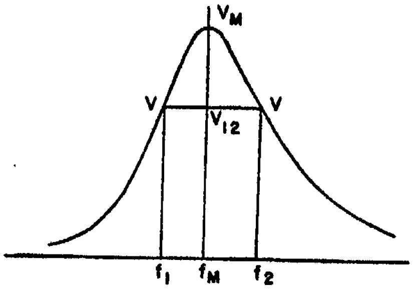

FIG. 6. Resonance curve, illustrating procedure for measuring Q.

Example: for a certain X-cut quartz plate radiating into water at 15 Mc, $C_1/C=144$, $Q=15$, so that from Eq. (29) $f_M=(1+0.00063)f_0$.

In all cases f_M is very close to f_0. For crystals of large Q, $f_M\approx(1+C/4C_1)f_0$. This value is midway between f_0 (series resonance) and $(1+C/2C_1)f_0$, the commonly used expression for antiresonance. The expression for f_M is also almost identical with that for $f_0'=1/2\pi(L'C')^{\frac{1}{2}}$, the frequency for series resonance of the combination $RLCC_1C_2$. As Q decreases, for example by increasing the mechanical load on the crystal, f_M also decreases, and becomes less than f_0 when $Q'^2<C_1/C$.

Measurement of Q

Method 1

11. With a crystal or transducer in the load arm of the bridge, the frequency f_M is found at which the d.c. output voltage V is a maximum, say V_M, while V_0 is constant. With V_0 at the same value, two frequencies f_1 and f_2 are selected at which V is the same, this value being anywhere from half to three-quarters of that at the peak. Then the frequency is again set at f_M, and the input voltage V_0 is decreased until the output voltage is diminished from V_M to the same V that was previously observed at the frequencies f_1 and f_2. The advantage in this method is that the effect of nonlinearity between V and V_0 is eliminated.

This procedure is illustrated in Fig. 6, in which $V_{12}=V$ is the value of the output voltage at frequency f_M after V_0 has been decreased from its original value to one that we will call $(V_0)_{12}$.

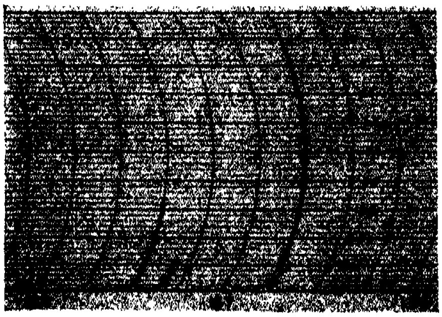

FIG. 7. 1.67 Mc crystal free in air. Diameter 1.27 cm, fully plated on one side, diameter of plated area on other side 0.95 cm.

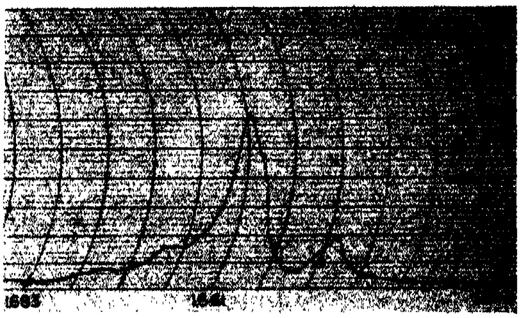

FIG. 8. Same crystal as in Fig. 7, but in cartridge. Note decrease in Q due to clamping.

Method 2

If a resonance curve at constant V_0 is drawn by a recording instrument the same procedure is followed, suitable marks being made on the curve. Two or more pairs of points may of course be selected, V_0 being reduced in each case to the appropriate value at frequency f_M.

Whichever method is used, Q is to be expressed in terms of V_0, $(V_0)_{12}$, f_1, f_M, and f_2. The admittance Y' of the $R'L'C'$ series chain described in Section 10 is

$$Y'=\frac{1}{(R'^2+X'^2)^{\frac{1}{2}}}\approx\frac{1}{\{R'^2+[2L'(\omega-\omega_0')]^2\}^{\frac{1}{2}}}\tag{30}$$

where ω_0' is the angular frequency for maximal Y', according to Eq. (26). Maximal Y' is $Y_m'=1/R'$. From the foregoing, calling $\omega_0'L'/R'=Q'$, and Y' the admittance at f_1 and f_2, it is found that

$$Q'\approx\frac{f_0'}{f_2-f_1}\left[\left(\frac{Y_m'}{Y'}\right)^2-1\right]^{\frac{1}{2}}.\tag{31}$$

Since in the present case the output V is the same at f_1 and f_2, it follows from Eq. (11) that V_{AB} is also the same. Therefore from Eq. (24), in terms of moduli,

$$M=\frac{V_{AB}}{V_0}=\frac{Y_1'}{\omega_1C_1}=\frac{Y_2'}{\omega_2C_1},\tag{32}$$

FIG. 9. Same crystal as in Fig. 7, free, in air, at third harmonic (5 Mc).

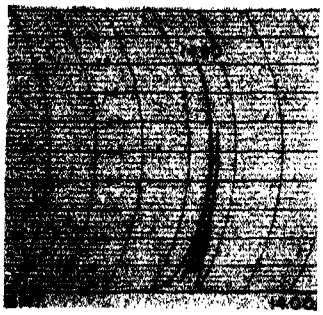

FIG. 10. Crystal 1.9 cm diameter, mounted in a special cell, air on both sides. One side fully plated, diameter of plated area on other side 1 cm.

where Y_1' and Y_2' are the admittances at f_1 and f_2. Y_1' and Y_2' are not quite equal, but they approach the common value Y' when $\omega_2-\omega_1 \ll \omega_M$. In this case $V_{AB}/V_0 \approx Y'/\omega_M C_1$.

At the frequency f_M we have maximal output voltage. As stated above, f_M is also almost exactly the frequency f_0' at which Y' has its greatest value Y_M'. Therefore $V_{AB}/(V_0)_{12} \approx Y_M'/\omega_M C_1$. Moreover, Eq. (27) shows that $Q \approx Q'$. Equation (31) can therefore be written in the form

$$Q \approx Q' \approx \frac{f_M}{f_2-f_1}\left[\left(\frac{V_0}{(V_0)_{12}}\right)^2-1\right]^{\frac{1}{2}}. \tag{33}$$

POSSIBLE REFINEMENTS TO THE BRIDGE

12. It should be stated first that capacitors rather than resistors were chosen for the ratio arms C_3 and C_4 owing to the difficulty in obtaining reactance-free resistors at megacycle frequencies.

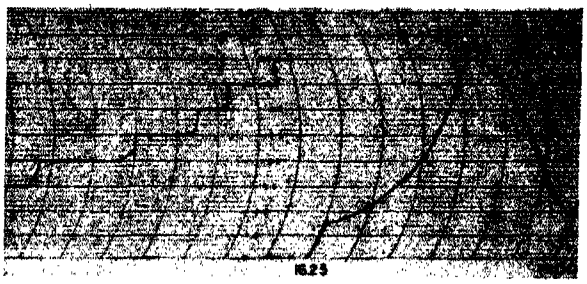

FIG. 11. Carbon tetrachloride in contact with crystal on one side. The left-hand portion of the figure shows how Q is measured according to Method 2, Section 11. Owing to the sources of error mentioned in Section 7 the measured values of Q varied from 14.7 to 15.4 with varying V_0.

If the bridge is to be used only as a mode analyzer, one terminal of C_2 can be grounded by interchanging C_2 and C_3, Fig. 1. For measuring impedances and their components the circuit has to be as in Fig. 1.

In the construction of a model for more precise measurements all parts of the bridge should be properly shielded. Insulation should be of the best. Means should be sought for a more accurate measurement of voltages. When these matters have been cared for, the chief source of error for which correction must be made will be the finite impedance of the rectifying circuit, discussed in Section 7.

RECORDINGS OF RESONANCE CURVES

13. Figures 7 to 11 are reproductions of original recordings with X-cut quartz crystals. Frequencies are given in Mc/sec. Ordinates are approximately proportional to $Y'/\omega C_1$ (Section 10).

Transmission Line Reflection Doubling Amplifier*

JOHN MARSHALL
Institute for Nuclear Studies, University of Chicago, Chicago, Illinois

(Received October 7, 1950)

A pulse amplifier has been constructed using voltage doubling by reflection at the open end of a transmission line. Cathode followers are used to couple the output of one line into the input of the next. An amplifier using in each stage the four triode units of two 6J6's in parallel driving 16 feet of 100-ohm line has theoretically a voltage gain of 1.32 per stage. With appropriate grid series compensation the gain can be made constant, theoretically, to 100 megacycles. Experimentally the gain is 1.3 per stage with a rise time less than 6×10^{-9} sec. Below 50 volts, distortion is not serious for pulses shorter than twice the transmission time of the line. Pulses up to 150 volts can be handled by the amplifier.

INTRODUCTION

A WIDE-band pulse amplifier has been constructed using the principle of voltage doubling by reflection at the open end of a transmission line. In essence, the amplifier is a series of lengths of coaxial line driven at the input end of each line by a cathode follower, and driving at the unterminated output end the grid of the next cathode follower. At frequencies where the grid has a high impedance relative to that of the line, the pulse amplitude is doubled at each grid, and the gain per stage is twice that of the cathode follower operating into line impedance.

The circuit of the amplifier is shown in Fig. 1. A description of the circuit is given below.

GENERAL CONSIDERATIONS

The gain of a cathode follower operating into a resistive load is, at low frequencies,

$$A=\frac{g_m}{g_m+(1/R_p)+(1/R_L)},$$

where g_m is the transconductance of the tube, R_p is its plate resistance, and R_L is the load resistance.

At high frequencies, the interelectrode capacitances become important and the gain is

$$A=\frac{g_m+j\omega C_{gk}}{g_m+(1/R_p)+(1/R_L)+j\omega(C_{kp}+C_{gk})},$$

where ω is 2π times the frequency, C_{kp} is the cathode-plate capacity which here includes the capacity between cathode and filament. C_{gk} is the grid-cathode capacity.

The admittance of the grid of a cathode follower, assuming that it never goes positive with respect to the cathode, is

$$Y=j\omega[C_{gp}+(1-A)C_{gk}],$$

where C_{gp} is the grid-plate capacity, A is the gain of the cathode follower which in general is a complex quantity smaller than one. The quantities A and Y can be derived easily using the equivalent circuit shown in Fig. 2.

If the output of a cathode follower is fed into the end of a lossless line of infinite length, the cathode follower behaves as if its load impedance were a resistor of value Z_0, the characteristic impedance of the line. If the line is finite in length, this condition still holds true provided that the pulse is shorter than twice the transmission time of the line. After this time, the signal reflected from the far end may interfere with the operation of the cathode follower.

Suppose a wave of amplitude E_1 to be traveling along a line the end of which is loaded with an impedance Z. A reflected wave is generated at Z with amplitude

$$E_2=E_1\frac{Z-Z_0}{Z+Z_0}.$$

E_2 is complex and contains the phase of the reflected

---

* This work was done with the joint support of the ONR and AEC.

wave as well as its amplitude. The voltage generated across Z is the sum of E_1 and E_2.

$$E_0=E_1+E_2=E_1\left(1+\frac{Z-Z_0}{Z+Z_0}\right)=E_1\frac{2Z}{Z+Z_0}.$$

Now consider an inductance L to be placed between the line and the grid of a cathode follower, the grid impedance of which is $1/Y$. The voltage appearing at the grid of the tube will be

$$E_g=\frac{1E_0/Y}{(1/Y)+j\omega L}=\frac{2E_1}{1+Y(Z_0+j\omega L)}.$$

The voltage gain per stage is

$$G=\frac{2A}{1+j\omega[C_{gp}+(1-A)C_{gk}][Z_0+j\omega L]},$$

where

$$A=\frac{g_m+j\omega C_{gk}}{g_m+(1/R_p)+(1/Z_0)+(1/R_k)+j\omega(C_{gk}+C_{kp})}.$$

The expression for A has changed here slightly in that $1/R_L$, the load conductance, has been replaced by $(1/R_k)+(1/Z_0)$ since it is necessary to have a cathode resistor in parallel with the input of the line to carry direct current.

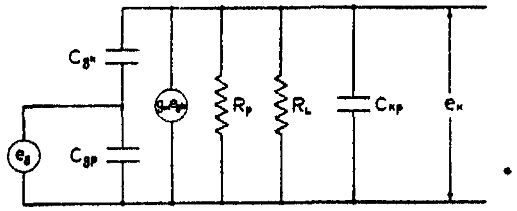

FIG. 2. Equivalent circuit for cathode follower.

The value of G has been calculated as a function of frequency assuming the following circuit constants: $g_m=21{,}200$ micromhos; $R_p=1500$ ohms; $C_{gk}=8.8$ pf.; $C_{kp}=12$ pf. including C_{kf}; $C_{gp}=6.4$ pf.; $R_k=2200$ ohms; $Z_0=100$ ohms.

The tube constants are the published values for the four triode units of two 6J6's in parallel. The other constants are those used in the amplifier, the circuit of which is shown in Fig. 1. The calculated values of G are given in Table I, and the absolute values are plotted in Fig. 3. Several values of the series inductance, L, have been used in the calculations. Inspection of Fig. 3 shows that, theoretically, the gain can be made approximately constant at about 1.3 per stage up to 100 Mc by using a series inductance of 0.05 microhenry in each grid circuit. The gain is a complex quantity, of course, because of phase shifts in the cathode follower and in the line termination. The phase shift is approximately linear with frequency, being about 45° for $L=0.05$ microhenry at 100 megacycles.

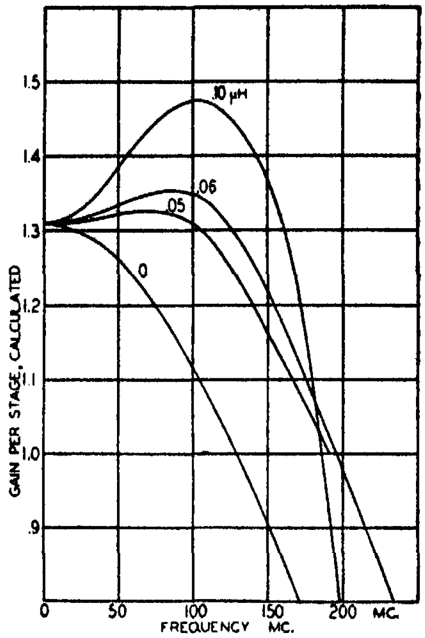

FIG. 3. Gain per stage *vs.* frequency for various values of grid series inductance.

DISCUSSION OF CIRCUIT

The tube type used is the 6J6 because of its high transconductance and ability to handle large bursts of cathode current. Two amplifiers were constructed, the first one using the two units of one 6J6 in parallel driving 20 feet of 250-ohm line for each stage. This amplifier performed satisfactorily, but was quite bulky and rather expensive because of the type line used. It had a gain of about 1.4 per stage which agreed quite well with the theoretical value.

A second amplifier was constructed using RG7U coaxial cable in 16-foot lengths. At this impedance level (100 ohms), it is necessary to use a transconductance greater than that afforded by a single 6J6. In consequence, two 6J6's were used in parallel in each stage. At first there was some trouble from high frequency oscillations in the parallel tube circuits. This trouble was overcome by orienting the tubes so that the connecting leads were as short as possible and by isolating the plates of the two 6J6's from each other with separate 10-ohm resistors to the +300 volt bus.

To make the gain as high as possible, it is necessary to use a cathode resistor large compared with the impe-

TABLE I. Gain per stage, as function of frequency and grid series inductance.

Frequency megacycles	$L=0$	0.05 μh	0.06 μh	0.10 μh
0	1.310	1.310	1.310	1.310
50	1.18 −0.45j	1.25 −0.48j	1.24 −0.49j	1.29 −0.52j
100	0.86 −0.71j	0.93 −0.92j	0.93 −0.97j	1.13 −0.95j
150	0.50 −0.76j	0.33 −1.12j	0.25 −1.20j	−0.23 −1.35j
200	—	—	−0.27 −0.94j	−0.52 −0.58j

dance of the transmission line. 2200-ohm resistors are used and, because of this high resistance, it becomes necessary to bias the grids positively. A grid bias of 50 volts above ground is used which gives a current of about 13 milliamperes per 6J6. Condensers and grid resistors are used to isolate each grid from direct connection to the cathode of the previous tube and to provide grid bias. Ceramic condensers are used with a capacity of 0.01 microfarad, and the grid resistors are 56,000 ohms to make them large compared to line impedance.

Some thought was given to the problem of reducing the effect of the filament-cathode capacity. If this capacity were reduced to zero, the gain of the cathode follower would increase with frequency and the amplifier would be able to handle faster pulses. Isolation of the filaments from ground with chokes is rather difficult because of distributed capacities in the chokes. It might be possible to heat the filaments with radiofrequency current through low capacity transformers, but neither of these methods was tried.

In principle, it should be possible to achieve a larger gain by using tapered lines. For instance, the central wire of the transmission line could be tapered in diameter so that the impedance would be 100 ohms at the cathode end and 200 ohms at the grid. This would give an additional voltage doubling besides that given by open end reflection. This was not tried because of the complication of preparing tapered lines. There would be certain disadvantages in the method because the frequency cut-off of the amplifier is due principally to reactive mismatch at the grid at high frequencies. This mismatch is worse with a high impedance line.

PERFORMANCE

The behavior of the amplifier was investigated with pulses from a Kay Megapulser. Its shortest pulse has a total length of about 0.04 microsecond and a rise time of about 0.015 microsecond. The pulses were reduced in amplitude with a resistor network so that they were barely visible on the screen of an oscilloscope.

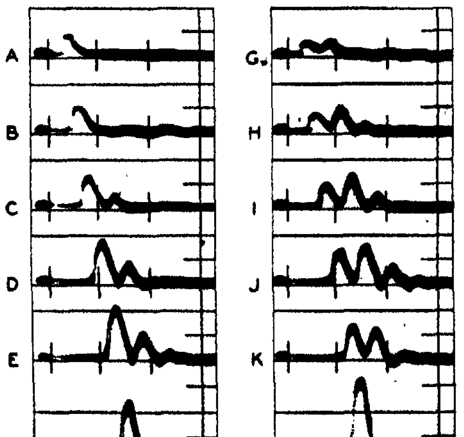

FIG. 4. Pulse of 0.04-μsec. length traced through amplifier with probe. A to E—grids 1 to 5; G to H—cathodes 1 to 5; F—end of output cable; L—output cable directly into oscilloscope. Sweep speed—0.1 μsec. per division.

A triode inverter probe was constructed to make it possible to observe pulse height and shape at various points in the amplifier without serious loading. A 6J6 was used with its two units in parallel. The cathode drove a terminated 173-ohm line connected to one deflection plate of the oscilloscope, while the plates were connected to the other deflection plate through an equal length of line also terminated. The grids were connected to a short, stiff length of wire which could be used as a probe. Appropriate blocking condensers and bias were used so that the tube could be operated with 300 volts on the plates.

Figure 4 is a composite photograph of the oscilloscope screen with the probe connected to a number of points in the amplifier. The encircled letters in Fig. 1 correspond to the labeling of the different traces of Fig. 4. Traces *A* through *E* were obtained at the grids of the successive amplifier stages. *G* through *K* are the cathodes of the same stages. The oscilloscope sweep speed was approximately 0.1 μsec. per division along the horizontal axis. The cathode pulses can be seen to have generally a two-peak structure, consisting of the original cathode pulse plus a reflection from the grid of the next stage. The grid pulses have an amplitude which increases from stage to stage by a factor of approximately 1.32 which agrees very well with the theoretical value as given in Fig. 3.

Trouble is to be expected from pulses reflected again from the cathode of a previous tube. The cathode impedance of a tube looking toward it from a line is approximately the reciprocal of its transconductance for small pulses or for pulses whose current direction is that in which d.c. can be transmitted through the tube. For small pulses, then, the line is terminated at the cathode end with a resistance of about $1/g_m$ or 50 ohms for the tubes used. This would be expected to produce reflections of one-third the amplitude and of opposite sign from the pulse arriving at the cathode. The grid of the next stage, then, receives first a positive pulse and then a negative one of one-third the amplitude arriving later by twice the transmission time of the line.

For large pulses, the situation is different. In this case, the reflected pulse coming back to a cathode from the grid of the next tube drives the cathode beyond cut-off so that the resistive impedance becomes very large. The result is that for large pulses, the later pulses arriving at the grid of a tube as a result of reflection from the cathode end of the line are characteristic of reflection from a high impedance termination. In other words, they are of the same sign as the first pulse. These secondary pulses are fed through successive stages where they blend with reflections in those stages.

The amplifier, then, at large amplitudes, transmits secondary pulses of the same sign as the first one. These pulses arrive later by integral multiples of twice the transmission time of the line and fall off rather rapidly in amplitude as the order of the reflection increases. In general, the size of the reflected pulses is relatively larger when the amplifier is handling high voltage signals than when the amplitude is small.

It is undesirable, of course, to have secondary pulses following the primary one. It is possible, by the sacrifice of a small amount of gain to remove, almost completely, the secondary pulses in the output circuit of the amplifier. This is done by terminating the cathode end of the output line, which for this purpose must be of the same length as the between stages lines, with a resistor of such a value that reflections from this cathode and transmitted reflections from previous stages cancel each other. The far end of the output line must of course be terminated in roughly the same way as the between stages lines are terminated by the grids. This has been done in the amplifier described here. It was found that the best termination was achieved with a 100-ohm resistor, the characteristic impedance of the line. The result can be seen in traces *F* and *L* of Fig. 4. In *F*, the triode inverter probe was connected to the end of the output line CL5. In *L*, the oscilloscope is driven directly by CL5.

The deflection sensitivity of the oscilloscope photographed in Fig. 4 is such that one vertical division is about 12.5 volts. The output pulse, then, was about 40 volts high. Pulses of considerably more than 100 volts in height can be handled by the amplifier. In general, however, there is more distortion at the higher pulse sizes. Up to 60 volts, there is no noticeable distortion attributable to excess amplitude.

The rise time of the amplifier was investigated using a mercury switch pulse generator designed by R. L. Garwin. This pulse generator has a rise time of less than 10^{-9} sec. so that it can be considered instantaneous as far as this amplifier is concerned. An oscilloscope photograph of the output of the amplifier which is reproduced in Fig. 5 shows a rise time of about 6×10^{-9} sec. from the beginning of the pulse to the top of the rise. It is possible that the rise time of the amplifier might be somewhat less if viewed on an oscilloscope designed for really fast pulses. The one used is a Tektronix type 511-A. The sweep speed in Fig. 5 is approximately 0.05 μsec. per division.

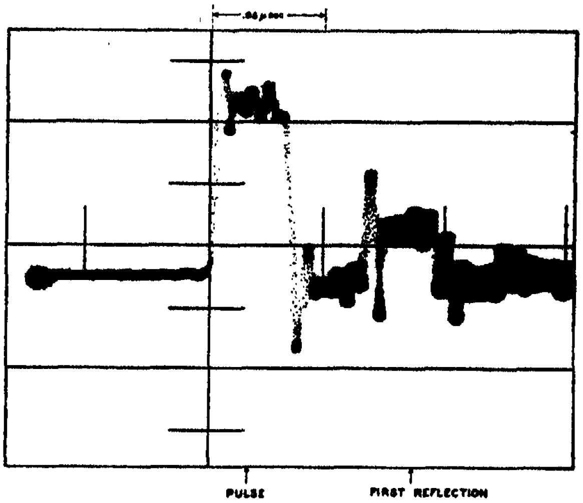

FIG. 5. Response of system to pulse of rise time less than 10^{-9} sec. Sweep speed 0.05 μsec. per division.

The behavior of the amplifier for pulses long compared to the line transmission time is roughly that the amplifier reproduces faithfully the part of the pulse up to 0.04 μsec. and then comes down sharply with reflections that vary very slightly depending on the length of the pulse.

CONCLUDING REMARKS

The line reflection amplifier is extremely simple to construct with no precise adjustments or critical conditions to meet. It is capable of handling pulses at quite high amplitudes and at low impedance levels. In these respects it is superior to the distributed amplifier. On the other hand the distributed amplifier can have a somewhat higher frequency response and can handle pulses of much longer duration.

The writer wishes to thank Mr. R. H. Miller and Mr. P. Shevick for helpful discussions of the properties of the amplifier. Mr. R. E. Mueller and Mr. H. W. Lamberty were responsible for a large part of the actual construction and mechanical design.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 12 DECEMBER, 1950

A Frequency Meter for Microwave Spectroscopy *

JOHN D. ROGERS, HENRY L. COX, AND PAUL G. BRAUNSCHWEIGER
The Mendenhall Laboratory of Physics, The Ohio State University, Columbus, Ohio

(Received July 10, 1950)

A frequency meter using known absorption lines as microwave frequency standards has been developed. By mixing signals of unknown microwave frequency f_s, standard microwave frequency f_0, and known radio-frequency signals nf_c from a crystal-controlled harmonic generator, it is possible to obtain a set of "beat" frequencies f_r which can be detected by a calibrated radio receiver. From the relation

$$f_r = \pm m(f_s - f_0) \pm nf_c$$

it is possible to determine values for the unknown microwave frequency f_s. Tests on methanol absorption lines with ammonia lines as microwave frequency standards show that microwave frequencies can be determined to ±0.03 mc/sec. Advantages of this device over other frequency meters are discussed; the accuracy is ultimately limited by the uncertainties in the value of the standard frequency f_0.

TWO distinct types of high precision frequency meters have been described earlier. The first type[1] involves the use of a series of frequency multipliers to obtain standard microwave frequencies from the standard radio frequencies broadcast from station WWV. Frequency meters of this type have been used to make careful measurements of certain strong absorption lines, which can now be used as secondary frequency standards for the microwave region. The second type[2] of frequency meter employs these spectral lines to stabilize microwave oscillators, which are then used to produce frequency markers in the microwave region. In the present paper we wish to describe a precision frequency meter that uses the carefully measured ammonia lines as secondary frequency standards but avoids the intermediate step of using the lines to stabilize a microwave oscillator. This meter is being used successfully in studies of microwave absorption spectra.

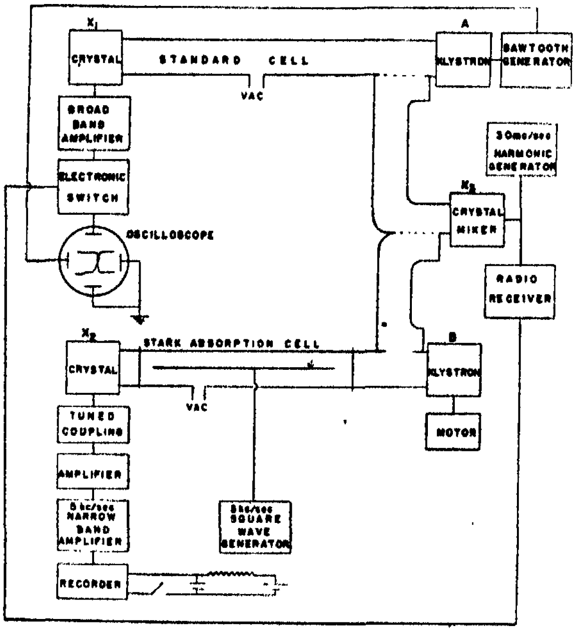

FIG. 1. Block diagram of frequency measuring system.

A block diagram of the circuits involved is given in Fig. 1. Two spectrographs are employed. A sweep-type[3] spectrograph A is used for observing one of the accurately measured lines in the inversion spectrum of ammonia. Application of a 60-cycle sawtooth voltage to the reflector sweeps the klystron frequency through a range containing the ammonia absorption line. The resulting output signal from crystal X_1, is amplified and applied through an electronic switch to the vertical deflection plates of an oscilloscope; the sweep for the horizontal deflecting plates is furnished by the 60-cycle sawtooth voltage applied to the reflector of klystron A. In cases where it is desirable to use some gas other than ammonia as the standard it is desirable to use a Wilson-type Stark-modulation spectrograph[4] utilizing a square-wave voltage biased to ground.

The search spectrograph B is of the type using Stark modulation, a narrow band-pass amplifier and detector, and a recorder for displaying the observed spectra on a chart.[5] A small amount of power can be fed from each klystron by means of a directional coupler to a crystal mixer X_3. The resulting "beat" frequencies are fed into a communications receiver, the output of which is displayed on the oscilloscope along with the ammonia line. This may be accomplished by means of the electronic switch as shown in Fig. 1, thus obtaining a double trace, or by applying the receiver output to the "Z-axis" terminal of the oscilloscope, thus using intensity modulation on the single trace showing the ammonia line. The

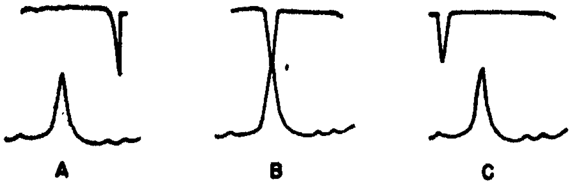

FIG. 2. Tracings of photograph of oscilloscope patterns. As klystron A is slowly tuned mechanically, the pip on the upper trace moves slowly toward the left. (Note: Separation of main ammonia line and its inner satellite is about 1.7 mc/sec. Width of main line at half-height is about 0.4 mc/sec.)

receiver output appears as a "pip" whenever one of the beat frequencies from crystal X_3 corresponds to the frequency f_r to which the communications receiver is tuned.

When the pip from the receiver coincides with the ammonia line on the oscilloscope screen, the frequency f_x of the search klystron B can be obtained from the relation

$$f_r = \pm m(f_0 - f_x),$$

where f_0 is the frequency of the ammonia line and m is an integer. In the present apparatus the search klystron is tuned mechanically by means of a drive operated from a synchronous motor and the pip moves slowly across the screen as shown in Fig. 2. A frequency marker is made on the recorder paper by a manually operated pulsing circuit or by a mechanically operated pen when the pip and the ammonia line coincide on the oscilloscope; for convenience and for somewhat improved precision, an electronic coincidence triggering switch may be used to actuate the marking device.

With only the signals from klystrons A and B reaching crystal mixer X_3, microwave frequencies within a range of at least a hundred mc/sec. from the ammonia frequency f_0 can be measured. In order to extend the frequency range of measurement with respect to a given standard absorption line, the output of a harmonic generator operated from a 30 mc/sec. crystal-controlled oscillator may also be applied to crystal mixer X_3 as shown in Fig. 1. When this arrangement is employed, the frequency relation applying when the pip and ammonia line are in coincidence is

$$f_r = \pm m(f_0 - f_x) \pm n f_c,$$

where f_c is the frequency of the crystal-controlled oscillator as measured in terms of WWV and n is an integer. Observable pips can be obtained when f_0 and f_x differ by as much as 4000 mc/sec. When frequencies f_x remote from f_0 are being measured, it is desirable to employ a resonant-cavity wave meter to give an approximate value of f_x so that m and n can be determined unambiguously.

TABLE I. Frequencies of several methanol lines.

	Frequency (mc/sec.)	
Line	Cole's value	Value obtained by present method
$J=5$	24,959.08	24,959.02±0.014
6	25,018.14	24,018.20±0.023
7	25,124.88	24,124.89±0.025
27	23,854.25	23,854.23±0.015

The accuracy of the frequency measurements made with the present device depends upon the sharpness of the standard spectral line, the frequency and amplitude of the sawtooth voltage applied to klystron A, the pass band of the communications receiver, the speed of the motor drive of klystron B, and, ultimately, the accuracy of the original measurement of the standard frequency f_0. The ammonia lines can be observed at low pressures and furnish highly satisfactory sharp standard lines. The *SX* 42 receiver calibrated by means of a signal generator checked against WWV has been employed and, when used as a broad band receiver, gives no distortion of the pips produced by a 60-cycle sawtooth voltage of amplitude sufficient to give a total frequency excursion of 3.7 mc/sec. for the low frequency bands and 37 mc/sec. for the high frequency bands.

In order to test the frequency meter with the Stark modulation spectrograph shown in Fig. 1, two somewhat inexperienced observers used it to make measurements of several hindered-rotation lines of methanol. The results obtained are shown in Table I along with the values reported by Coles.[6] The values given in Table I are the averages obtained from sixteen independent measurements of each line with the 3,3 ammonia line as the standard. The uncertainties given are the probable errors and hence give only a measure of the internal consistency of the data. The uncertainty in the frequency of the standard ammonia line is ±0.02 mc/sec. and, as stated above, this sets the ultimate limitations on accuracy with which frequencies can be measured. Including this uncertainty, we obtain a limit of approximately ±0.03 or ±0.04 mc/sec. for the methanol frequencies.

Although the frequency meter described above has been tested only in spectroscopic applications, it should be noted that it can be used to measure the frequency f_x of any *CW* microwave radiation.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 12 DECEMBER, 1950

Apparatus for Concentration of He^3 by Thermal Diffusion*

O. F. Schuette, Jr.,† A. Zucker, and W. W. Watson
Sloane Physics Laboratory, Yale University,‡ New Haven, Connecticut

(Received June 29, 1950)

A multistage thermal diffusion apparatus for the concentration of He^3 is described. Included is a novel three-stage, all-metal column based on a G. E. Calrod heater. Concentration was carried only to a He^3/He^4 ratio of 0.05 percent, a factor of 3.3×10^3. The performance indicates the importance of having the hot wall in concentric cylinder columns made of metal of good thermal conductivity to minimize azimuthal temperature gradients which can markedly increase parasitic remixing of the gas if a metal such as stainless steel is used.

DESPITE the extremely low value of 1.5×10^{-7} for the He^3/He^4 ratio in well helium, the thermal diffusion method is one of the possible ways of concentrating the rare and important He^3 isotope. Some details of the construction and operation of thermal diffusion apparatus for this purpose have been given by McInteer, Aldrich, and Nier.[1] Along with a complete development of the theory of isotope separation by thermal diffusion, Jones and Furry[2] calculated the design of a multistage helium apparatus. Our construction differs somewhat from the recommendations of Jones and Furry, but our calculations of critical dimensions and operating conditions are all based on the relations given in their article. Although the performance of our columns has not come up to expectations, we believe that we have the explanation for the deficiencies. A brief description of our experience may be helpful to others constructing similar apparatus.

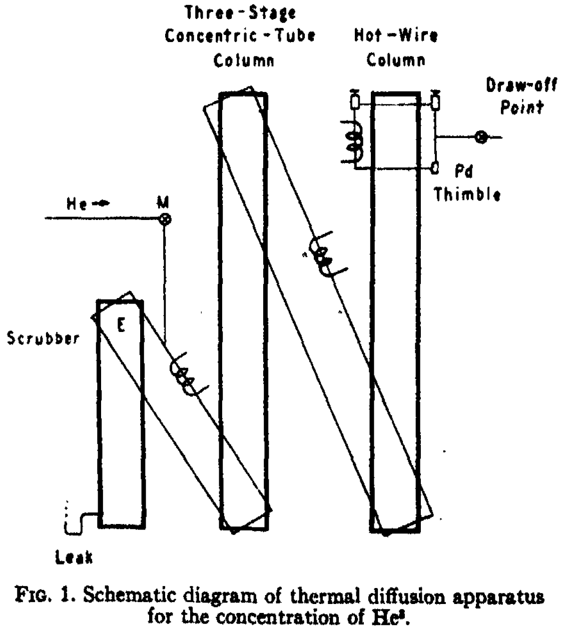

FIG. 1. Schematic diagram of thermal diffusion apparatus for the concentration of He^3.

DETAILS OF APPARATUS

Figure 1 is a schematic representation of our metal columns which were operated at that helium gas pressure, 4.5 atmos., calculated to give maximum separation factor in the hot-wire column. In addition to these columns, we have employed a single 3-meter, hot-wire glass column to recycle, batchwise, the gas enriched in He^3 from the top of the metal hot-wire column. Both the scrubber and the three-stage column have for the hot wall a G. E. Calrod heater with chrome steel sheathing. Many of the construction features of these two columns, such as the use of two-ply sylphon bellows to take up the differential expansion of the hot and cold surfaces, thin stainless steel end sections to minimize heat loss by metallic conduction, convective coupling between columns, etc., are similar to those of another thermal diffusion apparatus recently described in this journal.[3] The total consumption of power is 7 kw and of cooling water 3 gal/min.

Operation of the first column as a scrubber in order to make more effective use of the rare isotope in the original gas is in agreement with the Jones and Furry design. The Calrods are both 0.6 inch in diameter; that in the scrubber has a heated length of 130 cm and is mounted concentrically inside a 1⅛-inch o.d. copper pipe, so that the gap space $2w$ is 0.932 cm. Helium gas enters through a tee in one of the first coupler pipes while gas depleted in the light isotope is valved off at the bottom of the scrubber at the rate of 1.5 cm^3/sec. We compute that about half the He^3 in this ejected gas has been removed and transported up the longer separating column. The scrubber and this separation column may be considered as a single column with the gas entering the system between the two and flowing toward both ends.

The longer second column has a novel construction (Fig. 2), there being three sections with decreasing gap space in the order bottom to top, so designed as to match roughly the transport of the light isotope in the three stages. By such construction one should be using a long column at highest efficiency. At intervals of 50 cm, sets of thin stainless steel spacers in groups of four project from the copper cold wall to hold the heater accurately centered.

[2] R. C. Jones and W. H. Furry, Rev. Mod. Phys. 18, 151 (1946).

[3] Watson, Onsager, and Zucker, Rev. Sci. Inst. 20, 924 (1949).

In the choice of gap spaces in concentric cylinder columns, one is limited by available sizes of copper tubing for the cold wall; but the pressure is a variable that can then be adjusted to make for most efficient operation. Our choice for the scrubber column was made by calculating the transport coefficients H, K_c, and K_d (reference 2), assuming the remixing coefficient K_p due to parasitic convection to be $0.3K_c$, and taking the hot wall temperature to be the stated operating temperature of the heater in air (1200°F or 980°K for 2 kw input). This calculation indicated that the convenient gap space of 0.932 cm should give maximum efficiency at a pressure of 5.3 atmos.

From preliminary experiments with this shorter column plus calculations on the heat conduction through the gas, we could calculate that, for the available spaces of 0.932 cm, 0.773 cm, and 0.643 cm for a three-stage column based on the Calrod heater with heated length of 289 cm, the hot-wall temperatures for the rated power input of 5 kw are 985°K, 952°K, and 920°K, respectively. Calculation for balanced transport (cf. reference 2) between stages then showed that for stages 1 and 2 the lengths should be 92.5 cm and 57.5 cm, respectively. It was decided to make the remainder of the column into a final stage, for with any available gap space less than 0.643 cm there would be a much lowered hot-wall temperature plus probable increased parasitic convection from small absolute values of the error in centering of the hot wall.

We have also used the scrubber column with argon gas to measure by the method of Onsager and Watson[4] the Reynolds number at which the lamellar convective flow of the gas between the hot and cold walls becomes turbulent. At hot-wall temperatures of 1180°K and 805°K this Reynolds number is 89 and 40, respectively. These values are much smaller than those obtained for pure pressure flow through pipes, but are in agreement with other recent measurements with thermal diffusion columns.[4,5] Since the Reynolds number for the onset of turbulence should be about the same for all gases, we compute that for the scrubber column filled with helium a pressure of about 100 atmos. would be required to produce the necessary density to cause turbulence. Even higher pressures are required to produce turbulence in the smaller gap spaces of our long Calrod column. We are sure, then, that at the pressures of 6.5 atmos. or less the flow of the helium gas in these columns is lamellar.

The all-metal, hot-wire column is 3 meters long and consists of a copper pipe 9/16 inch i.d. surrounded by the usual water jacket and carrying a 15-mil Pt-Ir alloy wire down its axis. A direct current of 4.85 amperes produces a wire temperature of 1100°K. To keep this wire centered, crosswires are spotwelded on to it at 75-cm intervals. These crosswires carry quartz sleeves of 1-mm o.d., which are longer than the wires so that the latter cannot touch the metal cold wall. The current is led in and out by means of Stupakoff seals soldered to the metal end-fittings. Rubber O-rings used as gaskets make tight pressure seals between these fittings and the pipe ends. The wire carries at its lower end a 50-g weight, which connects to the bottom Stupakoff seal through an accordion-pleated copper ribbon made of copper cold-rolled to a thickness of 0.001 inch. The lower end-fitting which contains this weight-and-ribbon assembly is made of a brass tube lined with a glass tube for electrical insulation. This type of construction for a high pressure hot-wire column has proved successful in operation for considerable periods both in this apparatus for He^3 concentration and in another for separating the argon isotopes.

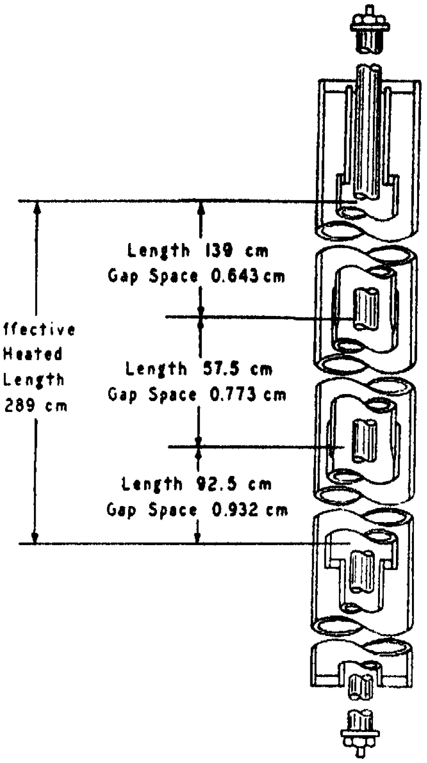

FIG. 2. Internal construction of three-stage all-metal thermal diffusion column based on a G. E. Calrod heater.

The end volume at the top of this hot-wire column consists of a rectangle of standard ½-inch o.d. copper tubing. Connections to the top of the column are made through sylphon bellows-type valves having clear ½-inch diameter openings. Convective circulation is maintained in this end volume, which contains upon closure of the two valves just one standard liter of gas.

To eliminate the hydrogen impurity, which is well concentrated in this end volume by the combined thermal diffusion and thermal siphoning action, a palladium thimble is silver-soldered re-entrant into one corner. This thimble is heated by means of a hot air blast to 200°C. As the gas in the end volume circulates continuously past the thimble, the hydrogen is effectively lost by diffusion through the palladium wall and is carried away by the air blast.

[5] R. Simon, Phys. Rev. 69, 596 (1946).

In order to make more accurate analyses with our mass spectrometer, which has a limit of sensitivity of 0.01 percent for He^3/He^4, we concentrated further with an available 3-meter hot-wire glass column the helium in this end volume, after a 40-day run had just consumed the contents of one large helium cylinder. The hot wire in this recycling column is made of 20-mil tungsten and the diameter of the glass cold wall is 2 cm. The wire was kept at 1200°K and the "heavy" end volume was so constructed that the one liter of enriched gas from the metal columns just brought this glass column to atmospheric pressure. One can compute with these data in the hot-wire approximation of Jones and Furry[2] that $H=8.43\times10^{-6}$ g/sec.; $K_c=1.73\times10^{-5}$ g-cm/sec.; $K_d=1.03\times10^{-3}$ g-cm/sec.; $2AL=2.44$; the equilibrium separation factor, $q=11.47$; and the time for equilibrium is but a few hours.

PERFORMANCE

In one of our first runs without the metal hot-wire column, the system was operated at a pressure of 6.5 atmos., and enriched gas was drawn off at the top of the three-stage column at a rate of 300 cm^3/day ($\sigma=6\times10^{-7}$ g/sec.). This gas was stored in an oil-sealed Toepler pump from which it could be pushed back into the (evacuated) main column for recycling after 40 days of collection at this rate. A sample of the once-through helium taken before the start of this stripping process was kindly analyzed for us by A. O. Nier who reported the He^3/He^4 ratio to be 6×10^{-6}. This corresponds to an experimental enrichment factor of 40.

With this datum, and assuming the transport to be balanced in this three-stage column, the thermal diffusion coefficients were computed for these operating conditions. These were introduced into the transport equations integrated for the case in which the concentration of the desired isotope is everywhere small, giving about 45 as the experimental equilibrium separation factor of the three stages. The product of the equilibrium separation factors $q=e^{(H/K)L}$ for the three stages, on the other hand, is 3240. We can account for practically the whole of this discrepancy by the assumption that in our theoretical analysis we underestimated the remixing coefficient K by a factor of 2. The most probable source of a remixing coefficient larger than expected is the presence of parasitic convection arising from azimuthal variation in temperature of the hot surface. From the analysis in reference 2, we compute that for our smallest gap space the coefficient of parasitic convection K_p equals the remixing coefficient for longitudinal convection K_c if an azimuthal temperature difference of about 7° exists on the surface of the hot wall.

It is possible that the small gap space in helium, a gas of high thermal conductivity, together with the fact that the sheath of the Calrod is made of stainless steel, a material of relatively low thermal conductivity, would permit such azimuthal thermal gradients to be maintained. Poor centering of the heater wire in the Calrod might be the cause of the gradients. We recommend, then, that the hot wall in thermal diffusion columns always be made of a metal of good conductivity, such as copper.

With this clear indication that a marked increase in the separation factor of the apparatus was needed, the metal hot-wire column described above was convectively coupled to the top of the three-stage column. To determine the gas pressure for maximum separation factor, it is only necessary to maximize the constant $2A=H/(K_c+K_d)$. The transport H is a function of the square of the pressure p, K_c varies as p^4, and K_d is independent of p. By numerical evaluation $2A$ is found to be a maximum for $p=4.5$ atmos., with $H=4.33\times10^{-5}$ g/sec., $K_c=4.86\times10^{-4}$ g-cm/sec., and $K_d=5.3\times10^{-4}$ g-cm/sec. This gives a theoretical separation factor of 3.6×10^5, a figure much larger than can be realized in practice because of the limitation imposed by the small amount of He^3 in the original gas. Of the 1 cm^3 of He^3 in the contents of a large cylinder of well helium consumed in 40 days of operation, we estimate that half is valved-off at the bottom of the scrubber. If the other half in its entirety were concentrated in the liter of helium gas in the "light" end volume, the He^3/He^4 ratio there would be 0.05 percent. The indication from our mass spectrometer analyses, however, was that the He^3 content of this enriched gas was somewhat less than 0.01 percent.

After recycling this liter of helium gas for 12 hours in the glass hot-wire column, three samples totaling 25 cm^3 were withdrawn from the top of the column. These samples averaged 0.050±0.005 percent for the He^3/He^4 ratio, and so the over-all separation factor for these operations is $5\times10^{-4}/1.5\times10^{-7}$ or 3.3×10^3. Upon considering the factor (11.5) of this glass column and the volumes involved, the He^3/He^4 ratio in the end volume of the metal columns is indicated to be about 0.005 percent.

We conclude that it would definitely be feasible by improvement of some of our design features and by operation of more columns in series-parallel combination to produce any reasonable amount of highly concentrated He^3; but, since this isotope has been made available by the AEC, the thermal diffusion method need not be further developed at present. Experience here detailed is, however, applicable to other isotope and gas-mixture separations for which thermal diffusion is the preferred method.

Gas Flow through the Mass Spectrometer Viscous Leak

R. E. HALSTED AND ALFRED O. NIER
Department of Physics, University of Minnesota, Minneapolis 14, Minnesota

(Received August 11, 1950)

An approximate expression for the flow of a binary gas mixture through a mass spectrometer "viscous" leak has been derived and compared with experimental data. The factors important in the design and use of the leak are determined from this result.

THE design of gas inlet systems for mass spectrometers must be such that the composition of the gas in the spectrometer bears a known relation to the composition of the sample to be analyzed. Two types of gas inlet systems which satisfy this criterion are commonly employed. The simplest of these employs a "molecular" leak. Its operation has been described by Honig.[1] The sample is placed in a large bulb at a pressure below 100 microns. Flow into the mass spectrometer is through a pinhole so small that the mean free path is much larger than the diameter of the hole. The flow through the hole is molecular. This is also true of the flow of gas out of the mass spectrometer tube. Hence the absolute pressure in the ionizing region of the mass spectrometer of any constituent of the gas sample is directly proportional to the absolute pressure of that constituent in the gas sample. The constant of proportionality is the same for all gases and all constituents regardless of the composition of the sample.

The second type of gas inlet system employs a "viscous" leak.[2] It has the virtue that the sample is admitted to the mass spectrometer from a high pressure region (several cm Hg, or more). This simplifies the inlet system and makes possible in a simple manner continuous gas analyses from, for example, a process stream.[3] Inghram[4] has discussed its use, but the literature contains no references on experimental tests or its performance. The present paper derives an approximate equation for the flow of a binary gas mixture through such a leak and compares it with experiment. Some general conclusions concerning the design and performance of viscous leak systems can be drawn from this result.

Figure 1 is a schematic diagram of a viscous leak gas flow system. For convenience in theoretical treatment, this system is divided into the three following flow regions: A. Flow through the spectrometer; B. Flow through the constriction; C. Flow through the capillary tubing on the high pressure side of the constriction. Equations are obtained for the flow of one component of a gas mixture through each of these regions. Since the gas flow through the system is continuous, these three flow equations may be equated. With suitable approximations one can then solve for the partial pressure of one component of a gas mixture in the mass spectrometer ion source in terms of its partial pressure in the sample. Finally, the ratio of the two such expressions obtained for a binary mixture gives one an expression for the variation in measured sample composition with sample pressure.

A. Flow through the Spectrometer

The pressure in the spectrometer itself is so low that the mean free path of a molecule is much larger than spectrometer dimensions. Therefore, between two points in the vacuum system, such as 3 and 4, the flow is molecular and can be described by the equation

$$Q_{a34} = (k_{34}/M_a^{\frac{1}{2}})(P_{a3} - P_{a4}), \tag{1}$$

where Q_{a34} = flow of component a of a gas mixture between points 3 and 4 expressed as the time rate of change of pressure-volume product; k_{34} = constant dependent upon the geometry and temperature in the region between points 3 and 4; M_a = molecular weight of component a; and P_{a3}, P_{a4} = partial pressures of component a in regions 3 and 4, respectively.

B. Flow through the Constriction

In the constriction the flow cannot be so simply described. If the pressure behind the constriction is lowered to the point where molecular mean free paths are much larger than constriction dimensions, the description must reduce to one of molecular flow. At high pressures the description should change to the form of Poiseuille's law for viscous flow. Knudsen[5] has given a rather complicated semi-empirical equation which meets

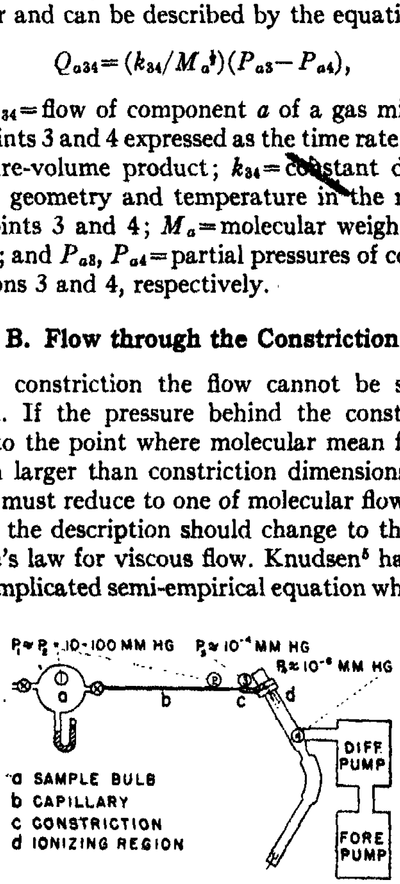

FIG. 1. Schematic diagram of spectrometer gas flow system with approximate pressure levels indicated.

[5] M. Knudsen, Ann. d. Physik [IV] 28, 75 (1909).

these requirements and accurately describes the flow over the entire pressure range through cylindrical tubes. However, the geometry of the constriction is not so well defined. A simple sum of molecular and viscous flow terms is used here as an approximate form of the Knudsen equation. For the flow of one component of a gas mixture through the constriction

$$Q_{a23}=(k_{23}/M_a^{\frac{1}{2}})(P_{a2}-P_{a3})+v(P_{a2}/P_2)\bar{P}(P_2-P_3), \quad (2)$$

where k_{23} = constant dependent upon the geometry and temperature in the constriction; $\bar{P}=(P_2+P_3)/2$; v = coefficient of viscous flow, proportional to $1/\eta$; and η = coefficient of viscosity of gas mixture.

C. Flow through Capillary Tubing

The variation of flow with mass, indicated by the first term of Eq. (2), would tend to change the composition of a gas mixture adjacent to the high pressure side of the constriction and establish concentration (or partial pressure) gradients along the capillary. The function of the capillary tubing is to create a mass flow of gas toward the constriction with a velocity sufficiently great to overcome any back diffusion which would result from such a gradient. The flow through the tubing is therefore described by competing mass flow and diffusion terms. For one component one can write with fair approximation

$$Q_{a12}=VAP_{a1}-AD_{ab}[(P_{a2}-P_{a1})/L], \quad (3)$$

where V = average velocity of mass flow along the capillary; A = cross-sectional area of capillary; D_{ab} = diffusion coefficient for a mixture containing two components a and b, and L = length of capillary behind the constriction.

In practice the pressure dependence of Eqs. (1) and (2) is simplified by the fact that $P_2 \gg P_3 \gg P_4$. Also the difference between P_1 and P_2, though finite to permit mass flow in the capillary, is sufficiently small to permit replacement of P_2 by P_1 in Eqs. (1) and (2). Equating the flow equations and solving for P_{a3} in terms of P_{a1}.

$$k_{34}P_{a3}=P_{a1}\frac{[VA+(AD_{ab}/L)][k_{23}+(VM_a^{\frac{1}{2}}P_1/2)]}{(k_{23}/M_a^{\frac{1}{2}})+vP_1/2+(AD_{ab}/L)}. \quad (4)$$

The expression which would be obtained for the b component is given by replacing the subscript a by b wherever it occurs alone. Noting that the ion current is in general directly proportional to the partial pressure of any particular gas in the ionizing region of the spectrometer (ionizing electron energy and intensity constant) one obtains for the ratio of ion currents

$$\frac{I_a}{I_b}=\frac{P_{a3}}{P_{b3}}=\frac{P_{a1}}{P_{b1}}\left\{\frac{[k_{23}+vM_a^{\frac{1}{2}}P_1/2][(k_{23}/M_b^{\frac{1}{2}})+v_1P_1/2+AD_{ab}/L]}{[k_{23}+vM_b^{\frac{1}{2}}P_1/2][(k_{23}/M_a^{\frac{1}{2}})+v_1P_1/2+AD_{ab}/L]}\right\}, \quad (5)$$

where I_a and I_b equal the ion currents from components a and b respectively.

Since D_{ab} = constant$/P_1$; as $P_1 \to 0$, Eq. (5) reduces to

$$(I_a/I_b)\to(P_{a1}/P_{b1}). \quad (6)$$

Here the gas inlet system has introduced no mass discrimination and has behaved like a molecular leak. However, as P_1 gets large,

$$(I_a/I_b)\to(M_a/M_b)^{\frac{1}{2}}(P_{a1}/P_{b1}). \quad (7)$$

This situation results when there is viscous flow through the capillary and constriction, and separation of components occurs only in the molecular flow through the source region.

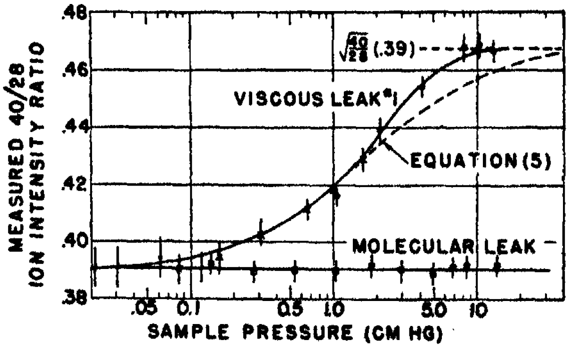

FIG. 2. Comparison of Eq. (5) with experiment for a mixture of argon and nitrogen (A/N$_2$ abundance ratio = 0.39) using viscous leak No. 1. Molecular leak data is plotted such that points along abscissa indicate same total gas flow through both leaks.

Within the pressure range of transition between Eqs. (6) and (7), a viscous leak would introduce an uncertain mass discrimination. Therefore, it is important to know where this change occurs for any given leak, and to design the leak in a manner which will remove the transition from the desired sample pressure range.

In order to compare Eq. (5) with experiment the quantities k_{23} and v must be determined. At pressures low enough for the viscous flow term of Eq. (2) to be neglected, $k_{23}=M^{\frac{1}{2}}Q_{23}/P_1$ for pure gases. One can obtain the value of k_{23}, therefore, if the relationship between the gas flow, Q, and the ion current is known. This relationship can be determined from the rate of depletion of a known quantity of sample from a constant volume under molecular flow conditions, for, making use of a molecular flow equation and the fact that I is proportional to P_3,

$$Q_{13}dt=(k_{13}/M^{\frac{1}{2}})P_1dt=-V_1dP_1.$$

Therefore,

$$Q_{13}=-(V_1P_1/\Delta t)\ln(P_{1f}/P_{1i})$$
$$=-(V_1P_1/\Delta t)\ln(I_f/I_i), \quad (8)$$

where Δt is the time difference between initial and final ion current measurements I_i and I_f, respectively.

The relationship between v and k_{23} for a given pure gas is chosen to fit an experimental curve for the equation

$$(I/P_1) \propto (k_{34}P_3/P_1) = k_{23} + (vM^{\frac{1}{2}}P_1/2), \tag{9}$$

obtained from Eqs. (1) and (2). For other gases v can be calculated since it is inversely proportional to the coefficient of viscosity. Unfortunately, this coefficient for even a binary gas mixture is not simply related to the coefficients of its components, so an approximate value must be used where exact values are not available. It might be noted here that at pressures where the viscous flow term of Eq. (2) predominates, $Q \propto v \propto (1/\eta)$. Therefore the total flow of a gas mixture through the leak is subject to the same variations, often unpredictable, with composition as the coefficient of viscosity. Equation (7) shows, however, that relative abundance measurements are not affected by variations in η.

Figure 2 gives one example of the degree of agreement between Eq. (5) and experiment, a mean v being used in this case. A consideration of the approximations involved in replacing P_2 with P_1 and assuming Eqs. (2) and (3) shows that a more elaborate treatment would improve the fit. The preceding development remains useful, however, for its simple physical picture of the gas flow.

Equation (5) suggests that the most feasible way of improving a leak of this design (i.e., extending the viscous flow portion of the curve to lower sample pressures) would be to decrease the cross-sectional area and/or increase the length of the capillary behind the leak. Figure 3 illustrates the effect of changing each in this manner by a factor of 2 for a frequently encountered type of isotope analysis. By changing each by the same factor the time response (i.e., transit time of gas through capillary) of the leak in the above example was essentially unchanged.

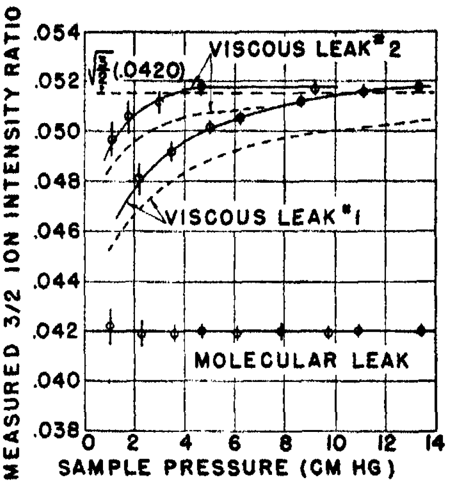

FIG. 3. Variation in measured $\frac{3}{2}$-ion intensity ratio as a function of sample pressure for several leaks. HD/H_2 abundance ratio for sample $=0.0420$. For viscous leak No. 1: $L=50$ cm; average i.d. $=0.010$ in. For viscous leak No. 2: $L=100$ cm; average i.d. $=0.007$ in. The constrictions were adjusted to give equal pumping speeds of 9×10^{-5} cm^3 sec.$^{-1}$ for N$_2$. Broken curves give Eq. (5) for each leak. Molecular leak data are plotted such that points along abscissa indicate same total gas flow through all leaks.

In practice, area reduction is limited by the requirement that the diameter of the capillary must be sufficiently greater than the mean free path to obtain viscous flow. An increase in length, without a corresponding reduction in cross section, will increase the time response. Therefore the leak dimensions for optimum performance will vary somewhat with application.

This research was supported in part by a grant provided by the Experiment Station of the Hawaiian Sugar Planters Association.

Erratum. Tektronix Advertisement

The Tektronix advertisement in the July issue, publicizing their Type 514-*D* Cathode Ray Oscilloscope, erroneously listed the sweep range as being ".01 usec/cm to .01 sec/cm." This should have read ".1 usec/cm to .01 sec/cm." They sincerely regret any inconvenience they might have caused to any of the readers of *The Review of Scientific Instruments*.

Detection of Tritiated Compounds in Paper Chromatography

IRVING GRAY,* SABURO IKEDA, ANDREW A. BENSON, AND DAVID KRITCHEVSKY
Radiation Laboratory,[1] *University of California, Berkeley, California*

(Received June 16, 1950)

A windowless tube has been developed which can be used to detect tritium activity on paper, glass, or aluminum. The tube is of glass, with a nichrome anode and a copper sulfide coated copper cathode, and utilizes a stream of helium saturated with alcohol. This device is convenient for detection of tritiated compounds in paper chromatography.

LOCATION of tritiated compounds in paper chromatography has posed a problem because of the difficulties involved in the detection of the active spots. Because of the low energy of its emitted β-rays, the assay of tritium has usually been done in the gaseous phase. This procedure does not lend itself to the location of tritiated compounds on paper. A possible method, which has been tried in this laboratory, involves cutting of the paper into squares and counting each square in a windowless counter such as the "Nucleometer." This method has the disadvantage that it renders the paper useless for further work. A counting tube has been developed which will measure the radiation from the spots in question easily and accurately.

The counting apparatus (Fig. 1) consists of a windowless Scott tube,[2] a gas flow regulator, and a source of helium saturated with alcohol at 0°C. The tube is wrapped in lead foil to minimize background radiation and to add ballast, so that a constant resistance to gas flow through the paper is maintained.

A rate of gas flow of 300 ml/min. was maintained. This rate insured a reproducible counting rate. At this rate of flow, the system showed the following characteristics: Starting voltage, Plateau, Optimum operating voltage, 1125 volts; 1200–1400 volts; 1350 volts.

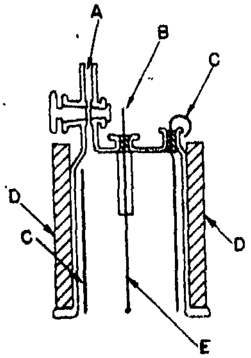

FIG. 1. Windowless counting tube. A. Gas flow inlet. B. To scaler. C. Cathode, CuS-coated copper. *D*. Lead shield. E. Anode, glass-tipped nichrome wire.

For scanning, the tube is allowed to rest on the paper and is slowly moved over the paper in a definite pattern. Where a particular area is to be counted, the tube is flushed for at least thirty seconds, after which a count is made.

This apparatus has been used to scan and count papers on which compounds containing either C^{14} or tritium have been adsorbed. Table I summarizes the results obtained using various types of counters. For counting in the "Nucleometer," papers were cut into 1¼-inch squares.

[a] Denotes tritium containing compound (tritiated cholesterol).
[b] Denotes C^{14} containing compound (stearic acid-1-C^{14}).
[c] No measurable activity.

Once the active spots have been located on the paper, it is desirable to make a radiogram of the paper in order to have an accurate outline of the active area.[3] Here again, the low energy of tritium radiation (0.018 Mev) and the high self-absorption indicated the necessity of altering the usual procedure. We have found, however, that a satisfactory image of an area containing a tritiated compound is obtained on Eastman "No-Screen" X-ray film in twenty-four hours if the area has an activity of 15,000 counts/min./cm² as recorded by the windowless tube. (C^{14}, 0.16 Mev, requires a recorded activity of about 200 counts/min./cm² in order to give a satisfactory image in twenty-four hours.)

A Simplified Percent Transmission Computer

A. L. McClellan* and G. C. Pimentel
Department of Chemistry, University of California, Berkeley, California

July 20, 1950

THE use of any single beam spectrometer requires the transformation of the spectra measured by the instrument into the related and more useful percent transmission curves normally reported in the literature. This task can be lightened to some extent with a device reported by Gershinowitz and Wilson[1] but this conversion remains a tedious and time consuming portion of spectral analysis.

The electric analog computer first reported by Fuoss and Mead[2] and modified by Zerwekh[3] can be further simplified to provide a rapid, reasonably accurate method of making these calculations. An alternative solution to the problem is the more arduous task of converting the single beam instrument into one using a split beam.

The basic changes reported here eliminate the need for a second recorder and avoid the use of specially wound coils. This allows construction of the computer as a compact unit attached directly to the door of the spectrometer recorder. The door is swung open to permit normal use of the recorder.

The electrical circuit is essentially the same as, and the component designation is identical, with that of Zerwekh. The values of the components used were $R_1 = RI_0 = 50{,}000\Omega$; $R_2 = RI = 100\Omega$; $R_3 = 500\Omega$; a 2 v battery. Beckmann Helipots, linear to 0.1 percent, were used for R_I and RI_0 as substitutes for the specially wound coils used by Zerwekh. Figure 1 shows a top view of the actual computer (not to scale).

Attached to each potentiometer is an extending shaft which is threaded in the center section and has a crank at the outer end. A flexible wire, fastened in the threads and over a pulley at the other end of the computer, is attached to a carriage sliding on a rail of rectangular cross section. As the crankshaft is turned, the wire moves the carriage. The diameter of the shaft in the threaded section is such that a pointer mounted on the sliding carriage moves over the entire range of the recorder scale as the resistance of the Helipot is varied from zero to maximum. The guide rail is rectangular to minimize vertical motion of the pointer. The other Helipot is connected, in a like fashion, at the opposite end of the computer to a second carriage on the same guide rail.

The same recording instrument used to register the spectra can be used to plot the I/I_0 curve. Jack connections must be placed in the input circuit of the recorder so that either the spectrometer signal or the computer signal can be received by the recorder.

The background and desired spectrum are superimposed as usual. The paper in the recorder is then turned back to the beginning of the two spectra. The computer output is substituted for the spectrometer signal by means of the appropriate jack connections and the power supply circuit closed. With the two Helipots set on zero resistance the zero adjustment clamps are loosened and the two carriages moved until both pointers are set on the no-signal reference line of the two spectra. Now the two pointers are placed together at the center of the scale and the value of R_3 is changed so that the pen records 100 percent transmission when the pointers are together. In the case that the two spectra do not have a common reference line, the independent zero-adjustments of R_I and RI_0 permit separate settings. The R_3 adjustment would then be made with the pointers not together but at equal distances from their respective reference lines.

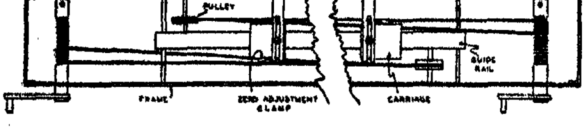

FIG. 1 Top view of computer.

The recorder is started and while the two cranks are manipulated so that the pointers follow the curves, the pen traces I/I_0. This latter curve will necessarily be displaced from the spectra since there must be clearance between the pointers and the pen. Adjustment screws are provided on the pointers so that this offset can be made a convenient amount. If the background is not perfectly aligned with the sample spectra, correction can be made with these screws.

In some spectra it may be difficult to record the background and sample spectra with the same amplification (e.g. solid spectra in which reflection loss is significant). If a standard test signal is recorded at the time of the experiment, the amplification need not be identical for both runs. In this case R_3 is adjusted so that the pen records the ratio of the test signal deflections when the pointers are together.

The ease of operation and accuracy of this computer are the same as those of the instrument described by Zerwekh.

Note on Crystals Suitable for Double Crystal X-Ray Spectroscopy in the Region 3 to 15A*

S. T. Stephenson and D. L. Martin
The State College of Washington, Pullman, Washington

July 26, 1950

THE problem of finding crystals of large enough grating space to be useful in the vacuum region above 3A has been considered from time to time. Typical of studies on crystals suitable for single crystal x-ray use in vacuum spectrometers was that of Stenstrom[1] who found mica, gypsum, beryl, sugar, $CaSO_4$ and $K_4Fe(CN)_6$ to be satisfactory. Double crystal work imposes more stringent requirements on the crystals than does single crystal work because the x-ray beam is of the order of a hundred times broader in the double crystal arrangement and correspondingly larger areas of the crystal faces are used. Thus one is limited to compounds for which large crystals are available and for which the crystal faces are relatively perfect. The test of perfection is the width of the parallel rocking curve obtained by rocking the second crystal about the position (1, −1) in which it is parallel to the first crystal, since the narrower the rocking curves, the higher the

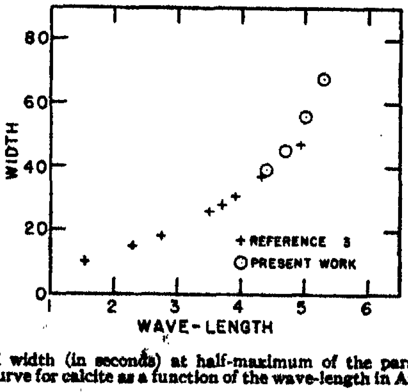

FIG. 1. Full width (in seconds) at half-maximum of the parallel rocking (1, −1) curve for calcite as a function of the wave-length in Angstroms.

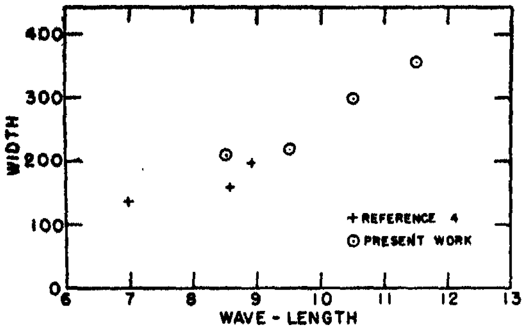

FIG. 2. Full width (in seconds) at half-maximum of the parallel rocking (1, −1) curve for beryl as a function of the wave-length in Angstroms.

resolution the crystals will achieve in the (1, +1) position. An additional requirement for the spectrometer used in this laboratory[2] is that the crystals must have properties suitable for use in a vacuum which is essentially as good as that in the x-ray tube itself, because there is no film covering the window between the x-ray tube and the spectrometer chamber.

As far as we are aware the only studies of the parallel rocking curves in this wave-length region are those of Parratt[3] who obtained curves on calcite out to 4.94A and on quartz out to 7A, and those of Munier, Bearden, and Shaw[4] who used beryl at wave-lengths up to 8.9A. It was the purpose of the present investigation to extend these results to longer wave-lengths and to determine if crystals of other compounds might be useful.

The results for calcite[3] and beryl[4] have been verified in the present work and have been extended to 5.3A and 11.5A, respectively. The data are presented in Figs. 1 and 2. It is evident that the resolution offered by calcite is excellent for use out to 5.3A which is about as far as one can go with the small grating space. Beryl offers satisfactory resolution out to 11.5A. Beryl had so low a reflecting power at wave-lengths shorter than the AlK edge as to be useless in this region. The calcite surfaces were cleaved and etched lightly with dilute HCl whereas the beryl surfaces were natural (10 $\bar{1}$0) faces. The radiation was the continuous spectrum from a tungsten target and the x-ray tube was operated at a voltage low enough so as not to produce second-order radiation for the particular glancing angle being studied.

An effort was made to find other crystals of large grating space which would be useful at these wave-lengths in the double crystal spectrometer. Other crystals investigated were mica, gypsum, quartz, and topaz. Mica and gypsum seemed particularly promising because of the large grating space for the natural cleavage faces and because these faces are easily available with large area. Many attempts were made to secure parallel rocking (1, −1) curves for two mica crystals, but without success. Thin crystals, thick crystals, and thin crystals pasted onto optical flats were all tried but no (1, −1) curves were obtained. Presumably this was because of macroscopic waviness of the natural mica crystal surfaces, which was reduced almost to microscopic waviness upon cementing to flat surfaces but was not eliminated; thus portions of the two crystal faces were parallel to each other over large rocking angles and no sharp (1, −1) peak was produced. Gypsum did not have suitable vacuum properties for use in an x-ray vacuum. The pumps did not achieve an operating vacuum even after prolonged pumping and the crystals gradually turned white. Presumably water of crystallization was slowly given off and plaster of Paris was formed. Coating the crystals with glyptal proved ineffective. Quartz and topaz were found to have too low a coefficient of reflection to be useful. Sugar and $K_4Fe(CN)_6$ were not tested because they were not available in large enough size. Gratings built up by successive dipping in a proper organic liquid have not as yet been tried nor would they appear to offer much promise because of the stringent requirements which double crystal work makes on the perfection of the grating.

A Greaseless Gas Flow Valve

R. E. HONIG*
Socony-Vacuum Laboratories, Research and Development Department, Paulsboro, New Jersey

August 25, 1950

IN experiments where appreciable pressures (1 mm Hg$<p<1$ atmos.) of highest purity samples are to be introduced into a high vacuum system, the following greaseless valve has been found very useful. In essence, it consists of a small volume that terminates in three sintered glass disks (Corning grade *F*) and is partially filled with Hg (see Fig. 1). Disk *A* connects to the gas sample, disk *B* to the vacuum system, and disk *C* to a manipulating vacuum-pressure line. The valve is closed when *C* is at atmospheric pressure (Fig. 1a). Gas will flow from the sample bulb through disks *A* and *B* into the vacuum system as soon as the pressure above disk *C* is reduced sufficiently to pull the mercury up (Fig. 1b). It is readily seen that this occurs when

$$p_c \leq p - \Delta h.$$

This valve will operate satisfactorily under all conditions if the following requirements are met:

1. When the valve is closed, the Hg level in the manipulating arm should lie above a (Fig. 1a), thereby keeping the pressure to the right of disk *B* somewhat above atmospheric. This will prevent air from bubbling from the system through disk *B*, the mercury, and disk *A* into the sample bulb at times when the system is let up to air and the sample is partially depleted. This requirement is met by arranging the three disks as shown in Fig. 1a and filling the tube to the level of disk *A*.

2. Disk *C* should be mounted in such a way that disk *B* is completely bared when the valve is open. At the same time, the bend of the *U*-tube should lie below level *b* to prevent part of the sample from bubbling through into the manipulating arm.

The valve may be thoroughly degassed at elevated temperatures before the mercury is distilled into it. In this respect it is more versatile than the simpler gas introduction system described by Taylor and Young[1] who obtain flow by making contact between two movable sintered disks in a pool of Hg. Because the gas flow rate through fine sintered disks is relatively slow, it is easy to time the valve manipulation so as to admit any desired pressure to the vacuum system.

In a simpler version of this valve, the mercury is moved mechanically by a stainless steel bellows (see Fig. 2) which is attached to a manipulating screw. While this method is not amenable to

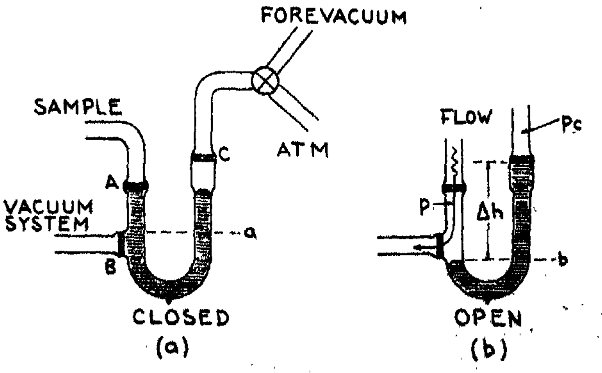

FIG. 1. Essential parts of sintered glass valve.

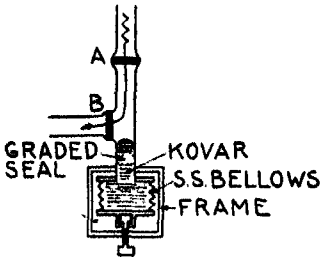

FIG. 2. Sintered glass-bellows valve.

thorough outgassing, it does eliminate the vacuum-pressure manipulating line and it is spill-proof.

Zero Inefficiency Anticoincidence Circuit

M. DEGALLIER
Laboratoire de Recherches Nucleaires, Ecole Polytechnique, Université de Lausanne, Lausanne, France

September 12, 1950

LET us consider a mixing circuit composed of two pentodes, one being normally conductive, receiving the negative coincidence pulse (*C*) formed somewhere else, and the other, normally cut off, receiving the positive square pulses (*S*) from the anticoincidence counters. Any *C*-pulse not accompanied by an *S*-pulse thus gives rise to a positive pulse which is termed anticoincidence ($A=C-S$).

A 100 percent efficiency has been claimed in the literature for such a circuit using a flip-flop to generate the *S*-pulses. That is not exactly true, though the inefficiency may be small enough to be negligible in certain experiments; in others it can be very harmful and intolerable. It is due to the existence of the recovery time of the flip-flop. The expression giving the inefficiency has been calculated in the following way:

Let n_c, n_s, n_{sa} be respectively the rates of pulses *C*, *S*, and spurious anticoincidences, and φ the dead time of the flip-flop, defined as the shortest interval between the end of a pulse and the front of the next one.

Thus every *C*-pulse falling in that interval will give rise to a spurious anticoincidence, the rate of which is therefore $n_{sa}=n_c\cdot n_s\cdot\varphi$. The resulting inefficiency is consequently $n_s\cdot\varphi$, and the only way to get rid of it is to design the circuit in order to have $\varphi=0$.

The proposed circuit for generating the anticoincidence pulses *S* (Fig. 1), similar to that of Putman, [Proc. Phys. Soc. 61, 312 (1948)] satisfies this demand: its essential characteristic is that it can be re-excited at full pulse duration inside or outside its cycle. At each positive input pulse on the grid of *T*1, the condenser *C* is fully discharged (this is true only if the input pulse is sufficiently long) and then recovers while generating the exponential timing wave which determines the duration of the *S* pulse.

This circuit, developed for very low inefficiency measurements of counters, has been tested by feeding the *S* input terminal from 17 counters counting altogether at 170 c.p.s. while the *C* input terminal was fed only from the pulses of one of these counters (4 c.p.s.). The pulses from the single counter were, of course, coincidences and not a single anticoincidence has been registered for 10^5 coincidences.

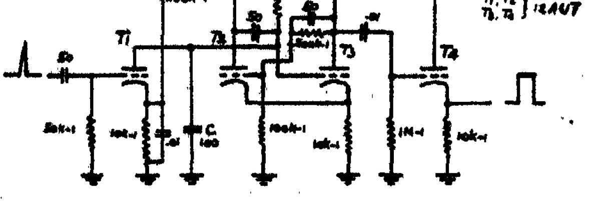

FIG. 1.

Varying Nuclear Emulsion Sensitivity with Altitude

ARTHUR BEISER
Department of Physics, New York University, University Heights, New York, New York

September 12, 1950

IN reviewing cosmic-ray detection techniques, Korff[1] points out that a major deficiency in nuclear emulsion work is the continuously sensitive property of emulsions, rendering uncertain the circumstances attendant upon the recording of a particular event. Methods of eradicating previous phenomena in a nuclear emulsion before use have been described[2] and are frequently helpful, but a process for sensitizing and desensitizing plates at prescribed times would be of very much greater value.

The dependence of the sensitivity-reducing action of photographic desensitizers on oxygen concentration[3] suggests the possibility of limiting the sensitivity time of nuclear emulsions by the use of such agents. The dyes used for this purpose apparently act as catalysts for the oxygen in its reaction with the emulsion, and are capable of preventing the formation of a latent image while not ordinarily sufficient to attack an existing one. Since the density of atmospheric oxygen varies with altitude, the use of desensitizers is of especial interest in connection with balloon and perhaps also airplane and rocket flights with nuclear plates.

To determine the degree of desensitization attainable and the magnitude of its reduction under the conditions of a balloon flight, preliminary experiments were performed with pinakryptol green (1:5000), Eastman Kodak NTB emulsions and a polonium alpha-particle source. It was found that the desensitized plates, irradiated and processed with a standardized procedure, exhibited an optical density at the area of exposure approximately ten percent that of untreated control plates. The tracks themselves were very faint, from one-half to two-thirds shorter than the control tracks, and exhibited a grain structure along almost all of their length, while the controls showed no grain structure beyond the first few microns of track length.

The simulated balloon flight occupied one hour, with the pressure in a chamber containing the desensitized plate and the source being reduced to 2.5 cm Hg (corresponding to ~75,000 ft. or 23,000 m altitude), where it was held for five minutes. After processing, the plate had a density almost three times that of a control, exposed for the same length of time outside of the chamber. Reduced pressures had no influence on plates not desensitized. Examination of the tracks revealed two distinct kinds, with relatively few transitional ones: a background of weak tracks identical to the ones in the control, and a number of heavier tracks as long as those in the non-desensitized plates but with a slight grain structure for part of their length. The latter tracks were presumably recorded at the lower pressures and account for the increased density. This moderately complete separation of the tracks in two classes would seem to indicate the existence of a discontinuity in the desensitizer action. Such a discontinuity, or cut-off region, if its dependence on altitude and rate of ascent can be determined, would be extremely desirable, making possible both fairly reliable measurements of recorded phenomena and their correlation with altitude.

A series of experiments is in progress to investigate the variation of the sensitivity of desensitized emulsions with the above factors and on the nature and concentration of the desensitizer and the emulsion composition and thickness. The ultimate utility of this method will depend largely on the magnitude of the sensitivity increase with altitude and on the existence and nature of a cut-off region. It is hoped that some conclusions may be reached on these points.

Cathode-Follower Fallacies*

Paul I. Richards
Brookhaven National Laboratory, Upton, Long Island, New York

October 19, 1950

It is often stated[1] in the literature that the low output impedance of a cathode follower offers the best solution to the problem of rapidly driving a large capacity or low impedance line. While the cathode follower is indeed an excellent driver for these loads and has certain definite advantages in many applications, the statement as it stands is somewhat oversimplified and has led to the use of cathode followers in circuits where they are unnecessary and some times even unsuited. Actually the ability to drive these loads rapidly is not a unique attribute of the cathode follower. Let us examine more carefully the relative properties of the cathode follower and conventional amplifier; various quantities of interest are listed in Table I. Note that the output capacity of the tube can safely be omitted because it will either be small compared to a large load capacity or, across a low impedance line, will affect the rise time less than preceding or succeeding stages.

Considering first the problem of driving a low impedance line, it is often stated that the low output impedance of the cathode follower is required to match the sending end of the line. But it is not always important to match the sending end, for if the far end is terminated by the proper resistor, the reflections will in many applications not be serious. In *such* applications, then, the problem reduces to obtaining maximum signal voltage across the low impedance without unduly loading earlier stages. With a given tube and given load resistance Z_0, greater gain is invariably obtained with the "amplifier" circuit (Table I). This gain, of course, will be unity or less with presently available tubes and coaxial lines, but it will still be greater than that obtained from cathode connection; moreover the low gains involved result in input capacities for the two circuits which differ, even for a triode, by less than might at first be expected. Therefore, in applications where maximum gain is desired, the amplifier circuit may be preferred.[2] The two circuits, of course, have opposite output polarity and this consideration alone will often save one (inverting) tube in such applications.

With a largely capacitative load, the situation is somewhat more deceptive. It might appear that the low output impedance of the cathode follower is required to give a reasonably fast rise time. If, however, C_L is given and G_L may be varied (the usual situation), Table I shows that the gain band-width product is the *same* for the cathode follower as for the amplifier. Physically, the greater "inherent" gain of the amplifier circuit allows one to use a lower resistor across C_L thereby compensating for the higher output impedance and resulting in the same final rise time for the same gain. However, it will be noted that a given tube (that is, a given maximum plate current) cannot develop as large a maximum output voltage across the lower shunt resistance as it could with cathode connection. In other words, although the *gain* band-width products are the same for the two connections, the maximum-output-voltage-band-width products are not. Again the gains involved are low in any case, and previous remarks apply to input capacities. Thus, in those applications where large voltages are not required, the difference in output polarity of the two connections may lead to the choice of the amplifier.

TABLE I.*

	Amplifier	Cathode follower
Output impedance	r_p	$\frac{r_p}{1+\mu}\approx 1/gm$
Gain $=A$	$\frac{\mu}{1+r_pY_L}$	$\frac{\mu}{1+\mu+r_pY_L}$
Rise time	$\frac{C_L(2\pi)^{\frac{1}{2}}}{G_L+1/r_p}$	$\frac{C_L(2\pi)^{\frac{1}{2}}}{G_L+(1+\mu)/r_p}$
Mid-band gain / rise time	$g_m/C_L(2\pi)^{\frac{1}{2}}$	$g_m/C_L(2\pi)^{\frac{1}{2}}$
Input capacity	Triode: $C_gK+C_{gp}(1+A)$ Pentode: $C_gK+C_{gS_c}$	Triode: $C_{gp}+C_gK(1-A)$ Pentode, triode-connected $C_{gS_c}+C_gK(1-A)$ Pentode-connected $(C_{gS_c}+C_gK)(1-A)$

* Notation: r_p = plate resistance. μ = amplification factor. gm = transconductance. $Y_L=G_L+j\omega C_L$ = load admittance. C_L = load capacitance. C_gK = grid to cathode capacitance. C_{gp} = grid to plate capacitance. C_{gS_c} = grid to screen capacitance. A = gain.

Some general remarks on the preceding observations must be made. First, a *pentode-connected* cathode follower has a lower input capacity than any of the other circuits; if input capacity is the prime consideration the pentode-connected cathode follower is definitely indicated. Secondly the cathode follower, being a feed-back circuit, has a slight edge as regards linearity and/or stability although the feed-back factor is not very large in those cases where $R_L\approx 1/gm$. Finally, as already noted above, the cathode connection will drive a large capacity to a higher maximum voltage than any other connection with the same rise time and the same tube.

Thus the cathode follower has a definite superiority in the more exacting applications, but many less critical circuits can be unnecessarily complicated by its use.

As a simple example, suppose that a triggering pulse of 3 volts must be sent down a very long line of 100 ohms characteristic impedance and that the circuit to be triggered will not respond to pulses less than about ½ volt. If the line is terminated by a 100-ohm resistor the reflections will usually be very much less than ½ volt, so there will be no need to match the input of the line. Suppose further that the available trigger comes out of its generating circuit at a level of 4 volts. If half of a 5687 tube ($gm=10{,}000$, $\mu=20$, $r_p=2000$) is available to drive the line, the amplifier connection will give a gain of 0.95 or an output pulse of 3.8 volts which is quite sufficient; the input capacity will be 10.2 $\mu\mu$f. Cathode-follower connection would give a gain of 0.5 or an output of only 2 volts, so that additional amplification would be required; the input capacity would be 5.1 $\mu\mu$f. If, instead, an amplitude of 2 volts were sufficient but the generator gave negative pulses while a positive trigger were required, the cathode follower would again require an extra tube to invert the signal whereas the amplifier alone would suffice.

As an example involving a large capacity, suppose that the layout of complicated equipment forces one to send a small signal (say 0.1 volt or less) through a length of cable (say 5 feet having a capacity of 60 $\mu\mu$f) to another chassis where the input capacity is 10 $\mu\mu$f. Suppose further that a rise time no greater than 0.05 μsec. is required and that the polarity must be inverted. It might seem that a cathode follower preceded by an inverting amplifier would be required. If, however, gain is not needed, a tube may be saved by using an amplifier to feed the cable directly. Thus a 6AK5 pentode ($gm=5000$, $r_p=\frac{1}{2}$ meg) with a 200-ohm plate resistor will feed the 70-$\mu\mu$f load at a rise time of 0.04 μsec. with a gain of unity and an input capacity of 4 $\mu\mu$.

Thus it appears that there are many non-critical applications where a low gain amplifier is actually preferable to a cathode follower. While none of the material here presented is especially new, it is hoped that the discussion will be of help particularly to those who are not electronics experts but who must often design their own circuits for experimental equipment.

* Work done at Brookhaven National Laboratory under the auspices of the AEC.

[1] For example, F. E. Terman *Radio Engineers Handbook* (McGraw-Hill Book Company, Inc., New York, 1943), pp. 430–432.
[2] Note that a large coupling condenser can be avoided by feeding the plate voltage through the terminating resistor.

Electron Optical Disk

L. Marton and J. Arol Simpson
National Bureau of Standards, Washington, D. C.

September 19, 1950

THE electron optical literature, while not abounding in descriptions of devices for the determination of the optical constants of axially symmetrical systems, lists some electron optical benches.[1] We were unable to find, however, a description of a device for the direct study of deflecting systems. There are a number of analog models which may be used for electrostatic deflection but none for magnetic systems of large aperture. Moreover, since these are but analog models, their usefulness and accuracy is rather limited. Because of this situation we decided to construct a simple electron optical device based on the analogy with the well-known optical disk now widely used in the teaching of elementary physics. This device in its usual form utilizes a beam at grazing incidence to a diffusing surface upon which the beam path may be observed as it is reflected or refracted. This apparatus permitted us not only to study magnetic deflection but also avoided most of the difficulties inherent in models since electrons form the beam.

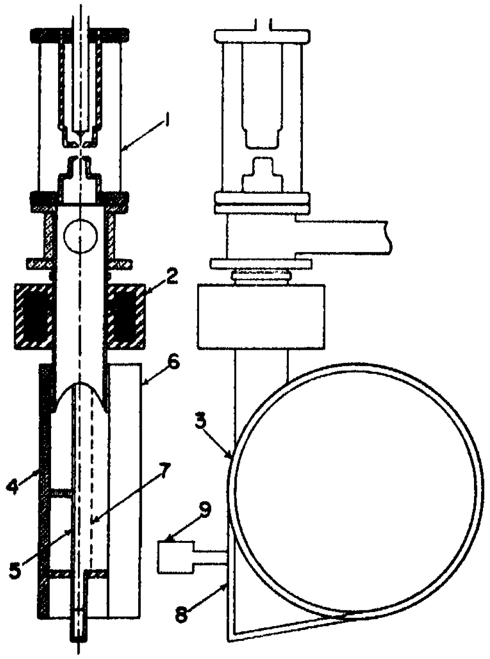

Fig. 1.

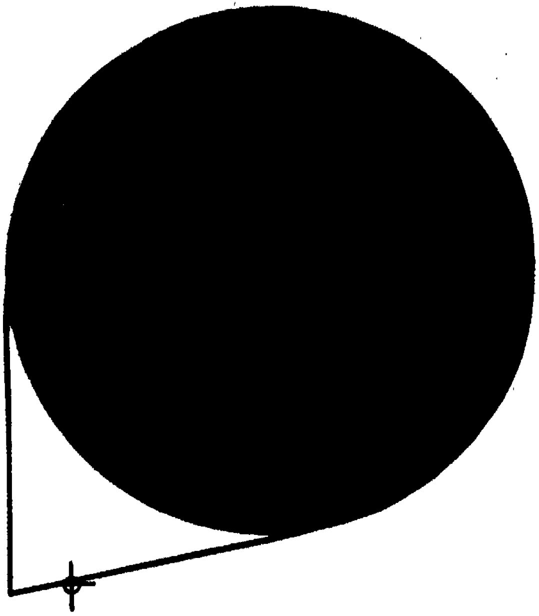

Fig. 3.

The electron optical analog is shown in Fig. 1. On Fig. 1, (1) is a 3-electrode electron gun of conventional construction; (2) is a focusing coil in an iron shield which fits over the $2\frac{1}{8}$-inches o. d. copper tubing supporting the gun; (3) is the body of the instrument. This latter consists of a 3-inch length of 10-inch wrought iron pipe grooved at each end for an *O*-ring vacuum seal. One end of the pipe is closed with a dural disk (4) which supports the phosphor screen (5) on a threaded rod. By means of this thread the screen may be accurately positioned in the median plane of the

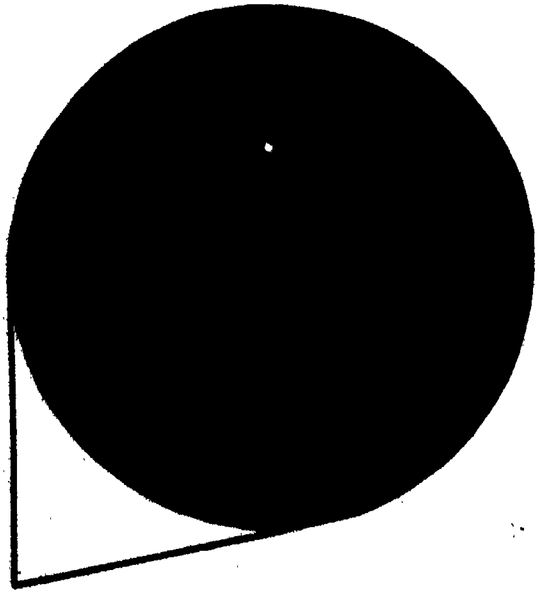

Fig. 2.

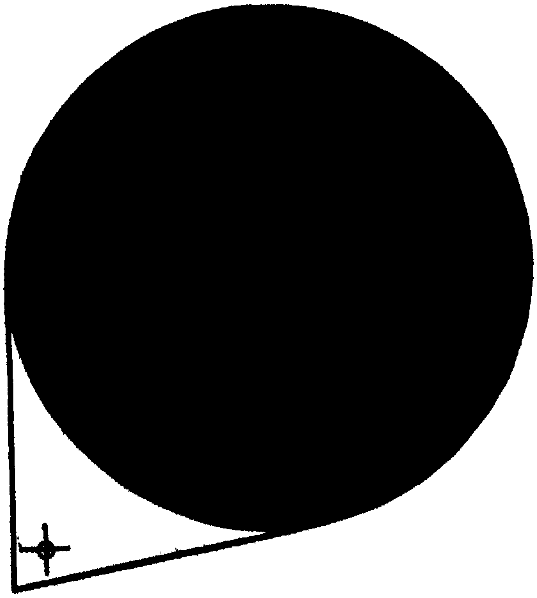

Fig. 4.

beam, or displaced a known amount if desired. In the present design this adjustment cannot be made from outside the vacuum. If this feature were desired it would easily be provided for by use of a "Wilson Seal." The other end is closed with a ¼-inch transparent plastic disk (6) which serves as an observation window. To prevent accumulation of surface charge on the plastic, a piece of bronze window screen (7) is inserted just outside the beam. The appendix (8) made of ⅛-inch brass and silver soldered, allows external positioning of the magnetic pole pieces being investigated. The pole pieces are energized by an electromagnet which is so constructed that pole pieces of various profiles may be conveniently interchanged. The optical disk is mounted on a pump wagon provided with an oil diffusion pump and a fore pump together with associated ion and thermocouple gauges.

The electrical circuit is conventional using a commercial 30 kv dc supply for the high voltage and an insulated transformer for heating the gun filament. The supply for the focus coil can deliver 400 ma into the 200-ohm load and is stabilized by negative feedback using 6 AS7's as series tubes.

It was originally planned to use a multiple slit diaphragm inserted through the "Wilson Seal" (9) to break up the electron beam into "rays." It was discovered, however, that the beam formed by the gun had observable structure so that this diaphragm was unnecessary. *Figures 2, 3, and 4 are examples of the quality of* results obtainable with this apparatus.

Figure 2 shows the convergent beam of the gun and focus coil; Fig. 3 shows the focusing pattern obtained after deflection by the field formed by parallel faced pole pieces; and Fig. 4 shows the focusing action of a dipole fringe field. The crosses in the lower left of Figs. 3 and 4 mark the center of the pole pieces, which consisted of 1-inch and ¾-inch cold-rolled rods, respectively.

In these photographs, the cross-overs are clearly visible and, although the caustic reproduces poorly, it is visible on the original photograph and may be used to estimate the order of magnitude of the axial and lateral aberrations.

To study the focusing action along the axis parallel to the field, the screen is displaced along this axis and a series of photographs give various cross sections of the beam.

The electron optical disk has proved valuable both as a research tool and as a striking demonstration of the properties of electron beams.

---

[1] J. H. Reisner and R. G. Picard, Rev. Sci. Inst. 19, 556 (1948), describes an example of such a bench. Another of unusual flexibility has been constructed in this laboratory and will soon be described in detail elsewhere.

A New Method for the Measurement of Hall Coefficients*

B. R. Russell and C. Wahlig
Randal Morgan Laboratory of Physics, University of Pennsylvania, Philadelphia, Pennsylvania

September 5, 1950

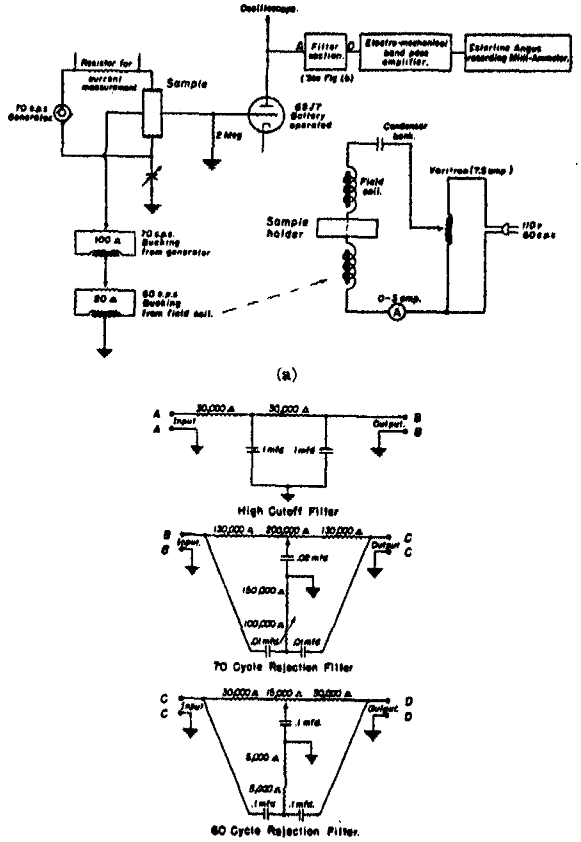
For the precise determination of Hall coefficients, the usual method is to measure the d.c. Hall voltage with reversed magnetic fields and average to eliminate misalignment and thermal voltage effects. The reversal of the magnetic field and the additional voltage measurement may require several minutes of valuable time in which the sample composition or temperature may be changing. We have been primarily interested in the Hall effect as a function of temperature and of necessity have developed a method of continuously recording Hall voltages.

If an alternating current I is passed through a sample and an alternating magnetic field H of a different frequency is produced externally perpendicular to the current, then the Hall voltage V created along the third axis consists of two parts, the sum and difference frequencies. We filter out the higher frequencies and measure the low beat frequency with the aid of a commercial ten-cycle amplifier. The output of the amplifier can be used, if desired, to drive a standard commercial recorder. Figure 1a illustrates the typical circuit. Power consideration dictates the use of sixty cycles for the magnetic field, and the high cut-off filter efficiency and availability of commercial ten-cycle amplifiers suggest that the sample current be seventy cycles.

The Hall coefficient may be calculated by means of the formula:

$$R=\frac{2V_{\text{rms-10 cycle}}\,t}{I_{\text{rms-70 cycle}}H_{\text{peak-60 cycle}}}\ \frac{\text{volt}-\text{cm}}{\text{ampere-gauss}},\tag{1}$$

where t is the sample thickness. A peak value of 2000 gauss is obtainable with our present a.c. magnet by neutralizing the inductance with a bank of condensers.



(a)

(b)

FIG. 1. Hall effect circuit.

The major difficulty is that the mixing of the sample current frequency and the magnetic field frequency in any part of the circuit will also produce a voltage of the same frequency as the Hall voltage. With the aid of the bucking sections, as shown in Fig. 1a, additional voltage of each frequency can be supplied at the sample in the proper phase so that this mixing is minimized. The adjustment of the sample current and Hall leads for minimum 60-cycle magnetic field pick-up first is essential, and then the bucking section is adjusted. The cancellation can be observed on the scope attached to the plate circuit of the first tube. Low resistance samples prove to be the more troublesome in the matter of pick-up.

The presence of the bucking section has an added advantage in that one can determine the sign of the Hall coefficient with it. Upon shifting the phase of the bucking voltage in one sense, the recorded Hall voltage increases, while a shift in the opposite direction decreases the observed voltage. With the use of a sample of known Hall coefficient sign, the bucking coil adjustment may be labeled so as to yield information about the sign of the Hall voltage for all following samples.

The magnitude of the recorded Hall voltage is determined by a calibration procedure. A known amount of ten-cycle voltage is fed into the grid of the 6SJ7 tube from a precision potential divider.

This calibration need be performed only at the beginning and the end of each temperature run.

We have made temperature runs as high as 600°C with semiconductors such as zinc oxide, copper oxide, and germanium with uniform success. These runs involved changes of Hall coefficients by factors of ten to ten thousand in the cases of zinc oxide and copper oxide, respectively. The sample resistances ranged from one ohm to three thousand ohms. The Hall coefficients observed upon decreasing the temperature repeat the ascending temperature coefficients closely. This is only possible, we believe, because of the advantageous time element.

The values of the Hall coefficients observed by this new method check within 5 percent of the measured d.c. values of the same samples at room temperature, and we believe it possible to measure Hall coefficients corresponding to sample mobilities of 1 cm^2/volt-sec.

Electrical Resistance of Platinum at High Temperatures

H. E. Bennett
Johnson, Matthey & Co., Limited, London, England

September 5, 1950

In a note on "A Temperature-Controlled Resistance Furnace for High Temperature Measurements," Schneider and Hollies[1] record that the resistance of a coil of platinum wire, of "commercial" or "thermocouple" purity, wound on a grooved alundum rod and supported in the center of a furnace, reached a maximum at about 1575°C and progressively decreased as the temperature was further increased up to about 1650°C. This is described as "a property of the platinum wire."

There is no reason to expect such an inflection in the resistance-temperature curve of platinum and the curve has been re-determined in order to check these results. A loop of pure platinum wire, with platinum current and potential leads attached, was freely suspended in the center of a rhodium-wound furnace using pure fused alumina insulators outside of the heated zone. Temperature measurements were made with a platinum/platinum-rhodium thermocouple and resistance measurements were taken at temperatures up to the melting point of platinum (1769°C) at which temperature the sample fused. The resistance of the platinum increased in a uniform manner up to the point of fusion in accordance with the usual equation.

It is suggested, therefore, that the inflection observed by Schneider and Hollies is caused by changes in the electrical resistivity of the alundum rod. It is well known that the electrical resistivity of most refractories decreases greatly at high temperatures and it would appear that at about 1575°C the resistance of the alundum rod decreased to so low a value that appreciable current leakage occurred between the turns of the platinum coil. By the use of a different refractory the temperature-control method described might be used at temperatures higher than 1550°C.

---

New Instruments

W. A. Wildhack: Associate Editor
in Charge of this Section
National Bureau of Standards, Washington, D. C.

These descriptions are based on information supplied by the manufacturer and in some cases from independent sources. The Review *assumes no responsibility for their correctness.*

Shaker The Model 44 Shaker has an armature weight of 8.25 lb., and a frequency range of 3 to 500 c.p.s. It will produce a 50 g acceleration with a mass load of ½ lb. or less and 20 g with up to 14 lb., except

at the lower end of the frequency range where displacement limits are imposed. Weight of the Shaker, with base included, is about 630 pounds, and its price is $2730. A trunnion mounting is incorporated for vertical or horizontal operation. It has a 1-in. total armature stroke with an automatic overtravel cutout. There is one flexure resonance in the operating range to 500 c.p.s. A signal generator attached directly to the table is supplied as optional equipment. The Model 45 power supply is a coordinated design capable of supplying the Model 44 Shaker at its rated output and consists of two motors, four generators, and a control console. The system operates from a 220- or 440-volt 3-phase line, and has a 2- to 500-c.p.s. frequency range with an output of 1.5 kva above 60 c.p.s. and proportional to frequency below 60 c.p.s. The rotary equipment weighs 3125 lb. and is priced at $3670. The control console houses all controls, indicators, condensers for power factor correction, circuit overload and short-circuit protection, and switchgear, exclusive of the magnetic motor starter furnished as a separate unit. It weighs 275 lb. and is priced at $1580.—The Calidyne Company, *751 Main Street, Winchester, Massachusetts.*

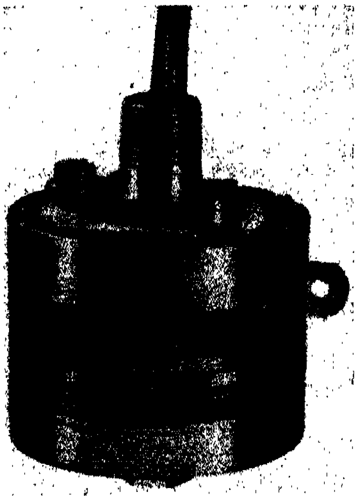
Torque Motor The Type 35-1 Torque Motor is an electromechanical device that utilizes an electrical current to produce a backlash-free translational motion, such as is suitable for displacing the piston on a hydraulic amplifier. By utilizing this torque motor design, electrohydraulic servomechanisms with natural frequencies as high as 100 c.p.s. have been constructed.

The Type 35 Torque Motor is characterized by high speed of response, high force output, and low required driving power. It provides a linear motion of ±0.004 in. and will move approximately 0.001 in. per mamp. of signal current. The locked-rotor force output is 4 lb. for a differential current of 5 mamp. When used with a normal pilot-valve load (0.02 lb.), the device has a response time of approximately 1 msec. The input of the torque motor may be connected directly to the plate circuit of a push-pull amplifier, and a pair of subminiature vacuum tubes are sufficient to provide full output from the motor. Weight 17 ounces, volume 12 cubic inches.—TRANS-SONICS, INC., *Bedford Airport, Bedford, Massachusetts.*

Differential Pressure Switch

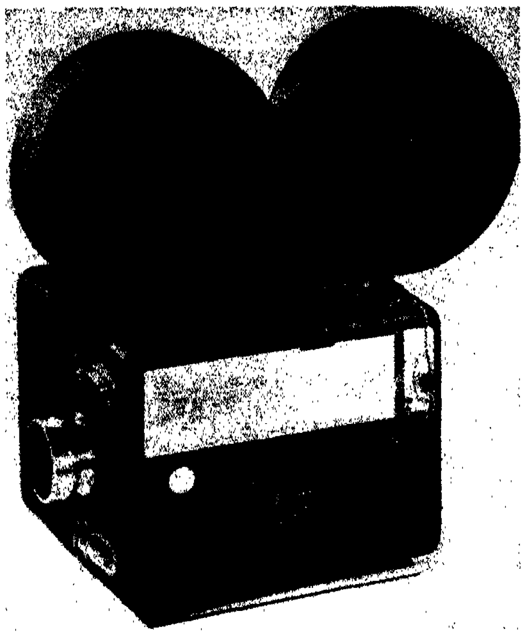
The new "Meletron" 427 differential-pressure actuated switch senses a difference between a variable and a reference pressure. It will make or break a circuit at any preset point within the adjustable range on increasing or decreasing pressure difference. Because the switching element is in contact with the reference pressure, air or an inert gas must be used. Six adjustable ranges are provided from 3 inches of water to 80 p.s.i. with proof pressures to 120 p.s.i.

A pressure-sensing diaphragm actuates a single-pole, double-throw, snap-action switch when a variable pressure on one side of the diaphragm differs by the preset amount from the reference pressure on the other. It incorporates an Underwriter's Laboratory approved SPDT switch rated for a.c. and d.c. circuits. It is ideal for maintaining a liquid level in a tank with respect to surface pressure on the liquid, for use on blower, ventilating, and heating ducts to sense a pressure difference, or to maintain a constant pressure in a system with respect to any reference pressure. The switches have two pressure ports and the housing is completely sealed by "*O*" rings; housing dimensions are 3 in. in diameter and 4¾ in. over-all. Its weight is 12 ounces. Pressure connections are to ⅛-27 internal threads and electrical connections are made through ¾-in. conduit connector.—BARKSDALE VALVES, *4905 Santa Fe Avenue, Los Angeles 58, California.*



Data Recording Camera

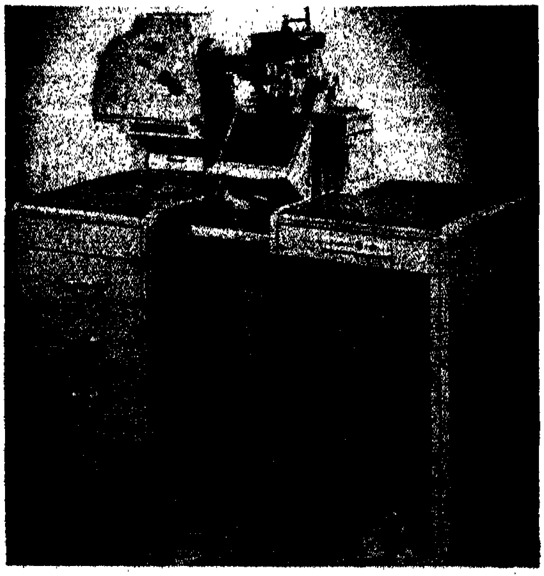
Features of this new 35 mm motion picture camera include remote selection of from four to sixteen frames per second, with constant exposure rate regardless of frame speed. Provisions are made for single frame operation, triggered either manually or by intervalometer. Integral counting circuits afford a remote means of making frame identification. The camera mounts interchangeable Mitchell magazines of 400-ft. or 1000-ft. capacity for loading standard 35-mm motion picture film.



Recommended lenses are situated in a focus-calibrated mount and have been selected for sharp definition, high resolution, and light transmitting qualities. A precision dovetail mounting slide is provided to insure exact camera indexing during removal and replacement. The Fairchild Data Recording Camera is of aircraft quality throughout and has been subjected to exhaustive tests throughout a temperature range of from minus 60°F to plus 160°F; at accelerations up to 12 g; and at altitudes ranging from 0 to 60,000 ft. Power requirements are 28 volts or 110 volts, optional. Further information on special models, high speed adaptations, or cyclic variations may be had on request.—THE FAIRCHILD CAMERA AND INSTRUMENT CORPORATION, *West Coast Division, 53 West Union Street, Pasadena 1, California.*

Metallograph

Designed as a routine control instrument, this new metallograph offers convenience and simplicity of operation together with good optical performance.



Directly in front of the operator are the 5×7 in. camera, the monocular or binocular microscope eyepieces, and the ball-bearing mechanical stage. Within easy reach is the electrical control panel for the arc and visual lamps. The four objectives on rotating turret, the photographic eyepieces mounted on a quick-change slide, the camera shutter and the color filters . . . all are operable from a sitting position.

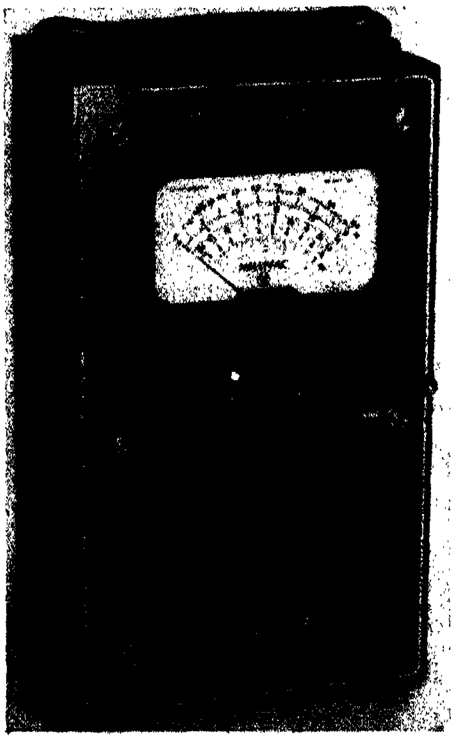
The optical systems for photography and visual observations are coupled to permit all focusing to be done through the visual system, eliminating the necessity of ground glass focusing.

Grain size measurements, ferrous or non-ferrous, are compared directly on the ground glass with standard grain size charts. Case depth and linear measurements are easily made with an accessory micrometer rule. Selection of magnification is a very rapid procedure; no tables or charts are required. The objective, eyepiece, and camera bellows setting are all identified by the standard A.S.T.M. magnifications; these range from 50× to 1500× with 2000× available on special request. Monocular or binocular bodies are available. A built-in visual lamp reduces the use of the arc lamp to photography only. Either a ribbon filament tungsten lamp or fully automatic motor-driven arc lamp may be selected to suit individual needs.

The AO Metallograph is equipped with a standard Graflex camera back using inexpensive double plate holders. An Autofocus coarse adjustment stop on the stage eliminates possible damage to optics. "Apergon" objectives are infinity-corrected, balanced for high contrast and good color correction.—American Optical Company, *Instrument Division, Buffalo, New York.*

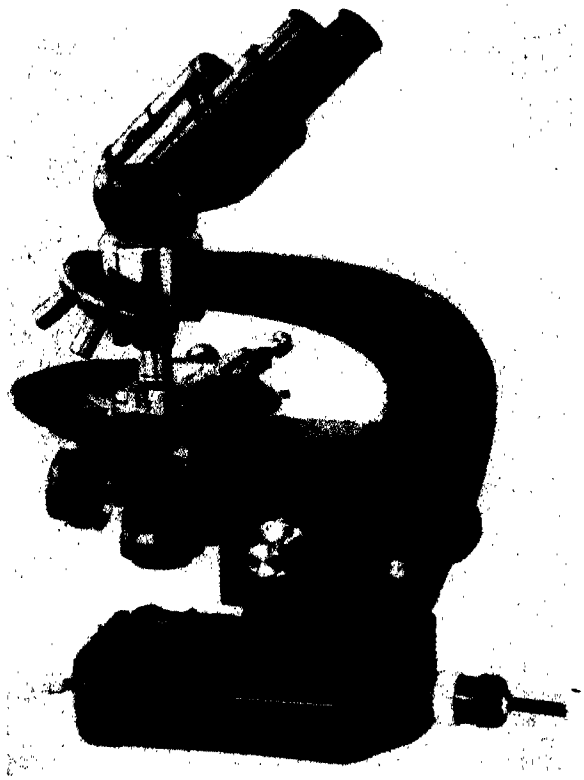
Microvoltmeter

A full scale sensitivity of 10 μv with an input impedance of 1000 ohms is claimed for the new mv-15A d.c. microvoltmeter. This instrument makes use of a new contact-type d.c. chopper with a condenser, which is charged by the d.c. voltage to be measured and then discharged through a pair of contacts and a tuned transformer. An oscillatory pulse which is set off in this manner, is then amplified, rectified, and metered. The new modulator not only increases the sensitivity of d.c. carrier-type amplifiers, but also eliminates to a considerable extent contact hazards commonly found in ordinary chopper circuits. Suggested applications for the new microvoltmeter include micro temperature changes, slowly changing strains and stresses, null detection in extremely sensitive bridges, medical research, geophysics, meteorology, chemical and nuclear research, as well as measurement of the output of high frequency vacuum thermocouples, bolometers, and crystal diodes. This instrument and the company's d.c. millivoltmeter and micro-microammeter are also available in combination with the Sanborn inkless recorder.—Millivac Instrument Corporation, *P. O. Box 3027, New Haven, Connecticut.*



Zeiss Instruments

Carl Zeiss Scientific Instruments now available in this country include the "Lumipan," a binocular research microscope with built-in illuminator (see figure), and the new Model "*G*" Abbe Refractometer. The microscope features a revolving substage with Pancratic System new type triple condenser; the Pancratic System permits the path of light used for illuminating the slides to be varied as desired and adjusted in accordance with the numerical aperture of the objective used. Thus the light is fully utilized for all objectives, increasing their efficiency. The Pancratic System makes the "Lumipan" particularly suitable for phase contrast examinations. The refractometer is provided with a stationary reading microscope, in place of the former movable magnifier, and is designed for maximum convenience, speed, and ease of operation. —Ercona Corporation, *Scientific Instrument Division, 527 Fifth Avenue, New York 17, New York.*



Manufacturers' Literature

Control—Instrumentation, Vol. 4, No. 6, Third Quarter, 1950, contains articles on instrument operating principles, spray drying, research in supersonics at Princeton University, and similar subjects.—Minneapolis-Honeywell Regulator Company, *Industrial Division, Wayne and Windrim Avenues, Philadelphia 44, Pennsylvania.*

Plasticizers—Technical Bulletin O-70, September 15, 1950, discusses vinyl film and sheeting formulations, plasticizers, and stabilizers, and lists 23 suppliers of raw materials.—Monsanto Chemical Company, *Organic Chemicals Division, St. Louis 4, Missouri.*

Koldwelds—Illustrated brochure describes new applications of cold pressure welding, including several trap welds.—Koldwell Corporation, *10 East 40th Street, New York 16, New York.*

Determination of *Q*—"Laboratory Report No. 2" explains the series resonance method for the determination of *Q* by means of a *Z*-angle meter and describes the type 500A wide-band decade amplifier with specifications and prices.—Technology Instrument Corporation, *1058 Main Street, Waltham, Massachusetts.*

Tape Recording—"Elements of single and dual track magnetic tape recording and 1001 applications," Second Edition, 144 pages, by A. C. Shaney, gives a technical discussion of the subject, illustrates typical mechanisms and schematic and block diagrams of circuits used in magnetic recording. Available postpaid upon receipt of $1.00.—Twin-Trax Division, *Amplifier Corporation of America, 398-30 Broadway, New York 13, New York.*

Cinemicrographic Focusing Unit—4 page brochure describes a focusing unit made by Cooke, Troughton & Simms, Ltd., of York, England, for the Vickers Projection Microscope to provide for normal or delayed motion pictures of translucent objects on 16-mm or 35-mm film.—Lovins Engineering Company, *8203 Cedar Street, Silver Spring, Maryland.*

Radio-Isotope Instruments—Directory of British Atomic Instrument Meanufacturers and their products produced in collaboration with the Atomic Energy Research Establishment, Harwell, England, includes a discussion of instrument requirements for tracer techniques.—Scientific Instrument Manufacturers' Association, *17 Princes Gate, London, S.W. 7, England.*

Experimenter—No. 5, Vol. XXV, October, 1950, contains a description of a Variac Phase-Shift Circuit, and accompanies a catalog supplement, Form 744-A, which illustrates and briefly describes the Company's new instruments announced since the publication of Catalog L.—General Radio Company, *275 Massachusetts Avenue, Cambridge 39, Massachusetts.*

New Materials

Borocarbon Film Resistors

The addition of boron to pyrolitically deposited carbon-film resistors has been found to give good stability, and considerably lower temperature coefficients than those of plain carbon-film resistors. In addition the borocarbon resistors provide access to resistance ranges previously impossible to attain in stable, accurate film-type resistors. Pyrolytic carbon resistors, known also as "cracked carbon" or "high stability carbon film" resistors, are composed of very thin films of microcrystalline carbon formed on ceramic surfaces. The carbon film is deposited by the thermal decomposition or pyrolysis of hydrocarbon vapors. The film-type of resistor is not only particularly useful at high frequencies as a result of the absence of skin effect, but is also well cooled by reason of its intimate contact with the ceramic core so that it can dissipate large amounts of power per unit area. Other characteristics include stability in use, relatively small and predictable temperature coefficient of resistance, low noise level, and tolerances to better than one percent attainable in production.

Pyrolytic carbon films are composed of minute graphite-like crystallites that are so closely and randomly packed as to lose all resemblance to graphite. Structural and analytical studies have shown that each crystallite is surrounded by a skin or layer of complex hydrocarbons separating it from its neighbors. This hydrocarbon skin increases the specific resistance and temperature coefficient of pyrolytic carbon relative to graphite. Decrease in the thickness of the skin or in the total volume it occupies results in a decrease in the specific resistance and in the temperature coefficient of the pyrolytic film. The temperature coefficient of resistance of the film, always negative, increases from about 180 p.p.m./°C in thick films to 750 p.p.m./°C for thin films having a resistance per square of 20,000 ohms. This variation results in part from film stresses due to the different thermal expansions of the film and its support. The average temperature coefficient of resistance of pyrolytic carbon resistors is about 300 p.p.m./°C. This large temperature coefficient has been a deterrent to their general use, even though a precision as good as 1 p.p.m./°C is attainable in matching coefficients. However, study has shown that the addition of boron to the carbon film greatly decreases the temperature coefficient of resistance and increases its stability.

Borocarbon films are produced by pyrolytic decomposition of boron and carbon from suitable gaseous compounds. Temperature coefficient depends on film thickness and boron content. By suitable variations in these, temperature coefficients as low as 20 p.p.m./°C are achieved. One-half-watt borocarbon resistors of 10 megohm values can be produced with temperature coefficients less than 100 p.p.m./°C while resistors of 250,000 ohms or lower have coefficients less than 50 p.p.m./°C. The specific resistance of borocarbon films depends on boron content, and films having a very high resistance per square can be produced by suitable variation of composition. Values of 500,000 ohms per square are readily obtained, and values in excess of 1 megohm per square have been studied. Temperature coefficients for these high resistance films are larger than for low resistance films but in the extremely high resistance ranges made available through use of these films, temperature variations are generally of lesser importance.—Bell Telephone Laboratories, *463 West Street, New York 14, New York.*

Industrial Noble-Metal Alloys

A new catalog and data book, available from the manufacturer, contains comprehensive technical and application data on Ney precious-metal alloys for industrial use. Various alloys are described for sliding contacts, brushes, wipers, slip-rings, commutator segments, resistance wire, and non-corrosive wear-resistant parts in electrical and other industrial components. In addition to data on physical properties and uses of individual alloys, the publication describes standard contacts and formed brush shapes now being manufactured, as well as details of the research, testing, and manufacturing facilities available for special application developments.—J. M. Ney Company, *71 Elm Street, Hartford, Connecticut.*

Micro-Burettes

Kimble Exax micro-burettes, with platinum-alloy delivery stems, are designed for microchemical work, and will deliver drops as small as 0.01 ml. The metal delivery tube, fused to a detachable glass tip holder, is easily cleaned; while the use of the metal eliminates the possibility of damage present in small glass tips. The tip is attached to the body of the burette by a ground joint of the size used for hypodermic syringes, and lugs are provided so that rubber bands can be used to help hold the tip in place. The platinum delivery tube extends a short distance inside the holder, so that dirt or grease tend to collect around this end rather than entering and clogging the opening. Hypodermic syringe needles can be substituted for the platinum-alloy delivery tube where there is no risk of contamination.—BURRELL CORPORATION, *2223 Fifth Avenue, Pittsburgh 19, Pennsylvania.*

Brazing Alloy

Genie is a new alloy rod for brazing aluminum without the need for a separate flux. In application the surfaces are first brushed under heat from a torch, to break up the surface oxide. The metal is then heated sufficiently to flow the brazing rod and tin the surfaces. As a third operation, the tinned surface is brushed under heat to fill all open pores. Finally enough of the brazing material is flowed in with the torch to fill the joint. The melting point of the brazing alloy is 732°F.—ALLADIN ROD AND FLUX MANUFACTURING COMPANY, *1302 Burton Street, Grand Rapids 7, Michigan.*

Self-Locking Screws

Spin-Lock screws have a ring of ratchet-like teeth on the under face of the head which will bite into the head-seat when the screw is driven tight. The screw is carburized so that the teeth do not flatten and so that they will dig into softer metal. No separate lock washer is required, and final tightening will produce an oil- and water-tight fit under the head. Flat, truss, and pan head screws are available from No. 4 to ⅜ inch, and hexagonal head screws from No. 4 to ½ inch. Self-tapping screws are available in all head styles. —RUSSELL, BURDSALL, AND WARD BOLT AND NUT COMPANY, *50 Midland Avenue, Port Chester, New York.*

Pyrex Sight Glasses

A line of sight-glasses, made from polished Pyrex plate glass, is available for high temperature service. The glass will also resist attack by chemicals other than hydrofluoric acid and strong hot caustic solutions. Circular units up to 16 in. diameter, or any rectangular or other shape that can be made from a 24×60 in. blank, can be made to order. Thicknesses range from ¼ to 1 in. Glasses can be supplied with cut or ground edges in thicknesses up to ¾ in., and with ground edges above ¾ in.—SWIFT LUBRICATOR COMPANY, *24 James Building, Elmira, New York.*

Polyethylene Pipe

Agaline plastic pipe is made of polyethylene and is designed for use at temperatures below 150°F. It is available in 4-foot lengths in diameters from 2 to 36 inches. The pipe is joined for runs of any desired length by chamfering an end and then heating a 5-inch section by immersion in water at 200°F. This causes the section to become flexible so that an unheated end can be inserted into it. The joint seals on cooling. The same treatment can be used for making bends.—AMERICAN AGILE COMPANY, *5804 Hough Avenue, Cleveland 3, Ohio.*

Refractory Material

A mullite refractory for furnace construction and repair is now in volume production. The material is being made into firebrick under the trade name of "Allmul." It is also available in bulk grain and in a ramming mix. Its melting point is 3335°F, and it has excellent resistance to deformation at 3050°F when loaded at 25 p.s.i. for 1½ hours. Spalling does not occur when the brick is heated to 3000°F for 24 hours and then subjected to 12 cycles of chilling in an air-water blast and reheating to 2550°F. Crushing strength is 3400 p.s.i.—BABCOCK AND WILCOX COMPANY, *85 Liberty Street, New York 6, New York.*

Corrosion Proofing

Ferro-Pak is a packaging paper which is treated on both sides with a volatile corrosion-inhibiting chemical to afford protection for ferrous articles wrapped in the paper. The wrapped product is ready for use without cleaning when the paper is removed. The coating evaporates slowly and does not flake off or stick to the wrapped product. Protection is maintained with the paper either wet or dry, and can extend into years. Sheets or rolls are regularly supplied, and bags, pouches or shrouds can be made to order.—CROMWELL PAPER COMPANY, *4803 South Whipple Street, Chicago 32, Illinois.*

Rinehart, John S. Simultaneous photography of self-luminous and non-self-luminous effects—939(L)
Roberts, B. W., Jr., K. E. Perry, and R. G. Fluharty. An improved resolving time measuring device—790
Roberts, James H. (see Keepin, George R., Jr.)—163
Robinson, C. S. (see Kerst, D. W.)—462
Robinson, C. V. Small probing Geiger-Müller counters—82
Robinson, Charles F. Observations on some properties of ultra-high frequency gas discharges—617
Robinson, James G. (see Lewis, Lloyd G.)—593
Rogers, G. L. Book review—88
Rogers, John D., Henry L. Cox, and Paul G. Braunschweiger. Frequency meter for microwave spectroscopy—1014
Rohrer, E. R. (see Goldin, A. S.)—554
Rojansky, V. Book review—90
Rose, Walter. Packless valve flow regulator—772(L)
Rosen, L. (see Allred, J. C.)—225
Rosenbaum, E. J. Book review—873
Rosenblit, George J. (see Steingiser, Samuel)—109

Rosenblum, Earl S. Sector-type double-focusing magnetic spectrometer—586
Rosenthal, Louis A. Low frequency sinusoidal voltage source —302
—— (see Freedman, Larry A.)—896
—— **and H. S. Zablocki.** Electronic a.c. differential voltmeter —799
Roulston, Kenneth I. (see Pringle, Robert W.)—216
Rubin, S. (see Snyder, C. W.)—852
Ruderman, I. W. (see Blau, M.)—232
Rudin, Robert (see Blau, Marietta)—978
Rudolph, O. B. Precision selector for voltage-regulator tubes —497(L)

Saltzmann, H. and C. G. Montgomery. Velocity of propagation of the discharge in Geiger-Müller counters—548
Samuel, A. L. Book review—387
Sasaki, Nobuji. New method for surface-temperature measurement—1
Savitzky, Abraham and Ralph S. Halford. Ratio-recording double beam infra-red spectrophotometer using phase discrimination and a single detector—203
Schawlow, A. L. Book review—659
Schneider, W. G. and N. R. S. Hollies. Temperature-controlled resistance furnace for high temperature measurements—94(L)
Scholander, P. F. Volumetric plastic micro respirometer—378
Schuette, O. F., Jr., A. Zucker, and W. W. Watson. Apparatus for concentration of He^3 by thermal diffusion—1016
Schulman, Martin P. Book review—665
Schumacher, Joseph G. (see Claffy, Esther W.)—575(L)
Schwed, Philip (see Levy, Gabor B.)—693
Scott, Arnold H. An instrument for mechanically differentiating curves—397(L)
Scott, B. I. H. (see Blüh, O.)—867
Scott, F. R. (see Bruner, Joseph A.)—545
—— (see Langer, L. M.)—522
Scott, Merit. Book review—659
Seaborg, Glenn T. (see Curtiss, L. F.)—94(L)
Sears, G. W. and E. R. Hopke. Effective vacuum cut-off—570(L)
Seemann, Herman E. Spectral sensitivity of two commercial x-ray films between 0.2 and 2.5 angstroms—314
Segal, Leon, Joseph J. Creely, and Carl M. Conrad. Rotating specimen mount for use with x-ray spectrometer in measuring crystallite orientation of cellulosic and other textile fibers—431
Selvin, G. J. (see Stang, L. G., Jr.)—97(L)
Seitz, Frederick. Book review—382
Seiwell, H. R. New mechanical autocorrelator—481
Sengstaken, Robert W. (see Grundfest, Harry)—360
Sessler, W. M. and A. V. Masket. High speed electronic scaler—494(L)
Shankland, Robert S. Book review—387
Shapiro, Jennie E. Method of preserving specimen grids for electron microscopy—500(L)
Sharbaugh, A. Harry. Design and construction of a Stark-modulation microwave spectrograph—120
Shaw, Robert F. Arithmetic operations in a binary computer —687
Sherr, R. Book review—657
Sherwood, Jesse E. Remote-control method of opening ampoules of active materials—570(L)
Shiflett, Chester H., Mark E. Steidlitz, and Wallace Davis, Jr. System for the collection and purification of radon by remote control—842
Shimizu, H., P. J. Elsey, and D. McLachlan, Jr. Machine for synthesizing two-dimensional Fourier series in the determination of crystal structures—779
Shoupp, W. E. (see Sun, Kuan-Han)—395(L)
Showers, Ralph M. Book review—875
Shrader, E. F. High speed short resolving time coincidence circuit for use with scintillation counters—883(L)
—— (see Strough, Robert I.)—575(L)
Shreffler, R. G. (see Fowler, C. M.)—740
Shutt, R. P. and W. L. Whittemore. High speed expansion valve for cloud-chamber control—643
Siegbahn, Kai and Stig Johansson. An electron pair spectrometer of lens type for hard gamma-radiation—442
Silver, L. M. and J. B. Warren. Behavior of rectangular and square section transparent beta-counters—95(L)
Simpson, J. A., Jr. Theory and properties of low voltage radiation counters—558
Simpson, J. Arol and Alan Van Bronkhorst. Modification of electron microscope for electron optical shadow method—669(L)
Sirvetz, M. H. (see Baird, D. H.)—881(L)
Sledge, O. D. (see Hunt, F. V.)—332
Smeltzer, Jack C. Energy dependence of the naphthalene scintillation detector—669(L)
Smith, Lloyd P. Book review—386
Smith, Otto J. M. Thermistors. Part I. Static characteristics —344
—— Part II. Dynamic characteristics—351
Smoluchowski, R. (see Turner, R. W.)—440
Smyth, Charles P. Book review—874
Snowden, F. C. (see Hamm, F. A.)—426
—— **and Harold T. Page.** Electronic circuit which extracts antilogarithms directly—179
Snyder, C. W., S. Rubin, W. A. Fowler, and C. C. Lauritsen. Magnetic analyzer for charged-particles from nuclear reactions—852
Snyder, S. D., C. J. Craven, and D. B. Trauger. Volumetric displacement flask—887(L)
Solomon, A. K. Regulated low voltage power supply—570(L); Erratum—789
Squire, C. F. Book review—663
Staker, William P. (see Pavalow, Melvin)—529
Stallings, Donald W. (see Weigl, John W.)—395(L)
Stang, L. G. Jr., and G. J. Selvin. Improved method of directing liquid flow in a closed system—97(L)
Steidlitz, Mark E. (see Shiflett, Chester H.)—842
Steingiser, Samuel, George J. Rosenblit, Robert Custer, and Chas. E. Waring. Precision Faraday effect apparatus—109
Stephenson, S. T. and D. L. Martin. Note on crystal suitable for double crystal x-ray spectroscopy in the region 3 to 15A—1023(L)
Stewart, Albert B. Degassing extended glass systems—258(L)
Stewart, H. J. Book review—384
Strauss, H. A. (see Bell, P. R.)—760
Strough, Robert I. and Erwin F. Shrader. Pulsed air core-series disk generator for production of high magnetic fields —575(L)
Sturcken, E. F. (see Heller, R. B.)—898
Sturdivant, J. H. Book review—662
Sullivan, H. M. Book review—381
Sultanoff, M. 100,000,000-frame-per-second camera—653
Sun, Kuan-Han and W. E. Shoupp. Scintillation counter for neutrons—395(L)
Sutton, Richard M. Book review—89
Swenson, C. A. Simple pressure balance—22

Taimuty, Samuel I. (see Van Atta, C. M.)—985
Tallmadge, F. K. (see Allred, J. C.)—225
Tang, Ting-Yuan (see Lawson, A. W.)—815(L)
Taylor, Harry W. (see Pringle, Robert W.)—216
Timmerhaus, K. D., E. B. Giller, L. H. Tung, R. B. Duffield, and H. G. Drickamer. High pressure fitting for scintillation counting—261(L)
Tisza, L. Book review—88
Toll, John (see Lewis, Lloyd G.)—593

Tomlinson, J. W. and J. O'M. Bockris. Vacuum furnace for use in the temperature range 1000–2000°C—507
Tonks, Lewi. Book review—873
Torrey, H. C. Book review—381
Towsley, F. E. (see Adams, G. D.)—69
Trauger, D. B. (see Snyder, S. D.)—887(L)
Trevoy, D. J. (see Huse, E. S.)—60
Tung, L. H. (see Timmerhaus, K. D.)—261(L)
Tunnicliffe, P. R. (see Fowler, I. L.)—734
—— (see Hurst, D. G.)—705
Turner, R. W., T. L. Wu, and R. Smoluchowski. X-ray determination of slip planes and slip directions—440

Ufford, C. W. Book review—384
—— Book review—389
—— Book review—876
Urey, H. C. (see McKinney, C. R.)—724

Valasek, Joseph. Book review—664
Van Atta, C. M., Sydney D. Warshaw, Joses J. L. Chen, and Samuel I. Taimuty. Double thin lens beta-ray spectrometer—985
Van Atta, L. C. Book review—383
Van Bronkhorst, Alan (see Simpson, J. Arol)—669(L)
Van Dyke, Karl S. Book review—658
Van Voorhis, S. N. Book review—665
Vonnegut, Bernard. Vortex thermometer for measuring true air temperatures and true air speeds in flight—136

Wang, P. K. S. Note on reduction of background fog in nuclear emulsion plates—816(L)
Waniek, Ralph W. Automatic equipment for electrolyzing heavy water—262(L)
Waring, Chas. E. (see Steingiser, Samuel)—109

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 12 DECEMBER, 1950

Analytic Subject Index to Volume 21

References with (L) are to Laboratory and Shop Notes

Amplifier Circuits
  D.c. amplifier for biological application, P. O. Bishop and E. J. Harris—366
  Improving differential amplifier rejection ratios, Richard McFee—770(L)
  Linear preamplifier for driving a long coaxial cable, L. G. Lewis, J. G. Robinson, and J. Toll—593
  Transmission line reflection doubling amplifier, John Marshall—1010
Anemometers
  Vortex thermometer for measuring true air temperatures and true air speeds in flight, Bernard Vonnegut—136
Biophysical Instruments
  Automatic isodose recorder with scintillation counter as gamma-ray detector, G. J. Hine, M. Berman, and M. M. Elkind—362
  Continuous flow respirometer utilizing the oxygen cathode, Francis D. Carlson, F. Brink, Jr., and D. W. Bronk—923
  D.c. amplifier for biological application, P. O. Bishop and E. J. Harris—366
  Design of a simple microflowmeter for biological perfusion experiments, A. C. Burton and J. T. Nichol—485
  Detection of tritiated compounds in paper chromatography, I. Gray, S. Ikeda, A. Benson, and D. Kritchevsky—1022

Differential vectorcardiograph, Stanley Briller, Nathan Marchand, and Charles E. Kossmann—805
4π-radiometer, T. Benzinger and C. Kitzinger—599
Infra-red microspectrometer for biological research, Darwin L. Wood—764
Making small metal tubes by electrodeposition on Nylon fibers, R. J. E. Gezelius—886(L)
Modification of the apparatus used for the Baldes thermoelectric method of measuring osmotic pressure, V. Everett Kinsey—767
Small probing Geiger-Müller counters, C. V. Robinson—82
Stainless steel micro-needle electrodes made by electrolytic pointing, Harry Grundfest, Robert W. Sengstaken, Walter H. Oettinger, and R. W. Gurry—360
Trigonometric computer with electrocardiographic applications, Richard McFee—420
Ultrasonic tissue disintegrator, F. F. Bird and K. S. Lion—189(L)
Vibrating probe electrometer for the measurement of bioelectric potentials, O. Blüh and B. I. H. Scott—867
Volumetric plastic micro respirometer, P. F. Scholander—378

Book Reviews (continued)
- Rideal, E. K. (see Frankenburg, W. G. and V. I. Komarewsky)—87
- Rossi, Bruno B. and Hans H. Staub, Ionization chambers and counters—390
- Rothmann, S. C. (edited by), Constructive uses of atomic energy—89
- Rushbrooke, G. S., Introduction to statistical mechanics—88
- Sands, Matthew (see Elmore, William C.)—665
- Schilpp, P. A. Albert Einstein: philosopher-scientist—660
- Schneider, Walter A. and Lloyd B. Ham, Experimental physics for colleges—91
- Schweitzer, G. K. and I. B. Whitney, Radioactive tracer techniques—665
- Scott, Merit, Mechanics, statics, and dynamics—664
- Seaborg, Glenn T., Joseph J. Katz, and Winston N. Manning, The transuranium elements—665
- Seely, Samuel, Electron-tube circuits—666
- Shannon, C. E. and W. Weaver, The mathematical theory of communication—875
- Siri, William E., Isotopic tracers and nuclear radiations with applications to biology and medicine—86
- Slater, John C., Microwave electronics—877
- Smith, R. A., Aerials for metre and decimetre wavelengths—383
- Soodak, Harry and Edward C. Campbell, Elementary pile theory—874
- Staub, Hans H. (see Rossi, Bruno B.)—390
- Stiles, W. B. (see Higdon, A.)—659
- Stoner, E. C., Magnetism—661
- Sullivan, William H., Trilinear chart of nuclear species—662
- Tolansky, S., Hyperfine structure in line spectra and nuclear spin—659
- Teago, F. J. and J. F. Gill, Mercury arcs—873
- Temple, G., The general principles of quantum theory—876
- Valasek, Joseph, Introduction to theoretical and experimental optics—386
- Wakerling, R. K. (see Guthrie, A.)—381
- Weaver, W. (see Shannon, C. E.)—875
- Weizel, Walter, Lehrbrich der theoretischen physik—663
- Whitney, I. B. (see Schweitzer, G. K.)—665
- Willers, F. A., Practical analysis, graphical and numerical methods—871
- Wolfe, Halley (see Frayne, John G.)—390

Bridge Circuits
- High megohm bridge, F. M. Glass and R. K. Abele—493(L)
- Capacitance bridge for high frequencies, J. S. Mendousse, P. D. Goodman, and W. G. Cady—1002

Centrifuge
- Magnetic suspension for small rotors, J. W. Beams—182

Chemical Analysis
- Precision Faraday effect apparatus, Samuel Steingiser, George J. Rosenblit, Robert Custer, and Charles E. Waring—109

Cloud Chambers
- Continuously sensitive cloud chamber, T. S. Needels and C. E. Nielsen—976
- Diffusion cloud chambers, E. W. Cowan— 991
- Expansion valve for triggered cloud chambers, Jacob L. Zar—812(L)
- High speed expansion valve for cloud-chamber control, R. P. Shutt and W. L. Whittemore—643
- Reprojection method for studying cloud-chamber photographs, D. A. Bromley and R. D. Bradfield—190(L)
- Self-triggering cloud-chamber counter, E. L. Fireman and G. M. McHaney—813(L)

Computing Devices and Techniques
- Analog computer, J. G. Bayly—228
- Analog computers for servo problems, Donald McDonald—154
- Arithmetic operations in a binary computer, Robert F. Shaw—687
- Differential analyzer for the Schrodinger equation, R. L. Garwin—411
- Electronic circuit which extracts antilogarithms directly, F. Curtis Snowden and Harold T. Page—179
- Electronic pile simulator, P. R. Bell and H. A. Straus—760
- Instrument for mechanically differentiating curves, Arnold H. Scott—397(L)
- Integrator for small beam currents, T. A. Hall, S. D. Warshaw, and J. Dorsey—177
- Machine for synthesizing two-dimensional Fourier series in the determination of crystal structures, H. Shimizu, P. J. Elsey, and D. McLachlan, Jr.—779
- New mechanical autocorrelator, H. R. Seiwell—481
- Nomogram for G-M counter resolving-time corrections, Howard L. Andrews—191(L)
- Note on the geometry of Geiger counter telescopes, H. E. Newell, Jr. and E. C. Pressly—918
- Random coincidence rates with unsteady sources—R. M. Littauer—750
- Rapid method for calculating and using platinum thermohm tables—R. A. Buerschaper—996
- Ratio-recording double beam infra-red spectrophotometer using phase discrimination and a single detector, Abraham Savitzky and Ralph S. Halford—203
- Recording fluxmeter of high accuracy and sensitivity, P. P. Cioffi—624
- Relation between apparent shapes of monoenergetic conversion lines and continuous beta-spectra in a magnetic spectrometer. II, G. E. Owen and H. Primakoff—447
- Simplified percent transmission computer, A. L. McClellan and G. C. Pimental—1023(L)
- Single element verniers reading two or three dimensions, Robert E. Lewis—647
- Slide rule for nuclear emulsion calculations, Arthur Beiser—933
- Solution of simultaneous equations through use of the a.c. network calculator, L. M. Haupt—683
- Trigonometric computer with electrocardiographic applications, Richard McFee—420

Cosmic Rays
- Balloon-borne instrumentation for neutron detection, M. Pavalow, W. O. Davis, and W. P. Staker—529
- Detaching device for balloon flights, Louis G. Collyer—496(L)
- Instrument for directional studies of cosmic-ray intensity, H. W. Boehmer and J. E. Coolidge—633

Counters and Counter Circuits
- Behavior of rectangular and square section transparent beta-counters, L. M. Silver and J. B. Warren—95(L)
- Boron trifluoride proportional counters, I. L. Fowler and P. R. Tunnicliffe—734
- Calcium and cadmium tungstate as scintillation counter crystals for gamma-ray detection, R. H. Gillette—294
- Chart recording of microsecond pulse amplitudes, J. T. Dewan and K. W. Allen—823
- Coincidence circuit for a scintillation detector of radiation, W. C. Elmore—649
- Coincidence experiments for noise reduction in scintillation counting, Hartmut Kallmann and Karl A. Accardo—48
- Construction and performance of a multiple gamma-ray counter of high efficiency, Tibor Gráf—285
- Decade pulse counter for Geiger-Müller tubes, Björn Åström—323
- Design of neutron counters using multiple detecting layers, R. D. Lowde—835
- Detection of tritiated compounds in paper chromatography, I. Gray, S. Ikeda, A. Benson, and D. Kritchevsky—1022

Distributed coincidence circuit, Clyde Wiegand—975
Duration of scintillations from organic phosphors, J. O. Elliot, S. H. Liebson, R. D. Myers, and C. F. Ravilious——631
Electric field in a Geiger counter, Arthur R. Laufer—252
Electron component in Geiger discharge, G. G. Kelley, W. H. Jordan, and P. R. Bell—330
Electron pair spectrometer of lens type for hard gamma-radiation, Kai Siegbahn and Stig Johansson—442
End and wall corrections for absolute beta-counting in gas counters, A. G. Engelkemeir and W. F. Libby—550
Gas phase counting of low energy beta-emitters, W. Bernstein and R. Ballentine—158
Geiger counter mounting for continuous counting of gas-phase radioactivity—Francis Bonner and Alfred Weinstein—934(L)
High pressure fitting for scintillation counting, K. D. Timmerhaus, E. B. Giller, L. H. Tung, R. B. Duffield, and H. G. Drickamer—261(L)
High speed short resolving time coincidence circuit for use with scintillation counters, E. F. Shrader—883(L)
Improved resolving time measuring device, B. W. Roberts, Jr., K. E. Perry, and R. G. Fluharty—790
Method of measuring spurious counts in Geiger-Müller counters, D. Willard and C. G. Montgomery—520
Nomogram for G-M counter resolving-time corrections, Howard L. Andrews—191(L)
Note on the detection of coincidences and short time intervals, Robert Hofstadter and John A. McIntyre—52
Note on the geometry of Geiger counter telescopes, H. E. Newell, Jr. and E. C. Pressly—918
Pentode counting or control ring, Benjamin L. Moore—337
RaDEF standard sources for beta-disintegration rate determinations, Theodore B. Novey—280
Random coincidence rates with unsteady sources, R. M. Littauer—750
Scintillation counter as a low resolution gamma-ray spectrometer, Robert W. Pringle, Kenneth I. Roulston, and Harry W. Taylor—216
Scintillation counter for fast neutrons, H. B. Frey—886(L)
Scintillation counter for neutrons, Kuan-Han Sun and W E. Shoupp—395(L)
Scintillation efficiency of anthracene for low energy electrons, W. J. Ramler and M. S. Freedman—784
Scintillation type alpha-particle detector, A. S. Goldin, E. R. Rohrer, and R. L. Macklin—554
Scintillation-type ion detector, Paul I. Richards and E. E. Hays—99(L)
Self-triggering cloud-chamber counter, E. L. Fireman, and G. M. McHaney—813(L)
Small probing Geiger-Müller counters, C. V. Robinson—82
Some properties of the parallel plate spark counter. II, Leon Madansky and R. W. Pidd—407
Study of plateau slopes in self-quenching Geiger-Müller counters, Sanborn C. Brown and Claudine Maroni—241
Theory and properties of low voltage radiation counters, J. A. Simpson, Jr.—558
Time lags in Geiger counters—Arthur R. Laufer—244
Transmission of beta-rays by Nylon and Formvar, R. B. Heller, E. F. Sturcken, and A. H. Weber—898
Two beta-gamma-counters for gas samples, Rodman Jenkins—940(L)
Useful fast coincidence circuit, Richard L. Garwin—569(L)
Velocity of propagation of the discharge in Geiger-Müller counters, H. Saltzmann and C. G. Montgomery—548
Zero inefficiency anticoincidence circuit, M. Degallier—1025(L)

Dielectrics
Measurement of secondary electron emission from dielectric surfaces, Howard L. Heydt—639
Recording microwave refractometer, George Birnbaum—169

Diffusion
Diaphragm cell for thermal diffusion measurements, E. S. Huse, D. J. Trevoy, and H. G Drickamer—60
Diffusion cloud chambers, E. W. Cowan—991
Tests of flowing junction diffusion cells with interference methods, L. G. Longsworth—524

Dilatometers
Measurement and amplification of minute displacements by frequency modulation, P. A. Bricout and M. Boisvert—98(L)

Electrical Conductivity
Temperature coefficient of resistance of tin oxide-coated electrically conducting glass between 1° and 300°K, D. N. Lyon and T. H. Geballe—769(L)

Electrical Machinery
Motor for use in vacuum systems, C. P. Butler and F. E. Carpenter—103(L)
Pulsed air core series disk generator for production of high magnetic fields R. I. Strough and E. F. Shrader—575(L)

Electrical Measurements
Chart recording of microsecond pulse amplitudes, J. T. Dewan and K. W. Allen—823
Direct reading phasemeter, L. H. O'Neill and J. L. West—271
Dust electricity analyzer, W. B. Kunkel and J. W. Hansen—308
Electronic a.c. differential voltmeter, L. A. Rosenthal and H. S. Zablocki—799
Electron tube potentiometer method for use in circuits involving very high resistance, H. Bloom and G. W. Butler—274
Experimental KVAH-meter, G. M. Petropoulos—187(L)
Frequency meter for microwave spectroscopy, J. D. Rogers, H. L. Cox, and P. G. Braunschweiger—1014
Wide-band audio phasemeter, John R. Ragazzini and Lotfi A. Zadeh—145

Electrical Networks
Analog computers for servo problems, Donald McDonald—154
Best arrangement of resistors in a series group, Herbert B. Brooks—491(L)
Cathode-follower fallacies, Paul I. Richards—1025(L)
Design and construction of universal function generating potentiometers, Granino A. Korn—77
Design of logarithmic voltage dividers, F. V. Hunt and O. D. Sledge—332
Improving differential amplifier rejection ratios, Richard McFee—770(L)
Solution of simultaneous equations through use of the a.c. network calculator, L. M. Haupt—683

Electronic Instruments
Apparatus for rapid measurement of internal friction, Herbert I. Fusfeld—612
Apparatus for the study of electrets, L. A. Freedman and L. A. Rosenthal—896
Automatically synchronized electronic switch, W. A. Budlong and Bruce C. Lutz—167
D.c. amplifier for biological application, P. O. Bishop and E. J. Harris—366
Decade pulse counter for Geiger-Müller tubes, Björn Åström—323
Differential vectorcardiograph, Stanley A. Briller, Nathan Marchand, and Charles E. Kossmann—805
Direct reading phasemeter, L. H. O'Neill and J. L. West—271
Distributed coincidence circuit, Clyde Wiegand—975
Electronic a.c. differential voltmeter, L. A. Rosenthal and H. S. Zablocki—799

Electronic Instruments (continued)
- Electronic circuit which extracts antilogarithms directly, F. Curtis Snowden and Harold T. Page—179
- Electronic recording analytical balance, Idas W. Lohmann—999
- Electronic water-level control, R. D. Miller and J. S. Hopkins—263(L)
- Frequency modulation pressure recording system, J. H. Hett and R. W. King, Jr.—150
- High speed electronic scaler, W. M. Sessler and A. V. Masket—494(L)
- High speed synchroscope, G. G. Kelley—71
- Improved electrical network for determining the eigenvalues and eigenvectors of a real symmetric matrix, Abraham Many—972
- Integrator for small beam currents, T. A. Hall, S. D. Warshaw, and J. Dorsey—177
- Low frequency sinusoidal voltage source, Louis A. Rosenthal—302
- Magnetic tape recorder for very low frequency phenomena, Paul E. Green, Jr.—893
- Measurement and amplification of minute displacements by frequency modulation, P. A. Bricout and M. Boisvert 98(L)
- Monitor for low intensity gamma-rays, J. B. H. Kuper and R. L. Chase—356
- Precision selector for voltage-regulator tubes, O. B. Rudolph—497(L)
- Radiofrequency spectrograph and simple magnetic-field meter, R. V. Pound and W. D. Knight—219
- Ratio-recording double beam infra-red spectrophotometer using phase discrimination and a single detector, Abraham Savitzky and Ralph S. Halford—203
- Regulated low voltage power supply, A. K. Solomon—570(L)
- Reliable Pirani vacuum safety circuit, W. Franzen and J. Horton—935
- Simple low power electronic relay, William P. Ratchford and M. L. Fein—188(L)
- Useful fast coincidence circuit, R. L. Garwin—569(L)
- Wide-band audio phasemeter, John R. Ragazzini and Lotfi A. Zadeh—145

Electron Microscope
- Laboratory modifications in the RCA model EMC electron microscope, S. G. Ellis—255
- Method of preserving specimen grids for electron microscopy, Jennie E. Shapiro—500(L)
- Modification of electron microscope for electron optical shadow method, J. Arol Simpson and Alan Van Bronkhorst—669(L)
- Molecular diffraction attachment for RCA microscope, B. O. Heston and P. R. Cutter—608
- Simple automatic recording microphotometer, R. M. Fisher and D. S. Miller—938(L)
- Ultrasonic tissue disintegrator, F. F. Bird and K. S. Lion—189(L)
- Vibration studies: related to electron microscopy, F. A. Hamm and F. C. Snowden—426

Electron and Ion Optics
- Beta-ray spectroscopes, E. Persico and C. Geoffrion—945
- Design of a magnetic focusing coincidence spectrometer, C. M. Fowler and R. G. Shreffler—740
- Double thin lens beta-ray spectrometer, C. M. Van Atta, S. D. Warshaw, J. J. L. Chen, and S. I. Taimuty—985
- Electron pair spectrometer of lens type for hard gamma-radiation, Kai Siegbahn and Stig Johansson—442
- Electrostatic beta-spectrograph, D. R. Hamilton and L. Gross—912
- Focusing device for the external 350-Mev proton beam of the 184-inch cyclotron at Berkeley, W. K. H. Panofsky and W. R. Baker—445
- Focusing properties of a generalized magnetic spectrometer, David L. Judd—213
- High resolution beta-ray spectrometer, J. A. Bruner and F. R. Scott—545
- Laboratory modifications in the RCA model EMC electron microscope, S. G. Ellis—255
- Magnetic analyzer for charged-particles from nuclear reactions, C. W. Snyder, S. Rubin, W. A. Fowler, and C. C. Lauritsen—852
- Method for increasing the safe power input of x-ray tubes, Arthur I. Berman—275
- Relation between apparent shapes of monoenergetic conversion lines and continuous beta-spectra in a magnetic spectrometer. II, G. E. Owen and H. Primakoff—447
- Ring focus in a thin magnetic-lens beta-ray spectrometer, Joseph M. Keller, Ernest Koenigsberg, and Arthur Paskin—713
- Sector-type double-focusing magnetic spectrometer, Earl S. Rosenblum—586
- Simple contamination-free electron gun, H. E. Farnsworth—102(L)
- Use of secondary electrostatic focusing in a magnetic beta-ray spectrograph, R. D. Hill, J. W. Mihelich, and M. T. Pigott—498(L)

Electron Tubes
- All-metal ionization gauge, F. M. Kelly—673
- High power pulsed magnetron with replaceable cathode, M. F. Amsterdam and W. E. Danforth—398(L)
- New method for the measurement of inhomogeneous magnetic fields, Peter M. Weinzierl—492(L)
- Ultra-high vacuum ionization manometer, J. J. Lander—672(L)

Errata
- Formation of insulating layers by the thermal decomposition of ethyl silicate, Harold B. Law—270(L)
- High speed synchroscope, G. G. Kelley—264(L)
- Note on sealing Nylon films to Geiger counters, Robert A. Becker—270(L)
- Regulated low voltage power supply, A. K. Solomon—789
- Slide rule for radiation calculations, M. W. Makowski—336

Gas Discharges
- Choice of suitable gap forms for the study of corona breakdown and the field along the axis of a hemispherically capped cylindrical point-to-plane gap, Leonard B. Loeb, James H. Parker, E. E. Dodd, and William N. English—42
- Electric field in a Geiger counter, Arthur R. Laufer—252
- Electron component in Geiger discharge, G. G. Kelley, W. H. Jordan, and P. R. Bell—330
- Investigation of the possible use of the glow discharge as a means for measuring air flow characteristics, F. D. Werner—61
- Observations on some properties of ultra-high frequency gas discharges, Charles F. Robinson—617
- Study of plateau slopes in self-quenching Geiger-Müller counters, Sanborn C. Brown and Claudine Maroni—241
- Theory and properties of low voltage radiation counters, J. A. Simpson, Jr.—558
- Time lags in Geiger counters, Arthur R. Laufer—244
- Velocity of propagation of the discharge in Geiger-Müller counters, H. Saltzmann and C. G. Montgomery—548

Gas Handling and Measurement
- Convenient gas sample tube holder and break-off applicable to mass spectrometers, Frederick Highhouse and Julius White—101(L)
- Data on porcelain rod leak, J. P. Molnar and C. D. Hartman—394(L)
- Gas flow through the mass spectrometer viscous leak, R. E. Halsted and A. O. Nier—1019

- Glass variable microleaks for gases, John J. Hopfield—671(L)
- Greaseless gas flow valve, R. E. Honig—1024(L)
- Measurement of rates of flow of gases by wet test meters, Robert L. Burwell, Jr., Max Metlay, and Frank W. Pfohl—681
- Method of supplying low pressure gases on a vacuum system, Raymond H. McFee—100(L)
- System for the collection and purification of radon by remote control, Chester H. Shiflett, Mark E. Steidlitz, and Wallace Davis, Jr.—842
- Volumetric displacement flask, S. D. Snyder, C. J. Craven, and D. B. Trauger—887(L)

Goniometry
- Combination two-circle goniometer and x-ray spectrometer, M. L. Baron and A. deBretteville, Jr.—458

High Voltage Techniques
- Device for measuring the high voltage for a photo-multiplier tube, Ingvar Nilsson—396(L)
- Pulse type regulated high voltage supply for the G-M tubes, Richard J. Watts—342
- Voltage stabilizer for 200-Kv acceleration, J. T. Dewan—771(L)

Infra-Red Technique
- Infra-red microspectrometer for biological research, Darwin L. Wood—764
- Ratio-recording double beam infra-red spectrophotometer using phase discrimination and a single detector, Abraham Savitzky and Ralph S. Halford—203
- Simple variable space infra-red absorption cell, John U. White—629
- Water-proofing rocksalt for infra-red absorption cells, Scott Anderson, William J. Anderson, and Martin Krakowski—574(L)

Ionization Chambers
- Boron trifluoride proportional counters, I. L. Fowler and P. R. Tunnicliffe—734
- Design of neutron counters using multiple detecting layers, R. D. Lowde—835
- High pressure ionization chamber counters and their use, R. Wilson, L. Beghian, C. H. Collie, H. Halban, and G. R. Bishop—699
- Monitor for low intensity gamma-rays, J. B. H. Kuper and R. L. Chase—356

Ion Sources
- Automatic equipment for electrolyzing heavy water, Ralph W. Waniek—262(L)

Laboratory Techniques
- Automatic equipment for electrolyzing heavy water, Ralph W. Waniek—262(L)
- High resolution recording with soot, K. R. Eldredge—199
- Improved method of directing liquid flow in a closed system, L. G. Stang, Jr. and G. J. Selvin—97(L)
- Liquid air level control, Mark S. Fred and Everett G. Rauh—258(L)
- Low temperature gasket, A. Wexler, W. S. Corak, and G. T. Cunningham—259(L)
- Making small metal tubes by electrodeposition on Nylon fibers, R. J. E. Gezelius—886(L)
- Method of making glass-metal seals, N. A. Eckstein, J. W. Fitzgerald, and C. A. Boyd—398(L)
- Packless valve flow regulator, Walter Rose—772(L)
- Positive displacement pump for corrosive fluids, E. E. Glenn, Jr. and Norman Hackerman—148
- Preparation of unbacked metallic films, F. E. Carpenter and J. A. Curcio—675(L)
- Remote-control method of opening ampoules of active materials, Jesse E. Sherwood—570(L)
- Rubber tubing pump, John W. Weigl and Donald W. Stallings—395(L)
- Simple low power electronic relay, William P. Ratchford and M. L. Fein—188(L)
- Simple method to seal liquids of high vapor pressure into glass or quartz capillaries, Z. V. Harvalik—260(L)
- Stainless steel micro-needle electrodes made by electrolytic pointing, Harry Grundfest, Robert W. Sengstaken, Walter H. Oettinger, and R. W. Gurry—360
- Test of rupture strength of thin plastic films, Joses J. L. Chen—491(L)
- Volumetric displacement flask, S. D. Snyder, C. J. Craven, and D. B. Trauger—887(L)
- Waterproof cable connectors, K. Feldman—812(L)
- Water-proofing rocksalt for infra-red absorption cells, Scott Anderson, William J. Anderson, and Martin Krakowski—574(L)

Light and Radiation Sources
- High intensity ultraviolet continuum source for use in spectrophotometry, Nisson A. Finkelstein—509
- Improved electrode cutter for spectrographic laboratories, Esther W. Claffy and Joseph G. Schumacher—575(L)
- Power supply for the Cenco concentrated-arc lamp, James M. Mitchell—497(L)

Low Temperature Technique
- Automatic level controller for liquid nitrogen, E. H. Quinnel and A. H. Futch—400(L)
- Design and operation of liquid nitrogen-cooled solenoid magnets, James J. Fritz and Herrick L. Johnston—416
- Design and performance of a Joule-Kelvin helium liquefier, J. G. Dash, D. B Cook, M. W. Zemansky, and H. A. Boorse—936
- Float for liquid helium, Julius Babiskin—941
- Further techniques in single-crystal x-ray diffraction studies at low temperatures, S. C. Abrahams, R. L. Collin, W. N. Lipscomb, and T. B. Reed—396(L)
- High-low temperature microscope stage, R. E. Cech—747
- Liquid air level control, Mark S. Fred and Everett G. Rauh—258(L)
- Low temperature gasket, A. Wexler, W. S. Corak, and G. T. Cunningham—259(L)
- Low temperature x-ray diffraction apparatus, Donald F. Clifton—339
- Metal Dewar for liquid helium, Warren E. Henry and Richard L. Dolecek—496(L)
- Resistance-temperature relation for low temperature thermometry, Harold J. Hoge—815(L)
- Transfer device for low boiling liquids, Aaron Wexler and William S. Corak—583

Luminescence
- Calcium and cadmium tungstate as scintillation counter crystals for gamma-ray detection, R. H. Gillette—294
- Duration of scintillations from organic phosphors, J. O. Elliot, S. H. Liebson, R. D. Myers, and C. F. Ravilious—631
- Energy dependence of the naphthalene scintillation detector, Jack C. Smeltzer—669(L)

Magnetism
- Design and operation of liquid nitrogen-cooled solenoid magnets, James J. Fritz and Herrick L. Johnston—416
- Focusing properties of a generalized magnetic spectrometer, David L. Judd—213
- Magnetic suspension for small rotors, J. W. Beams—182
- Measurement of the magnetic field in a nuclear spectrometer, L M. Langer and F. R. Scott—522
- New method for the measurement of inhomogeneous magnetic fields, Peter M. Weinzierl—492(L)
- Null-coil pendulum magnetometer, C. A. Domenicali—327
- Pulsed air core series disk generator for production of high magnetic fields, R. I. Strough and E. F. Shrader—575(L)

Magnetism (continued)
  Radiofrequency spectrograph and simple magnetic-field meter, R. V. Pound and W. D. Knight—219
  Recording fluxmeter of high accuracy and sensitivity, P. P. Cioffi—624
  Recording torque magnetometer, D. S. Miller—605
  Small milligaussmeter, G. D. Adams, R. W. Dressel, and F. E. Towsley—69
Mass Spectrograph and Mass Spectrometer
  Convenient gas sample tube holder and break-off applicable to mass spectrometers, Frederick Highhouse and Julius White—101(L)
  Gas flow through the mass spectrometer viscous leak, R. E. Halsted and A. O. Nier—1019
  Improvements in mass spectrometers for the measurement of small differences in isotope abundance ratios, C. J. McKinney, J. M. McCrea, S. Epstein, H. A. Allen, and H. C. Urey—724
  Large Dempster-type double-focusing mass spectrograph, Henry E. Duckworth—54
  Mass indicator, V. J. Caldecourt—772
  New type mass spectrometer, Larkin Kerwin—96(L)
  Scintillation-type ion detector, Paul I. Richards and E. E. Hays—99(L)
Mechanics
  Apparatus for rapid measurement of internal friction, Herbert I. Fusfeld—612
  Comments on "Velocity-acceleration response from a seismic pick-up via controlled damping," A. J. Hermont—675(L)
  Tungsten helical spring balance, Samuel L. Madorsky—393(L)
  Velocity-acceleration response from a seismic pick-up via controlled damping, Robert J. Jeffries—115
Micro Manipulation
  Design of a simple microflowmeter for biological perfusion experiments, A. C. Burton and J. T. Nichol—485
  Microtome specimen holder advanced by thermal expansion—M. Eden, A. W. Pratt, and H. Kahler—802
  Volumetric plastic micro respirometer—P. F. Scholander—378
Microwave Spectroscopy
  Design and construction of a Stark-modulation microwave spectrograph, A. Harry Sharbaugh—120
  Frequency meter for microwave spectroscopy, John D. Rogers, Henry L. Cox, and Paul G. Braunschweiger—1014
  Stark effect absorption cells for microwave spectroscopy, D. H. Baird, R. M. Fristrom, and M. H. Sirvetz—881(L)
Microwave Techniques
  Apparatus for recording fluctuations in the refractive index of the atmosphere at 3.2 centimeters wave-length, C. M. Crain—456
  Fabrication of a high power resonant wave-guide window, E. V. Edwards and K. Garoff—787
  Frequency meter for microwave spectroscopy—J. D. Rogers, H. L. Cox, and P. G. Braunschweiger—1014
  Microwave power stabilizer, Ivan K. Munson—622
  Recording microwave refractometer, George Birnbaum—169
Multiplier, Electron
  Device for measuring the high voltage for a photo-multiplier tube, Ingvar Nilsson—396(L)
  Photo-multiplier gamma-ray detector, J. D. Graves and G. E. Koch—304
  Ultraviolet photon counting with an electron multiplier, A. H. Morrish, G. W. Williams, and E. K. Darby—884(L)

New Instruments
  Aerolog wind recording system—193
  Air-cooled high vacuum pump—194
  All-purpose scaler—502
  Alpha-counter—193
  Analascope—776
  Audiomatic generator—197
  Bulb temperature pick-ups—942
  Cartesian manostat—266
  Chain pulse amplifier—676
  "CO-AX" very low capacitance cables and flexible feeders—196
  Data recording camera—1030
  D.c. integrator motor—403
  D.c. magnetic amplifier—192
  D.c. power supply—192
  Dew point indicators—774
  Differential pressure switch—1030
  Diffusion pump—196
  Diode modulator for video frequencies—579
  Earth resistivity apparatus—403
  Electrically controlled camera—820
  Electron-diffraction camera—890
  Electronic blackboard—268
  Electronic flowmeter—889
  Electron microscope—576
  Electrostatic generator—578
  Exposure photometer—775
  Film tape sound recorder—105
  F-m generator—265
  F-m signal generator and amplitude modulator—403
  Frequency standard—818
  Gamma-survey meter—192
  Gas flow counter—773
  Ground resistance—820
  H-42 strainalyzer—502
  Improved RCA-1P21 multiplier photo-tube—105
  Improved ultra-sensitive d.c. amplifier—401
  Industrial electron tubes—194
  Industrial Rouy-Photrometer—402
  Industrial television—501
  "Infinite life" counters—196
  Infra-red detector—817
  Infra-red spectrophotometer—503
  Interference cooler filter—401
  Ionization gauge—502
  Labmarkers—195
  Laboratory coating unit—888
  Logarithmic attenuator—404
  Manufacturers' literature—106, 197, 268, 405, 504, 580, 679, 776, 821, 891, 1031
  Metallograph—1031
  Michelson interferometer—820
  Micro burette—818
  Micro manometer—580
  Micromanometer—941
  Microphotometer—265
  Micro-photometer—819
  Microvoltmeter—1030
  Microwave signal sources—677
  Miniature seismograph—501
  Miniature speed changes—404
  Mini-chopper—576
  Model F-1 oscillograph—404
  Model On-5 oscillosynchroscope—678
  New gamma-ray detector—677
  New stabilized d.c. indicating amplifier—774
  Nuclear fluxmeter—942
  Oscillograph—103
  Oscillo-tracer—677
  Oscilloscope camera—890
  Photographic exposure computer—819
  Platinum thermometer—819
  Power level indicator—887

Pressuregraph—775
Principal stain computer—675
"Printed-circuit" TV tuner—577
Projection-microphotometer—678
Proportional counters—194
Pulse generator—501
Pulse rise time indicator—503
Radiation monitor—818
R-F mass spectrometer tube—888
"Ruggedized" electrical instruments—267
Shaker—1029
Spectrograph and excitation unit—773
Spectrophotometer—264
Spectrum analyzer—503
Spring motor—888
Square wave generator—265
Subminiature electrometer type CK5889—577
Super-brilliant light source—105
Synchronous camera—268
Temperature control—579
Temperature pick-up—106
Thermocouple and ionization type vacuum gauge—402
A Three-stage non-magnetic mass spectrometer—578
Torque motor—1029
2000-MPH timing equipment—889
TV amplifier—267
Ultra-low frequency oscillator—401
Ultra low frequency oscillator—677
Ultra-sensitive d.c. current measuring device—579
Ultrasonic equipment—103
Ultrasonic generator—104
Ultrasonic soldering iron—195
Universal monochromator—104
Vacuum fusion apparatus—266
Vacuum gauge—105
Vacuum gauge—195
Variable electronic filter—196
Variable electronic filter—776
Variplotter—402
Ventilation meter—818
Versatile photo-micrographic apparatus—676
VHF signal generator—504
Volometer—193
Zeiss instruments—1031

New Materials

Abrasion-resistant plastic—892
Aluminum-silicone paint—679
Aluminum thermal insulation—406
Aluminum wire—680
Carbide marking pencil—822
Cellulose acetate cement—198
Centrifugal bronze castings—107
Chemical developments—778
Coated safety lenses—778
Coated tubing—777
Coaxial cable—777
Conducting rubber vee-belts—198
Copying film—198
Core material—198
Decontamination—892
Degreaser—680
Diamond abrasive kit—822
Electrosensitive recording paper—269
Flame retardant insulation—822
Flashlight battery—680
Flaw detection—892
Flexible stainless tubing—270
Fluoride lens coating—107
Fluorocarbon plastic—582
Fluoro carbons—778
Front-surface mirrors—892
Glass bearings—778
Glass building blocks—406
Glass orifice plates—506
Heat insulation—582
Heat-resistant steel castings—777
High speed hacksaw blade—680
Heat treating material—582
Hydrophobic starch—270
Insulating screws—944
Interlocking lead bricks—506
Knitted metal—581
Laboratory aids—680
Lead-glass fabric—944
Low expansion steel—892
Mercury battery—582
Mercury filter—405
Metal-ceramic materials—680
Metal cleaning sponge—892
Mildew preventive—944
Molding compound—582
Molybdenum lubricant—269
New organosilicons—107
Nickel-clad copper—505
Non-crazing plastic—944
Nuclear track emulsions—506
Nylon thread-lock plug—270
Oil-proof flexible conduit—582
Optical quartz—891
Permanent magnets—822
Pipe insulation—198
Plastic bonding agent—944
Plastic lenses—943
Plastic packing—892
Plastic products—822
Porous bearing—581
Porous bronze—944
Powdered stainless steel—581
Precision casting alloy—107
Printed circuits—198
Protective tape—582
Radiant glass panels—892
Rolled gold plate—506
Rust inhibitor—198
Rust preventive—107
Sapphire gauge points—270
Sealing rings—943
Self-adhesive marking tape—943
Silicone molding compound—679
Silicone rubber—506
Silicone rubber sponge and shock mounts—680
Silicone sealing compound—270
Silicone-treated paper—582
Silver storage battery—270
Solder alloys—680
Stainless steel—581
Static elimination—822
Static eliminator—778
Strippers for organic finishes—944
Surface-active chemical—198
Synthetic mica—406
Teflon applications—679
Teflon gaskets—406
Teflon rods and tubes—506
Teflon tape—506
Vibration isolation—892
Vibration isolator—582
Vinyl insulation—944
Vacuum pump fluid—506
Welding glass—680
Woven glass fabric—198
Zirconium in surgery—821

Non-linear elements
- Thermistors, Part I. Static characteristics, Otto J. M. Smith—344
- ——, Part II. Dynamic characteristics, Otto J. M. Smith—351

Nuclear Machines
- *Betatrons*
  - 80-Mev model of a 300-Mev betatron, D. W. Kerst, G. D. Adams, H. W. Koch, and C. S. Robinson—462
  - Ejection of the electron beam from a betatron—S. L. Fawcett and E. C. Crittenden, Jr.—935(L)
  - Orbit-bender to assist injection into betatrons, Leverett Davis, Jr.—971
- *Cyclotrons and Synchrotrons*
  - Design study for a three-Bev proton accelerator, M. S. Livingston, J. P. Blewett, G. K. Green, and L. J. Haworth—7
  - Focusing device for the external 350-Mev proton beam of the 184-inch cyclotron at Berkeley, W. K. H. Panofsky and W. R. Baker—445
  - Synchrotron-oscillation resonance, N. M. Blachman—908
  - Synchrotron radiofrequency system, M. H. Dazey, J. V. Franck, A. C. Helmholz, C. S. Nunan, and J. M. Peterson—436
  - Theory of the capture process in a betatron-injected synchrotron, D. C. dePackh and M. Birnbaum—451
- *Linear Accelerators*
  - 500-kilovolt linear accelerator using selenium rectfiers, Wayne R. Arnold—796

Nuclear Technique
- Apparatus for concentration of He^3 by thermal diffusion, O. F. Schuette, Jr., A. Zucker, and W. W. Watson—1016
- Background eradication in thick-layered nuclear emulsions, Martin Wiener and Herman Yagoda—39
- Beta-ray spectroscopes, E. Persico and C. Geoffrion—945
- Chalk River single crystal neutron spectrometer, D. G. Hurst, A. J. Pressesky, and P. R. Tunnicliffe—705
- Construction and performance of a multiple gamma-ray counter of high efficiency, Tibor Gráf—285
- Design of a magnetic focusing coincidence spectrometer, C. M. Fowler and R. G. Shreffler—740
- Design of neutron counters using multiple detecting layers, R. D. Lowde—835
- Electron pair spectrometer of lens type for hard gamma-radiation, Kai Siegbahn and Stig Johansson—442
- Electrostatic beta-spectrograph, D. R. Hamilton and L. Gross—912
- Gas phase counting of low energy beta-emitters, W. Bernstein and R. Ballentine—158
- Improvements in the Li^6 technique, G. R. Keepin, Jr.—933(L)
- Magnetic analyzer for charged-particles from nuclear reactions, C. W. Snyder, S. Rubin, W. A. Fowler, and C. C. Lauritsen—852
- Measurement of fast neutron energies by observation of $Li^6(n,\alpha)H^3$ in photographic emulsions, George R. Keepin, Jr., and James H. Roberts—163
- Microcalorimeter suitable for study of easily absorbed nuclear radiations, C. V. Cannon and G. H. Jenks—236
- Note on reduction of background fog in nuclear emulsion plates, P. K. S. Wang—816(L)
- Nuclear emulsions and the measurement of low energy neutron spectra—N. Nereson and F. Reines—534
- On the use of photographic plate detectors in neutron experiments, J. C. Allred, A. N. Phillips, L. Rosen, and F. K. Tallmadge—225
- Photographic methods of measuring slow neutron intensities, M. Blau, I. W. Rudarman, and J. Czechowski—232
- Photo-multiplier gamma-ray detector, J. D. Graves and G. E. Koch—304
- Preparation of carbon targets, G. C. Phillips and J. E. Richardson—885(L)
- Scintillation counter as a low resolution gamma-ray spectrometer, Robert W. Pringle, Kenneth I. Roulston, and Harry W. Taylor—216
- Scintillation counter for neutrons, Kuan-Han Sun and W. E. Shoupp—395(L)
- Scintillation-type in detector, Paul I. Richards and E. E. Hays—99(L)
- Semi-automatic device for analyzing events in nuclear emulsions, Marietta Blau, Robert Rudin, and Seymour Lindenbaum—978
- Slide rule for nuclear emulsion calculations, Arthur Beiser—933(L)
- Variation of grain density with temperature of exposure in nuclear emulsions, Elsie M. Dollmann—118
- Varying nuclear emulsion sensitivity with altitude, Arthur Beiser—1025(L)

Optical Instruments
- High-low temperature microscope stage, R. E. Cech—747
- Improved Schlieren apparatus employing multiple slit-gratings, Tage A. Mortensen—3
- Lens tester for photographic lenses, F. G. Back—722
- Microtome knife sharpness, Oscar W. Richards—670(L)
- Multiple Kerr-cell camera, A. M. Zarem and F. R. Marshall 514
- Optical centering system for x-ray diffraction samples, Eugene L. Perrine—262(L)
- Precision Faraday effect apparatus, Samuel Steingiser, George J. Rosenblit, Robert Custer, and Charles E. Waring—109
- Recording polarimeter, Gabor B. Levy, Philip Schwed, and David Fergus—693
- Reprojection method for studying cloud-chamber photographs, D. A. Bromley and R. D. Bradfield—190(L)
- Simple automatic recording microphotometer, R. M. Fisher and D. S. Miller—938(L)
- Tests of flowing junction diffusion cells with interference methods, L. G. Longsworth—524

Oscilloscopes
- High speed synchroscope, G. G. Kelley—71

Photography
- Background eradication in thick-layered nuclear emulsions, Martin Wiener and Herman Yagoda—39
- Dust electricity analyzer—W. B. Kunkel and J. W. Hansen—308
- High resolution recording with soot, K. R. Eldredge, 199
- Measurement of fast neutron energies by observation of $Li^6(n,\alpha)H^3$ in photographic emulsions, George R. Keepin, Jr., and James H. Roberts—163
- Multiple Kerr-cell camera, A. M. Zarem and F. R. Marshall—514
- Note on reduction of background fog in nuclear emulsion plates, P. K. S. Wang—816(L)
- Nuclear emulsions and the measurement of low energy neutron spectra, N. Nereson and F. Reines—534
- On the use of photographic plate detectors in neutron experiments, J. C. Allred, A. N. Phillips, L. Rosen, and F. K. Tallmadge—225
- 100,000,000-frame-per-second camera, M. Sultanoff[illegible]
- Photographic methods of measuring slow neutron in[illegible]ties, M. Blau, I. W. Ruderman, and [illegible]
- Semi-automatic device for analyzing [illegible] sions, Marietta Blau, Robert Ru[illegible] denbaum—978
- Simultaneous photography of self-luminous and non-self-luminous effects, J. S. Rinehart—939
- Slide rule for nuclear emulsion calculations, Arthur Beiser—933(L)

Spectral sensitivity of two commercial x-ray films between 0.2 and 2.5 angstroms, Herman E. Seemann—314
Variation of grain density with temperature of exposure in nuclear emulsions, Elsie M. Dollmann—118
Varying nuclear emulsion sensitivity with altitude, Arthur Beiser—1025(L)

Photometry
Circumferential recording microphotometer, T. C. O'Connell and A. G. Barkow—573(L)

Piezoelectricity
Design and use of piezoelectric gauges for measurement of large transient pressures, A. B. Arons and R. H. Cole—31

Polarimetry
Polarimeter for the study of low frequency radio echoes, A. H. Benner and H. J. Nearhoof—830

Potentiometers
Electron tube potentiometer method for use in circuits involving very high resistance, H. Bloom and G. W. Butler—274

Pressure Measurement and Technique
All-metal ionization gauge, F. M. Kelly—673(L)
Design and use of piezoelectric gauges for measurement of large transient pressures, A. B. Arons and R. H. Cole—31
Diamond bomb for obtaining powder pictures at high pressures, A. W. Lawson and Ting-Yuan Tang—815(L)
Extension of the low pressure range of the ionization gauge, R. T. Bayard and D. Alpert—571(L)
Frequency modulation pressure recording system, J. H. Hett and R. W. King, Jr.—150
High pressure fitting for scintillation counting, K. D. Timmerhaus, E. B. Giller, L. H. Tung, R. B. Duffield, and H. G. Drickamer—261(L)
Investigation of the possible use of the glow discharge as a means for measuring air flow characteristics, F. D. Werner—61
Manometer leveling procedure, John E. Wertz—263(L)
New vacuum gauge, R. Havens, R. Koll, and H. LaGow—596
Rotary McLeod gauge, M. Axelbank—511
Simple method to seal liquids of high vapor pressure into glass or quartz capillaries, Z. V. Harvalik—260(L)
Simple pressure balance, C. A. Swenson—22
Simple recording manometer, Fraser P. Price and Paul D. Zemany—261(L)
Ultra-high vacuum ionization manometer, J. J. Lander—672(L)
Versatile pneumatic instrument based on critical flow, W. A. Wildhack—25

Radiation and Radiometry
Automatic isodose recorder with scintillation counter as gamma-ray detector, G. J. Hine, M. Berman, and M. M. Elkind—362
Energy dependence of the naphthalene scintillation detector, Jack C. Smeltzer—669(L)
4π-radiometer, T. Benzinger and C. Kitzinger—599
Series parallel linear thermopile with interchangeable receiving units, Robert A. Crane and Francis E. Blacet—259(L)

Radioactive Techniques
[illegible] determination of the mission rate of beta-rays, [illegible] K. Clark—753
[illegible]ratus and method for testing radium or thorium cap[illegible]le—400(L)
[illegible] compounds in paper chromatography, I. Gray, [illegible]keda, A. Benson, and D. Kritchevsky—1022
End and wall corrections for absolute beta-counting in gas counters, A. G. Engelkemeir and W. F. Libby—550
RaDEF standard sources for beta-disintegration rate determinations, Theodore B. Novey—280
Scintillation type alpha-particle detector, A. S. Goldin, E. R. Rohrer, and R. L. Macklin—554
System for the collection and purification of radon by remote control, Chester H. Shiflett, Mark E. Steidlitz, and Wallace Davis, Jr.—842
Transmission of beta-rays by Nylon and Formvar, R. B. Heller, E. F. Sturcken, and A. H. Weber—898
Units of radioactivity, L. F. Curtiss, R. D. Evans, Warren Johnson, and Glenn T. Seaborg—94(L)

Refraction and Refractometry
Apparatus for recording fluctuations in the refractive index of the atmosphere at 3.2 centimeters wave-length, C. M. Crain—456
Tests of flowing junction diffusion cells with interference methods, L. G. Longsworth—524

Secondary Emission
Measurement of secondary electron emission from dielectric surfaces, Howard L. Heydt—639

Seismology and Seismographs
Comments on "Velocity-acceleration response from a seismic pick-up via controlled damping," A. J. Hermont—675(L)
Velocity-acceleration response from a seismic pick-up via controlled damping, Robert J. Jeffries—115

Servo Mechanisms
Electronic recording analytical balance, Idas W. Lohmann—999
Microwave power stabilizer, Ivan K. Munson—622
Recording polarimeter, Gabor B. Levy, Philip Schwed, and David Fergus—693
Regulated low voltage power supply, A. K. Solomon—570(L)
Voltage stabilizer for 200-Kv acceleration, J. T. Dewan—771(L)

Shop Technique
Apparatus for cutting metals strain-free, Robert Maddin and W. R. Asher—881(L)
Improved electrode cutter for spectrographic laboratories, Esther W. Claffy and Joseph G. Schumacher—575(L)

Spectroscopy and Spectrometer Technique
Design and construction of a Stark-modulation microwave spectrograph, A. Harry Sharbaugh—120
Simple variable space infra-red absorption cell, John U. White—629

Thermal Diffusion
Apparatus for concentration of He^3 by thermal diffusion, O. F. Schuette, Jr., A. Zucker, and W. W. Watson—1016

Thermodynamics
Convenient cell-stage for fluid profile measurements, William Fox—499(L)
Design and performance of a Joule-Kelvin helium liquefier, J. G. Dash, D. B. Cook, M. W. Zemansky, and H. A. Boorse—936(L)
Method for measuring the thermal conductivity of small samples of poorly conducting materials such as optical crystals, Stanley S. Ballard, Kathryn A. McCarthy, and William C. Davis—905
Microcalorimeter suitable for study of easily absorbed nuclear radiations, C. V. Cannon and G. H. Jenks—236

Thermoelectricity and Thermal Properties of Matter
New method for surface-temperature measurement, Nobuji Sasaki—1
Series parallel linear thermopile with interchangeable receiving units, Robert A. Crane and Francis E. Blacet—259(L)

Thermometry and Temperature Control
Electrical resistance of platinum at high temperatures, H. E. Bennett—1029

Thermometry and Temperature Control (continued)
New method for surface-temperature measurement, Nobuji Sasaki—1
Precision thermostat for high temperatures, William R. Eubank—845
Rapid method for calculating and using platinum thermohm tables, R. A. Buerschaper—996
Resistance-temperature relation for low temperature thermometry, Harold J. Hoge—815(L)
Technical apparatus for determining thermal conductivity of steels up to 500°C, Z. Horak and F. Krupka—827
Temperature-controlled resistance furnace for high temperature measurements, W. G. Schneider and N. R. S. Hollies—94(L)
Vacuum furnace for use in the temperature range 1000–2000°C, J. W. Tomlinson and J. O'M. Bockris—507
Versatile pneumatic instrument based on critical flow, W. A. Wildhack—25
Vortex thermometer for measuring true air temperatures and true air speeds in flight, Bernard Vonnegut—136

Time measurement
High speed short resolving time coincidence circuit for use with scintillation counters—E. F. Shrader—883(L)
Improved resolving time measuring device, B. W. Roberts, Jr., K. E. Perry, and R. G. Fluharty—790
Multiple Kerr-cell camera, A. M. Zarem and F. R. Marshall—514
Nomogram for G-M counter resolving-time corrections, Howard L. Andrews—191(L)
Note on the detection of coincidences and short time intervals, Robert Hofstadter and John A. McIntyre—52
100,000,000-frame-per-second camera, M. Sultanoff—653
Some properties of the parallel plate spark counter. II, Leon Madansky and R. W. Pidd—407
Time lags in Geiger counters, Arthur R. Laufer—244
Useful fast coincidence circuit, R. L. Garwin—569(L)
Wire recorded magnetic pulse timing circuit, C. R. Emigh—142

Ultrasonics
Ultrasonic projector design for a wide range of research applications, E J. Fry—940(L)
Ultrasonic tissue disintegrator, F. F. Bird and K. S. Lion—189(L)

Vacuum Technique
All-metal ionization gauge, F. M. Kelly—673(L)
Convenient leak for testing helium leak detectors, G. H. Jenks—674(L)
Data on porcelain rod leak, J. P. Molnar and C. D. Hartman—394(L)
Degassing extended glass systems, Albert B. Stewart—258(L)
Effective vacuum cut-off, G. W. Sears and E. R. Hopke—570(L)
Extension of the low pressure range of the ionization gauge, R. T. Bayard and D. Alpert—571(L)
Glass variable microleaks for gases, John J. Hopfield—671(L)
Method of making glass-metal seals, N. A. Eckstein, J. W. Fitzgerald, and C. A. Boyd—398(L)
Motion within a vacuum system, Fred A. McNally—813(L)
Motor for use in vacuum systems, C. P. Butler and F. E. Carpenter—103(L)
New Pirani-type vacuum gauge, E. Blasco and L. Miranda—494(L)
New porcelain rod leak, H. D. Hagstrum and H. W. Weinhart—394(L)
New vacuum gauge, R. Havens, R. Koll, and H. LaGow—596
Reliable Pirani vacuum safety circuit, W. Franzen and J. Horton—935(L)
Rotary McLeod gauge, M. Axelbank—511
Suppressing mercury vapor in vacuum systems, Frederic Ayer, II—496(L)
Ultra-high vacuum ionization manometer, J. J. Lander—672(L)
Vacuum furnace for use in the temperature range 100 2000°C, J. W. Tomlinson and J. O'M. Bockris—507
Vacuum tests of rubber, lead, and Teflon gaskets and vin acetate joints, Robert W. Cloud and Sanborn F. Philp—731

X-Ray Diffraction
Bent crystal x-ray monochromators, B. E. Warren—102(L
Circumferential recording microphotometer, T. C. O'Connell and A. G. Barkow—573(L)
Combination two-circle goniometer and x-ray spectrometer, M. L. Baron and A. deBretteville, Jr.—458
Diamond bomb for obtaining powder pictures at high pressures, A. W. Lawson and Ting-Yuan Tang—815(L)
Further techniques in single-crystal x-ray diffraction stud at low temperatures, S. C. Abrahams, R. L. Collin, W. Lipscomb, and T. B. Reed—396(L)
Improved double-crystal spectrometer for small an scattering measurements, Leo Broussard—399(L)
Note on crystal suitable for double crystal x-ray spectroscopy in the region 3 to 15A, S. T. Stephenson and D. L. Martin—1023(L)
On adapting a powder x-ray diffraction camera for reflection patterns, Jonathan Parsons—185
Optical centering system for x-ray diffraction samples, Eugene L. Perrine—262(L)
Point-focus x-ray monochromators for low angle diffraction, Jesse W. M. DuMond—188(L)
Rotating specimen mount for use with x-ray spectrometer in measuring crystallite orientation of cellulosic and other textile fibers, L. Segal, J. J. Creely, and C. M. Conrad—431
X-ray determination of slip planes and slip directions, R. W. Turner, T. L. Wu, and R. Smoluchowski—440

X-Ray Equipment and Technique
Method for increasing the safe power input of x-ray tubes, Arthur I. Berman—275
Spectral sensitivity of two commercial x-ray films between 0.2 and 2.5 angstroms, Herman E. Seemann—314
